* For other stack and atmospheric temperatures add or deduct before multiplying by H 100 as follows: For 60° F. atmospheric temperature, add 0.05 in.; for 100° F. atmospheric temperature, deduct 0.05 in.; for 750° F. stack temperature add 0.17 in.; for 700° F., add 0.14 in.; for 650° F., add 0.11 in.; for 600° F., add 0.08 in.; for 550° F., add 0.04 in.; for 450° F., deduct 0.04 in.; for 400° F., deduct 0.09 in.; for 350° F., deduct 0.14 in.

ture of gases 600° F. (0.0008 at 350°). If the stack is required to impart velocity to the gas stream, as from space of infinite volume where initial velocity is zero, further correction of theoretical draft is necessary.

The available draft, D_a, for any stack is, using the same notation as before,

$$D_a = 0.52\,PH\{(1/T) - (1/T_1)\} - (fW^2\,MH/A^3). \quad [4]$$

$$= KH - (fW^2\,MH/A^3) \quad [5]$$

Table 3 calculated from formula [5], gives available draft that a steel stack, 100 ft. high from base measuring point, will produce when serving boilers at different steaming rates.

ECONOMICAL SIZE OF CHIMNEY.—Formula [5] indicates that if a stack of given diameter be made higher, it will produce the same available draft as one of larger diameter, the additional height being required to overcome the added friction losses. The most economical stack is the one that will meet draft requirements at the least construction costs. Deilein and Cotton have suggested that the least expensive of several possible chimneys will be the one in which (height × diameter) is the smallest.

A Convenient Method for Determining Chimney Diameters, that has been accepted by many as satisfactory, is to use a diameter giving 1 sq. ft. of cross-sectional area for each 1000 lb. per hr. of flue gas.

CORRECTION FOR ALTITUDE. ACTION OF WIND MOVEMENT.—From equation [1], draft produced by a given height of chimney is proportional to barometric pressure. Conversely, for a given draft, required height is inversely proportional to barometric pressure. Hence, stacks operating at altitudes higher than sea level must be increased both in height and diameter, as increased height causes added frictional resistance in the stack. The increase in height over that at sea level is proportional to the inverse ratio of the barometric pressures, while stack diameter increases as the $^2/_5$ power of the inverse ratio. Table 4 gives correction factors for altitudes above sea level.

When calculating draft available with any stack, possible effects from the action of the air at the top of the stack are not considered.

KENT'S EMPIRICAL FORMULA.—William Kent's empirical formula (*Trans.* A.S.M.E. vi, 1885, p. 81) is based on: 1. Velocity of the gas varies as the square root of the height. 2. Retardation of ascending gases by friction within the stack has the effect of decreasing the inside-cross-sectional area, or of lining the chimney with a layer of gas of no velocity. Thickness of lining is assumed to be 2 in. for all chimneys, or a decrease in area equal to the perimeter multiplied by 2 in. (neglecting overlapping of corners of the lining). If D = diameter, ft.; A = area, sq. ft.; effective area E, sq. ft., is

Square chimneys, $$E = D^2 - (8D/12) = A - {}^2/_3\sqrt{A} \quad [6]$$

Round chimneys, $$E = A - 0.591\sqrt{A} \quad [7]$$

The coefficient of $\sqrt{A}$ may be assumed as equal to 0.6, thus reducing the formulas to

$$E = A - 0.6\sqrt{A} \quad [8]$$

3. Boiler horsepower capacity varies as effective area E. 4. Available draft is sufficient to effect combustion of 5 lb. of coal per hr. per rated boiler horsepower.

Since power of the chimney varies directly as effective area E, and as the square root of height H, the formula for the horsepower of a boiler for a given size chimney becomes

$$\text{Boiler Hp.} = CE\sqrt{H} \quad [9]$$

C is a constant. Its average value, from plots of actual test results, is 3.33; therefore

$$\text{Boiler Hp.} = 3.33\,E\sqrt{H} \quad [10]$$

$$= 3.33(A - 0.6\sqrt{A})\sqrt{H} \quad [11]$$

With a given boiler Hp., height usually is assumed and

$$E = 0.3\,\text{Boiler Hp.}/\sqrt{H} \quad [12]$$

* Calculated on basis of 1 Boiler Horsepower = 5 lb. of coal burned per hour. For any other rate of combustion multiply the value in the table by the ratio of 5 to the actual rate of combustion.

For round chimneys diameter, in inches, is $d = (13.54\sqrt{E} + 4)$, and the side of a square chimney, in inches, is $s = (12\sqrt{E} + 4)$. Table 5 has been calculated from formula [11].

If the coal consumption varies from 5 lb. per boiler Hp. per hr., the actual capacity of the stack expressed in terms of boiler Hp. will be the boiler Hp. indicated by the formula, multiplied by the ratio of 5 to the actual coal consumption per boiler horsepower.

An approximate formula for chimneys above 1000 boiler Hp. is

$$\text{B.Hp.} = 2.5 D^2 \sqrt{H} \qquad [13]$$

RELATION OF AVAILABLE DRAFT AND DRAFT LOSSES.—Available draft must equal the summation of draft losses, which are the various flow resistances encountered. They can be expressed as $D_t - h_f = D_A = h_F + h_B + h_R + h_A$, in which D_t = static draft; h_f = loss of draft due to friction and inertia of chimney gases; D_A = available draft; h_F = loss of draft through fuel bed; h_B = loss of draft through the boiler, h_R = draft loss through breeching, including loss due to turns, bends, and damper friction; h_A = additional losses due to added auxiliary equipment (economizers, air heaters, etc.) and to the sudden enlargement of an opening or section.

Draft Loss in Furnace or through fuel bed varies with the type and condition of coal, rate of combustion, volume of interstices of the coal, percentage of ash, and thickness of fuel bed. In general, when burning coal, the loss of draft through the fuel bed increases as the percentage of volatile matter decreases and as the percentage of fixed carbon increases. The loss, therefore, is least for free-burning bituminous coals and greatest for small sizes of anthracite. Table 6 gives values which may be used as a basis for estimating. With pulverized fuel, gas, and oil there is no draft loss through the fuel bed, and h_F represents draft loss through burner parts.

Draft Loss through Boiler varies between wide limits, and depends on the type and size of boilers, arrangement of heating surface and baffles, type and quantity of fuel burned, combustion conditions, and design of furnace and boiler setting. Losses in well-designed water-tube boilers will be about 0.25 in., 0.4 in., and 0.65 in., at 100, 150, and 200% of boiler rated capacity, respectively. Fire-tube boilers with tubes 18 ft. long, 2 in. O.D., and an entering gas temperature of 1800° F., will have a draft loss of approximately 1 in. of water at rated boiler capacity, and 2 1/4 in. water at 150% of rated capacity. These figures should be used only in preliminary calculations, since they may represent values far from the actual loss of draft through the boiler actually used. Value selected should represent the draft loss through the boiler, when its steaming rate is a maximum.

Draft Loss in Straight Flues due to friction can be calculated approximately from formula [3], taking M as actual perimeter of the flue in ft., and H as length in ft. The greater resistance of the more or less uneven surface in concrete flues is provided for in the values of the constants given for formula [3]. The retarding effect of a square flue is 12% greater than that of a circular flue of equal area. Short, 90-deg. turns reduce draft by approximately 0.05 in., for each turn. Turns from the boiler into the flue and from a flue into the stack should be included in calculations. Cross-sectional area of flues should be of ample size to provide against undue frictional loss, and it is wise to allow 1 sq. ft., of flue area for each 2500 lb. per hr. of flue gas. The area of a flue at any point should be proportional to the volume of gases passing at that point; therefore, the area of a flue, serving more than one boiler, should progressively increase as it approaches the stack. With circular flues of approximately the same size as the stack, or reduced proportionately to the volume of gases they will handle, a convenient rule is to allow 0.1 in. draft loss per 100 ft. of flue length, and 0.05 in. for each 90-deg. turn. These figures are good for square or rectangular flues with areas sufficiently large to provide against excessive frictional loss. For brick or concrete flues they should be increased 35%.

STACKS FOR FUELS BURNED IN SUSPENSION, as pulverized coal, oil, or natural gas, require heights and diameters less than those for similar stoker-fired boilers. At a given steam rate the required area of stack, and the draft loss through the boiler, when burning fuels in suspension, will be less because of the smaller volume of gases. However, with oil or natural gas, the temperature of gases entering the stack will be lower, resulting

Table 6.—Draft Loss through Fire with Various Grades of Coal

Kind of Coal	Lb. of Dry Coal per sq. ft. of Grate per hr.

in a decrease of available draft from a stack of given height. A draft suction must be assured within all parts of the setting, under all operating conditions. If the suction is not sufficient to remove products of combustion the heat is detrimental to the setting.

Present day practice of burning fuels in suspension is to admit combustion air with the fuel by means of a turbulent type of burner. When burning relatively small amounts of fuel, it may be possible to provide sufficient draft by introducing air at room temperature through the burner throat. Most turbulent burners using natural draft are designed to operate at a draft loss of approximately 0.3 in. of water.

In burning fuels in suspension with natural draft burners, the possibility should be eliminated of too much draft at low steaming rates, with consequent high quantities of excess air. Stack height, however, must be sufficient to provide draft necessary for operation at maximum capacity.

MECHANICAL DRAFT.—When the natural draft provided by a stack is insufficient to overcome the losses attending the admission of air for combustion and the subsequent travel of the products of combustion over the heat transfer surfaces, other means must be used to make up the deficiency. In general, this situation exists when the total draft required exceeds 1.5 in. of water.

When natural draft will carry the normal operating load, and peak loads are infrequent and of short duration, expensive auxiliary equipment is not justifiable. In such cases, steam jets may be placed in air-tight ashpits under the grates, to overcome the resistance of the fuel bed. The burning of coals which have a tendency to mat on the grate is materially aided by the presence of the steam. Jets also may be located in the breeching or in the base of the stack to impart kinetic energy to the products of combustion. When the stack is of moderate or of large diameter, one or more rings of jets is necessary. Because of the large quantities of steam required, this method is uneconomical for creating pressures of over 1 in. of water, or suctions above 0.75 in., in excess of that given by the stack alone. A more flexible method of economically meeting draft requirements for wide variations of load is the use of forced or induced draft fans, or both.

Forced draft fans supply the air for combustion at sufficient pressure to overcome the resistances encountered by the air in its passage to the furnace. Such resistances may be the friction losses through air heaters, ducts, heat exchangers, burners or fuel beds.

A combination of forced and natural draft is used when the stack is capable of maintaining a sufficient suction in the furnace to remove the products of combustion from the apparatus. Induced draft alone is used, when the resistance of the fuel burning equipment is not excessive, and the fan is capable of supplying sufficient suction to overcome this, in addition to supplying draft to the rest of the apparatus.

As equipment is added behind the boiler to increase the efficiency of the unit, greater suction is required to overcome the resistance of these auxiliaries. The lower exit gas temperature reduces the stack draft and induced draft fans are installed to supply the necessary suction. Since these fans handle dust-laden gases, especially in waste heat work, they are subject to erosion and consequent maintenance costs. Their service conditions are more severe than those of forced draft fans for other reasons: the temperature of the gas is higher and the weight handled is greater. They are the only practical means of increasing the capacity of waste heat units.

Forced and induced draft fans are so operated as to give a balanced draft, or better, a slight suction in the furnace at all times. This usually is accomplished by some means of automatic control, based either on steam pressure or furnace suction. In some large central stations, forced and induced draft fans are furnished to deliver static pressures and suctions, respectively, of from 12 to 14 in. of water.

For data on selection of fans see pp. 1–57 to 1–79. See also the chapters on Mechanical Draft in Air Conditioning and Engineering, published by American Blower Corp., and in Fan Engineering, published by Buffalo Forge Co.

2. DESIGN AND CONSTRUCTION OF CHIMNEYS

General classes of chimneys are: 1. Steel, guyed. 2. Steel, self-supporting. 3. Masonry. 4. Reinforced concrete. In recent years a large number of steel chimneys have been installed due to their advantages over masonry construction. These include less weight and lower cost for a given size, ease of construction, and less surface exposed to wind. Steel stacks are economical where space limitations necessitate or warrant erection of the stack over the boiler. A special breeching then usually forms the stack foundation, both breeching and stack being supported by the boiler structural work.

WIND PRESSURE.—The relation between wind velocity and wind pressure per sq. ft. of flat surface usually is expressed by $P = KV^2$, where P = wind pressure, lb. per sq. ft. of flat surface; V = wind velocity, miles per hr.; K = an experimental coefficient,

whose value ranges from 0.0029 to 0.005; 0.004 generally is used. Practically all tests to determine K have been made on small flat surfaces. Later tests show that average pressure on large surfaces is less than on small surfaces. Prof. Kernot states that it does not exceed approximately $^2/_3$ of that upon surfaces of 1 or 2 sq. ft.

In stack design, total wind pressure is considered as the product of pressure per sq. ft. and projected area. Effective pressure per sq. ft. of projected area (flat surface = 1.00) is 0.80 for hexagonal, 0.71 for octagonal, and 0.67 for round stacks. Ordinarily, in stack calculations, 100 miles per hr. is used as maximum wind velocity. This corresponds to a pressure of 40–50 lb. per sq. ft. of flat surface, depending on value of K used, or a 26–33 lb. per sq. ft. of projected area for a round stack. In the U. S., 25–30 lb. per sq. ft. of projected area is commonly used for round stacks. Most cities set, by building ordinance, the allowable wind pressure to be used in stack design. European practice usually considers the variation in pressure between base and top of stack.

STABILITY OF CHIMNEYS.—Stresses in chimneys result from wind pressure and weight of the chimney, whose combined effect tends to overturn the chimney. Pressure due to weight of the stack, with no wind movement, is distributed uniformly over the bearing surface at its base. Wind pressure tends to overturn the stack. The resultant pressure at the base, due to wind pressure and weight, decreases on the windward side and increases on the leeward side. This, in effect, moves the center of pressure away from the center of gravity, toward the leeward side. Distance e, or eccentricity, from center of gravity to center of pressure is $e = M/W$, where e = eccentricity, ft.; M = wind moment, ft.-lb. (total wind pressure, lb. × distance from section under consideration to center of wind pressure); W = weight of stack above section under consideration, lb.

The condition of least stability is when resultant pressure at the windward side becomes zero. The distance q from center of gravity to center of pressure for the condition of least stability is the *radius of statical moment* or *radius of the kern*. For stability, assuming that tension is not allowable, center of pressure must fall within the area of the kern and $e \lesseqgtr q$ or $M \lesseqgtr Wq$. Values of q for sections of stacks and bases encountered in chimney design, as given by G. F. Gebhardt (Steam Power Plant Engineering, 6th Ed. 1928) are

Section	q	Section	
Solid Circular	$D/8$	Solid Square (min.)	$0.118L$
Hollow Circle	$(D^2 + d^2)/8D$	Hollow Square (max.)	$(L^2 + l^2)/6L$
Solid Square (max.)	$L/6$	Hollow Square (min.)	$0.118(L^2 + l$

D, d = outside and inside diam., respectively, ft.; L, l = length of outer and inner sides, ft.

SELF-SUPPORTING STEEL STACKS usually are made with a straight conical flare at the base, the apex of the cone being at the top of the stack, and the height of the frustum approximately one-fourth the height of the stack. The conical section is built of plates of uniform thickness with a base diameter about $^4/_3$ × diam. of straight portion of the stack. By flaring out the base, a larger diameter is provided for receiving the flue opening, resulting in a better flow of gases and necessitating less reinforcement than would be necessary with a straight stack. In fabricating the stack, each section may be made a truncated cone overlapping the previous section enough to allow for riveting. Better practice uses a true cylindrical section, with one end provided with an overlap for riveting. Stacks may be built with or without linings. Vitrified asbestos linings, seldom over 4 $^1/_2$ in. thick and supported by the stack, have replaced the earlier independent brick linings.

In design, due to the liberal factor of safety, and because a cylinder of large diameter with thin walls will probably fail by flattening or buckling on the leeward side, stack weight is neglected and the stack treated as a hollow cylindrical cantilever beam subjected only to the wind pressure. Therefore, at any section, $S = M \div (I/c)$, where S = stress in outer fiber due to wind pressure, lb. per sq. in.; I/c = section modulus; M = wind moment, in.-lb. The section modulus for a hollow cylinder $= \pi(d_1^4 - d_2^4)/32\, d_1$, but since the thickness of the wall is a small fraction of the diameter, the modulus becomes approximately $0.785\, d_1^2\, t$, and $S = M/0.785\, d_1^2\, t$, where d_1 = outside diam. of stack, in.; t = wall thickness, in. Considering stress per linear inch instead of per square inch, stress, S_2, per inch of circumference is $S_2 = M/0.785\, d_1^2 = M/A$, where A = the cross-sectional area of stack, sq. in. Maximum stress due to wind pressure per linear inch of circumference is determined at each joint. Table 7 gives the values for use in design of self-supporting steel stacks. Calculations are based on a wind pressure of 25 lb. per sq. ft. of projected area, weight of stack is neglected, and there should be no danger of failure should corrosion reduce plate thickness $^1/_{16}$ in. Stack weight will increase stress in the compression, or leeward side, by approximately 5 to 12% and decrease stress in the tension, or windward side, the same amount.

When calculating total wind pressures, wind moments, section moduli and bearing pressures, the stack is divided into sections from the top downward, all calculations being made above the lower edge of the section under consideration. In designing self-supporting stacks, if stack weight be neglected, stress per sq. in. or per linear inch of circumference can be calculated as described above.

In order to simplify the formula used to determine stress S_2 per inch of circumference, a wind pressure of 25 lb. per sq. ft. of projected area is assumed. Then $S_2 = M/A = 150\,H^2\,D/A$, where H = height, ft., from section considered to top of stack; D = diam. of stack, ft.; A = cross-sectional area, sq. in. The self-supporting steel stacks in Table 8 were calculated on the basis of Table 7. The stacks are unlined, but if a lining is to be used, calculations should be made for bearing and shear of rivets, limits of which should not exceed those given in Table 7.

STACK FOUNDATIONS are designed in accordance with the type of stack supported. Foundations for masonry stacks have practically no effect upon stability, and are designed to provide support only, with no particular attention to weight or distribution of weight. Steel and reinforced concrete stacks are anchored to the foundation, the stack and foundation forming an integral structure. Weight and shape of foundation affect stability of the stack, and foundations must be designed to meet conditions of flexure and stability.

Maximum Pressure on the Soil is the sum of pressures due to weight and to wind moment. Foundation sizes in Table 8 are based on pressures due to weight, of 160 lb. per sq. ft. per ft. of depth of foundation, and 160 lb. due to wind, or a total of 320 lb. per sq. ft. per ft. depth of foundation.

GUYED STEEL STACKS are used, primarily, because of their relative cheapness. Heavy foundations are unnecessary, and usually stacks are carried by boiler structural supports. Guyed stacks seldom exceed 72 in. diameter and 100 ft. height. They generally are built of lighter material than self-supporting steel stacks. The material must be heavy enough to support its own weight, to prevent buckling under stresses due to wind pressure (assumed 25 lb. per sq. ft. of projected area), and initial tension in guy wires, and to allow a liberal margin for corrosion. Thickness of material ordinarily is based on rules determined and set by practice. See Table 9.

The overturning moment of the stack, due to its weight and wind pressure is resisted by the guy wires. These usually are supplied in one to three sets, each set consisting of 3 to 6 strands. Let B = number of guy bands; G = total number of guy wires; α = angle between stack and guy wire, usually 60°; θ = angle between guy wires of a set or band, 120° for set of 3; L = height of stack, ft.; D = diam. of stack, ft.; h_1, h_2, h_3 = height of guy bands, ft. (if only two sets of bands are used, $h_3 = 0$); W = vertical load due to weight of stack, lb.; wind pressure = 25 lb. per sq. ft. of projected area. Then calculations for maximum stress in each guy wire are:

$$\text{Total wind pressure} = 25\,DL;\quad \text{overturning moment} = 12.5\,DL^2$$

The entire overturning moment is assumed to be resisted by one strand, or guy wire, in each set of guys; thus,

Horizontal pull in each guy $= 12.5\,DL^2/(h_1 + h_2 + h_3)$ . . . . [14]

Direct pull on each guy due to wind $= 12.5\,DL^2 \operatorname{cosec} \alpha/(h_1 + h_2 + h_3)$ . . . [15]

Initial stress on each guy = 1/2 of direct pull due to wind

Maximum stress in each guy due to wind and initial stress

$$= 1.5 \operatorname{cosec} \alpha\{12.5\,DL^2/(h_1 + h_2 + h_3)\} \quad [16]$$

Calculations for vertical load on base, due to weight of stack, and maximum stress in guys when wind blows between two guy wires are:

Vertical load due to wind $= B \cot \alpha \sec (\theta/2)\{12.5\,DL^2/(h_1 + h_2 + h_3)\}$ . . . [17]

Vertical load due to initial stress $= (G/2) \cot \alpha\{12.5\,DL^2/(h_1 + h_2 + h_3)\}$ . . . [18]

Vertical load due to maximum stress in guys

$$= \{12.5\,DL^2/(h_1 + h_2 + h_3)\}\{B \sec (\theta/2) + (G/2)\} \cot \alpha \quad [19]$$

Total vertical load in base

$$= W + \{12.5\,DL^2/(h_1 + h_2 + h_3)\}\{B \sec (\theta/2) + (G/2)\} \cot \alpha \quad [20]$$

For working conditions allow a safety factor of at least 2.

MASONRY STACKS usually are of circular, octagonal, hexagonal or square section, circular stacks being most common. The use of radial brick in circular stacks is almost universal. Octagonal and hexagonal stacks require special-shaped brick for best construction.

Stacks are built either with a single or double shell. Single-shell stacks are used where the bricks are not affected by the heat. Double-shell stacks are more common, and consist of a masonry outer shell with an inner lining extending partly or all the way up the stack. The lining is independent of the outer shell. Procedure for determining strength is practically the same for both single- and double-shell stacks.

The thickness of the walls, as ordinarily built, decreases in a series of steps from bottom to top of the stack. The thickness of wall at any section is determined by a considera-

* Weight includes laps, rivets and manufacturer's maximum allowance for overweight—10% should be added to these figures for guy wires, bands, clips, turnbuckles, etc.

tion of the resultant stress, at that section, due to wind and weight of stack. This stress should not put the masonry in excessive compression on the leeward side and, in general, should not result in tension on the windward side. At any section, compressive stress, S_c, due to weight of stack above that section is $S_c = W/A$, where S_c = compressive stress due to weight of stack, above section, lb. per sq. in.; W = weight of stack above section, lb.; A = area of bearing surface, sq. in.

Stress due to the wind, $S_w = M \div I/c$, where S_w = stress in outer fiber due to wind pressure, lb. per sq. in.; M = wind moment, in.-lb.; I/c = section modulus. Total compressive stress on leeward side is $S_1 = S_c + S_w$; total stress on the windward side is $S_2 = S_c - S_w$. If S_2 is positive, the stack is subjected to compression throughout the section, but if S_2 is negative, the masonry will be in tension on the windward side. Prof. Lang states that the compression on leeward side should not exceed

$$P = 71 + 0.65\,L \text{ (single shell)};\ P = 85 + 0.65\,L \text{ (double shell)}.$$

Tension on windward side should not exceed

$$P = 18.5 + 0.056\,L \text{ (single shell)};\ P = 21.3 + 0.056\,L \text{ (double shell)},$$

where P = pressure, lb. per sq. in.; L = distance, ft., from section under consideration to top of stack.

Custodis and Wiederholt Chimneys.—The Custodis chimney is constructed of a number of sizes of specially-molded, radial bricks, which conform to the circular and radial lines of each part of the chimney. The bricks contain several vertical holes, and after being set in position in the chimney the holes are filled with mortar. This forms an excellent bond, and together with the use of different lengths of radial bricks results in a thoroughly interlocked structure.

In the Wiederholt chimney, inner and outer surfaces are formed by specially designed tiles of vitrified fire-clay. The annular space between inner and outer surfaces is filled with concrete and steel reinforcing bars. This chimney combines features of both masonry and reinforced concrete chimneys.

THE REINFORCED CONCRETE CHIMNEY together with its base forms an integral structure. Wall thickness decreases progressively to the top of the stack. Less area is required than for a masonry or self-supporting steel stack because of the relatively thin walls as compared with masonry stacks and the elimination of the conical flare of the self-supporting steel stack. Reinforced concrete stacks usually are lined, either partly or to top of the stack. They can be erected rapidly, and contour easily may be changed as erection proceeds. The success of the reinforced concrete stack depends to a great extent upon the care with which material is selected, mixed and poured.

SMOKE

The Chicago Assoc. of Commerce Committee (Report on Smoke Abatement and Electrification of Railway Terminals in Chicago) defines smoke as " the gaseous and solid products of combustion, visible and invisible, including . . . mineral and other substances carried into the atmosphere with the products of combustion." Smoke from all fuels, solid, liquid or gaseous, results from non-combustion, or incomplete combustion, of volatile and heavy-hydrocarbon constituents, which are rapidly distilled and are unstable at furnace temperatures. Carbon or soot particles in smoke from solid fuels is due to incomplete combustion of the fixed carbon of the fuel.

The color of smoke, imparted to the gases by the particles of carbon, does not give a true indication of the stack loss. A small amount of carbon or soot will color large volumes of invisible or practically colorless gases, which may represent a combustion loss many times as great as that due to the actual carbon present in the gases. Gases also may be colored by particles of ash and mineral matter, neither of which represents a combustion loss.

With very dense smoke, the loss due to unconsumed carbon, passing from the stack as soot, seldom exceeds 1% of the total burned. However, the loss due to unburned, or partly burned, volatile hydrocarbons, although not indicated by the appearance of the stack, may represent an appreciable percentage of the heat value of the total fuel. Soot deposited on boiler tubes may result in a much greater loss of efficiency than that due to unburned fuel in visible smoke by reducing the conductance to the heating surface.

A plant, whose stack discharges large volumes of dense smoke, may be more economical than one with a smokeless stack. A furnace operating with a small percentage of excess air may cause considerable smoke, and yet lead to a higher evaporation rate than a similar furnace made smokeless by a large percentage of excess air.

SMOKE PREVENTION.—Smokelessness depends largely on the intelligence of the operating force, except when the furnace is wholly unsuitable for burning smoke-producing fuels. Many plants with hand-fired furnaces operate without smoke under ordinary conditions when the design provides for proper mixing of air and combustible gases and temperatures are maintained above the ignition point of the gases. If fires must be brought up quickly to maintain steam pressure, frequent use of the slice bar is necessary. This working of the fire will result in smoke.

In hand-fired furnaces, to prevent smoke, fires should be worked as little as possible. A combination of spreading and alternate firing should be used, coal being fired evenly, quickly, lightly, and often. Long flame travel of gases before striking boiler heating surfaces diminishes smoke. An extension furnace increases length of gas travel, and is particularly desirable with high-volatile coals and low boiler settings. Air introduced over the fire, heating arches, etc., to mingle air with gases distilled from the coal will diminish smoke. To prevent smoke, gases should be distilled from the fuel at a uniform rate, brought into intimate mixture with sufficient air for combustion, and have adequate temperature space and time to completely mix and burn before meeting the relatively cold boiler surfaces.

Stoker-fired furnaces under usual conditions are more nearly smokeless than hand-fired furnaces. With chain-grate stokers, ignition and mixing arches often are used to lengthen gas travel, and to permit rich gases from the front of the fuel bed to mix with excess air passing through the rear of the grate. Zoning of air supplied to different portions of the fuel bed, and proper control of fuel bed thickness and uniformity across the furnace, are important in preventing smoke. With pulverized coal, and fuels burned in suspension, burner design must insure turbulent mixing of fuel and combustion air as they enter the furnace. Fineness of particle size, or degree of atomization, also are critical factors in correct operation.

SMOKE ORDINANCES of cities and communities vary widely. They include such features as: 1. Organization of a department of smoke inspection. 2. Necessity of a permit, issued by the smoke inspector, before a new plant can be built, or an old one remodeled. 3. Necessity of a permit, issued by the inspector, before a new, or remodeled plant, can be placed in operation. 4. Regulation of emission of smoke, and penalties for violation of the ordinance.

SMOKE DETERMINATION.—The most widely known, and at one time the only method used in the qualitative determination of smoke is the Ringelmann chart. This consists of four cards ruled with horizontal and vertical lines, forming squares. Each card is 14 squares wide by 24 squares long. The width of the lines and spacing are as follows:

No. of chart	1	2	3	4
Thickness of lines, mm	1.0	2.3	3.7	5.5
Distance between lines, mm. (Length of one side of square)	9.0	7.7	6.3	4.5

At a distance of 50 ft. the lines are invisible and the cards appear to be different shades of gray, ranging from very light gray to almost black. The observer places the four cards, together with a white card and a solid black card, at a distance of 50 ft. from, and on a level with, his eyes, and in line with the stack. He rapidly compares the color of the smoke, emitted by the stack, with the cards, and judges which one corresponds with the color and density of the smoke. This method now is regarded as inaccurate, because it depends on the judgment of the observer, the angle of observation, the thickness of the gas stream and the background against which observation is made.

Various types of smoke indicators have been developed to permit the fireman to check his operation. One device resembles a periscope, one end of which is connected to the stack or breeching, while the other end, equipped with a glass observation window, is at a convenient position in the boiler room. In the stack, directly opposite the periscope opening, an incandescent lamp with a reflector projects a beam of light through the gas stream. Intensity of the light beam is affected by the amount of visible smoke in the gases, and variations may be instantly seen at the observation point in the boiler room. Automatic smoke recorders, actuated by variations in intensity of a light beam passing through a predetermined thickness of smoke layer, and falling on a photo-electric cell, also have been developed.

The method of determining the quantity of smoke adopted by the Chicago Assoc. of Commerce, consists of withdrawing a continuous sample of stack gases by means of a special pitot tube and exhauster, and entrapping the solid particles in a filter. Rate of flow through the apparatus is maintained the same as in the stack. Since area of the tube openings is fixed in relation to stack area, the weight of solid particles in the filter represents a definite proportion of the total weight emitted from the stack.

Section 7

THE STEAM ENGINE

W. Trinks

TABLE OF CONTENTS

THE STEAM ENGINE

By W. Trinks

General References.—Heck, Steam Engine and Turbine, 1911; Foster, Manchester Association Engineers, Jan. 23, 1915; Ninde, Design and Construction of Heat Engines, 1920; Ripper, Steam Engine Theory and Practice, 1914; Hütte, Vol. II, 23rd Edition, 1920; Dalby, Steam Power, 1915; Ewing, Steam Engine and Other Heat Engines, 1927. Dubbel, Kolbendampfmaschinen, 1923. Gutermuth, Die Dampfmaschinen, 4 vol., 1928. Allen, Uniflow, Back Pressure and Steam Extraction Engines, 1931.

The displacement-type steam engine, made practical by the inventions of James Watt between the years 1768 and 1790, revolutionized manufacturing, and for over a hundred years was the principal prime mover. To-day it is being supplanted by the large steam turbine, working in conjunction with electrical transmission of power, but continues to be built for a number of specific uses. In sizes up to 500 or 600 kw., the non-condensing engine is found to be more economical than the turbine. Combined heating and power plants, needing the most economical prime mover during hot weather, give preference to steam engines.

Certain types of pumping machinery, including water pumps, air compressors and gas exhausters, require wide variations of speed. For driving these, the steam engine is in great demand, both for the foregoing reasons and because the compression efficiency of the displacement-type pump is, as a rule, higher than that of the centrifugal or velocity-type pump.

For many years, economical steam engines will replace less economical units, because the arrangement of boilers and piping in many existing mills and factories favors the continued use of steam engines rather than a complete change to centralization and electrification.

CHARACTERISTIC PROPERTIES.—The steam engine is a "displacement" machine in which work is done by pressure acting on a moving piston. The whole cycle is carried on in a given space, whose walls are exposed alternately to high and to low temperatures. These conditions result in:

1. Condensation of part of the entering steam on the walls of the cylinder, and re-evaporation of the film of water near the end of expansion and during exhaust, involving a transfer of heat energy into the exhaust instead of its conversion into mechanical energy. 2. Variable torque, and cyclical speed fluctuations, necessitating either a flywheel or a multi-cylinder engine with several cranks. 3. Packing between cylinder walls and moving parts, requiring lubrication, which contaminates the exhaust steam with lubricating oil. 4. Valve gearing to alternately admit and exhaust steam.

1. CLASSIFICATION OF ENGINES

I. CLASSIFICATION AS REGARDS CONSTRUCTION.—*1a.* Horizontal Engine, Fig. 1. The motion of the piston is in a horizontal plane. For explanation of running "over" or "under," see illustration. A horizontal engine is *right hand*, if the flywheel is on the right-hand side of a person standing back of the cylinder and looking toward the shaft.

1b. Vertical Engine.—The piston moves in a vertical direction. A vertical engine may have the crank-shaft either below, Fig. 2, or above the cylinder, Fig. 3.

1c. Angle-type or Horizontal-vertical Engine, Fig. 4, has one vertical and one horizontal cylinder. Usually they act on one and the same crank.

1d. Some hoisting engines have cylinders at 45° (inverted V, Fig. 5).

2a. Single-acting Engine, Fig. 6. The steam acts against one side only of the piston and does work during only one stroke, or half a revolution.

2b. Double-acting Engine, Fig. 1. Steam acts alternately on opposite sides of the piston, doing work during the whole revolution.

3a. Reciprocating Engine, Fig. 1. That type in which the piston moves always in a straight line, but alternately in opposite directions, reversing its direction at fixed points.

3b. Rotary Engine, Fig. 7. The piston moves continuously, in a circular or other

curved, closed path, never reversing its direction of motion. The term applies only to displacement machines and not to turbines.

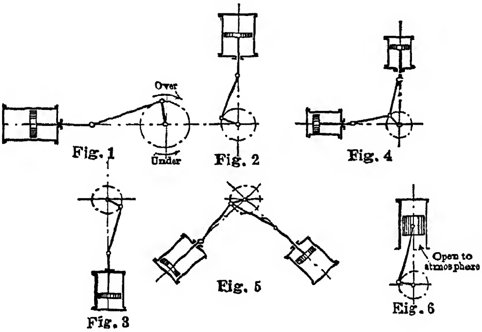
II. CLASSIFICATION AS REGARDS CONDITIONS OF OPERATION.—**1*a*. A Condensing Engine** discharges its exhaust steam into a condenser in which a pressure lower than atmospheric is maintained by condensation of the steam and exclusion of atmospheric pressure.

1*b*. A Non-condensing Engine discharges its steam either into the atmosphere or against pressure higher than atmospheric.

1*c*. A Bleeder-type or Extraction-type Engine is one from whose cylinder a part of the steam is extracted, during either expansion or compression, at a pressure that is higher than the back pressure acting during the exhaust stroke of the engine.

2*a*. Simple Engine, Figs. 1 to 6. The complete expansion of the steam from boiler pressure to exhaust pressure is carried out in one cylinder, or in each of several cylinders.

2*b*. Multi-stage Engine.—One in which the expansion of the steam is divided up into stages. The steam expands in a high-pressure cylinder from boiler pressure to an intermediate pressure; it then flows into another cylinder and expands still further, and so on.



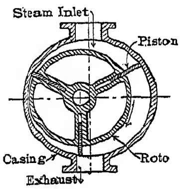


Fig. 7.
Rotary Engine

Figs. 1–6. Simple Engines

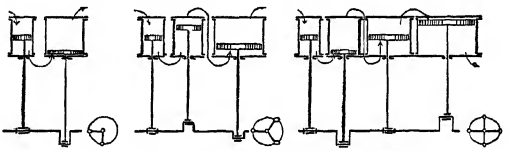

Fig. 8 Compound | Fig. 9 Triple-expansion | Fig. 10 Quadruple-expansion

Depending upon whether the expansion is divided into two, three or four stages, the engine is classified, respectively, as *compound*, Fig. 8, *triple-expansion*, Fig. 9, or *quadruple-expansion*, Fig. 10. A compound engine is a *tandem-compound* when the cylinders are arranged in line, one behind the other and both acting on the same piston rod. See Fig. 11. If the cylinders are side by side, and act upon cranks at right angles to each other, it is a *cross-compound*. See Fig. 8. If there are two low-pressure cylinders, the engine is a *three-cylinder* compound. See Fig. 12.

Twin Engines, Fig. 13, are simple engines having two cylinders side by side with cranks at 90°, as reversing mill-engines and locomotive engines.

3*a*. Uniflow Engine, Fig. 16. The steam flows in one direction only, from the ends to the center of the cylinder. The admission valves are in or near the cylinder heads; the exhaust ports are uncovered by the piston near the center of the cylinder. (See also Figs. 86 and 87.)

3*b*. Duoflow or Counterflow Engine, Figs. 14 and 15.—Steam flows alternately in opposite directions in each end of the cylinder, being first admitted and later exhausted near the ends. The term covers all engines other than the uniflow type.

III. CLASSIFICATION AS REGARDS TYPE OF VALVE AND VALVE-GEAR.—(See Valve Gears.)—1. *Slide valve* engines. 2. *Piston valve* engines. 3. *Poppet valve*

engines. 4. *Corliss* or *rocking valve* engines. 5. *Automatic* engines; the valves are always mechanically connected to the driving crank or eccentric, and the cut-off is varied automatically by a governor. 6. *Releasing engines*; the governor causes the valve to be periodically disconnected from the eccentric. The valve is closed by another force.

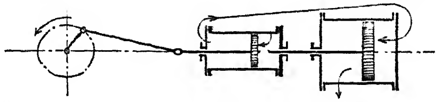

FIG. 11. Tandem-compound.

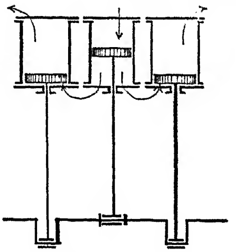

FIG. 12. Three-cylinder Compound

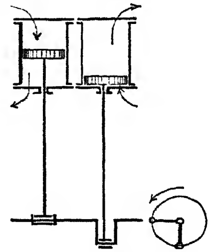

FIG. 13. Cross-compound

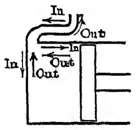
IV. CLASSIFICATION AS REGARDS USE.—1. Power engines drive electric generators or deliver power to machinery through a belt, rope, or shaft drive. They are, as a rule, constant-speed engines.

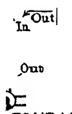
2. Blowing engines drive compressors for supplying air under pressure to blast furnaces or converters, or to compress gas for transmission through long pipe lines.

3. Hoisting engines drive hoists for elevating solid materials, or liquids in containers.



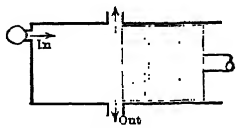
SINGLE VALVE

FIG. 14



FOUR VALVE

FIG. 15



UNIFLOW

FIG. 16

4. Pumping engines are used to elevate water or other liquids, or to supply it under pressure.

5. Reversing mill-engines drive reversing blooming-mills in steel plants.

6. Marine engines propel ocean-going or lake ships. (Engines for paddle-wheel river steamers are of an entirely distinct type from other boat engines.)

7. Automotive engines propel vehicles on land, as tractors, locomotives, and automobiles.

2. CAPACITY OF STEAM ENGINES

HORSEPOWER OF STEAM ENGINES.—The rate at which steam does work upon the engine piston = *Indicated horsepower*,

I.Hp. = (Average total pressure on piston, lb.,
× distance moved by piston in ft. per min.) ÷ 33,000. . [1]

Also, I.Hp. = (Average effective pressure on piston, lb. per sq. in.
× piston displacement, cu. in. per min.) ÷ 396,000. . [2]

. . . . . . [3]

where P = mean indicated pressure, lb. per sq. in.; L = length of stroke, ft.; A = effec-

tive area of piston, sq. in., after deducting area of piston rod or tail rod; N = number of working strokes per minute.

Also,

$$\text{I.Hp.} = \frac{\text{M.E.P., lb. per sq. in.} \times \text{piston area, sq. in.} \times \text{piston speed, ft. per min.}}{33{,}000}. \qquad [4]$$

The mean effective pressure is the average pressure shown by the indicator diagram (see Fig. 17) to be acting on the piston. The *indicated horsepower* is the power actually given up by the steam. Friction causes some loss, hence the *brake horsepower*, or the power available at the engine crank-shaft, is less than the indicated horsepower. The ratio of brake horsepower to indicated horsepower is called the *mechanical efficiency* of the engine. (For values, see Table 8.)

MEAN EFFECTIVE PRESSURE depends on: initial steam pressure; relative length of steam admission (cut-off); back pressure; compression; clearance volume; area of ports; type of valve gear; tightness of valves and pistons, and degree of superheat.

Initial Steam Pressure is determined by the cost of fuel *vs.* the first cost, or the price one will pay for fuel saving. From that standpoint, high steam pressures pay good dividends in localities where fuel is expensive, but the state of the art, including methods of lubrication and packing, sets limitations to high-pressure equipment. Pressures in excess of the heretofore common standard of 250 lb. per sq. in. make the first-cost high, not only of the engine but also of boilers and piping. Few engine builders have drawings

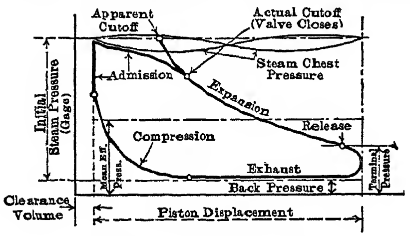


FIG. 17. Indicator Diagram

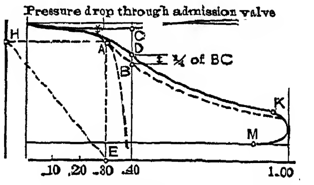

FIG. 18. Approximation of Indicator Diagram

and patterns of engines suitable for pressures in excess of 250 lb. per sq. in., and equipment for higher pressures must be designed and built specially. A number of installations for 450 lb. per sq. in. however, have been made, and in one plant triple-expansion engines operate regularly at 1400 lb. per sq. in.

Clearance volume depends on the type of valve gear and piston speed. High piston speed necessitates large valves, which means more clearance space.

Cut-off depends on the relation of economy to cost. Economy requires a short cut-off. Low engine cost (or high power from a given engine) requires a longer cut-off, with consequently higher steam consumption.

Back pressure depends on the possible use of exhaust steam from non-condensing engines, or on the temperature and quantity of cooling water available for condensing engines.

Compression must be high enough to insure quiet running of the engine, but must not be so high as to seriously decrease the engine economy. (See page 7–23.)

Area of ports depends upon piston speed, and grade of engine (whether expensive or cheap).

Valve gear depends on the use for which the engine is intended, on the rotative speed, and also on the grade of the engine.

TO FIND MEAN EFFECTIVE PRESSURE FOR GIVEN CONDITIONS.—Mean effective pressure (M.E.P.) from indicator cards of an existing engine is found by planimetering or by addition of ordinates.

$$\text{M.E.P.} = \frac{\text{area of card, sq. in.}}{\text{length of card, in.}} \times \text{spring scale.}$$

The spring scale is the pounds per square inch required to produce 1 inch of deflection, corrected by calibration.

For predicting the mean effective pressure of a new engine, there are three methods: 1. Comparison with indicator cards of existing similar engines. 2. Design of the probable indicator card and measurement of its area. 3. Estimation from the ideal indicator card, by means of a diagram factor.

The first is the best method and should be used wherever indicator cards from similar engines are available. (See Table 2.) The second method is desirable, but involves a large amount of numerical work. The third method is the most convenient, but it has led to great errors in calculation of the greatest possible horsepower, the error consisting in assuming that the apparent cut-off of the indicator card will be equal to the actual cut-off of the valve gear.

Design of Probable Indicator Card

ADMISSION.—The pressure in the cylinder is always less than boiler pressure. This pressure loss is due to four causes: 1. Friction in pipe line from boiler to engine. This part of total pressure drop can be computed from pipe friction formulas (see pages 5–20 to 5–23). Average values are from 2 to 6 lb. per sq. in., but with long pipe lines, may amount to 10 lb. per sq. in. In some instances it is unduly large because of the resistance to flow through throttle valves and quick closing safety stop valves. It is advisable to keep the steam velocity in pipes below 6000 ft. per min., except in very short lines or for very highly superheated steam; and in throttle valves it should not exceed 5000 ft. per min. The steam velocity through throttle valves may be calculated from the formula

$$\frac{\text{Piston area, sq. in.} \times \text{piston velocity at cut-off, ft. per min.}}{\text{Area through valves, sq. in.}} \qquad [5]$$

For pressure drop through valves, see p. 5–22.

2. Inertia of steam nearest engine. Pressure is required for its acceleration. Accurate calculation is almost impossible on account of superposition of impressed vibration and natural vibration. It seldom exceeds 4 lb. per sq. in.

Both (1) and (2) are reduced, and vibrations of the pipe line are eliminated by a large receiver-separator, with a comparatively small inlet, designed for a high or average velocity of steam flow (7000 to 8000 ft. per min.) and a larger outlet designed for low instantaneous velocity of flow to the engine (5000 to 6000 ft. per min.) The volume of the receiver-separator should be $1^3/_4$ to $2^1/_4$ times piston displacement, the higher value applying to high rotative speeds.

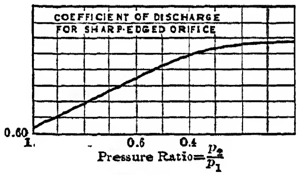

FIG. 19

3. Velocity head or pressure drop required to produce steam flow through the steam admission valve. It causes the apparent cut-off (Fig. 17) to be 6 to 15% earlier in the stroke than the actual cut-off of valve. The correct amount is difficult of exact calculation; increase of volume of the steam in the cylinder due to the motion of the piston, and condensation on the cylinder walls both tend to decrease the pressure in the cylinder, while the inflow of steam as well as expansion tend to keep up the pressure.

Referring to Fig. 18, a close approximation to the correct indicator diagram is obtained by calculating, for various piston positions, the pressure drop due to throttling by the steam admission valve, just as if the steam were inexpansible; merging the admission line thus found into the hyperbolic expansion line ($pv = k$) where the two have a common tangent, at A, and then correcting by raising the pressure at cut-off, *i.e.*, at actual valve closure, by one-fourth of the difference between initial steam pressure and the pressure found from the expansion curve from A; and starting the final expansion curve from D. In making this calculation it is advisable to tabulate as in the following example, which applies to a 10 × 14-in. slide-valve engine, 250 r.p.m., 40% valve cut-off.

1. Piston travel, % of stroke	10	20	25	30	35	40
2. Piston speed, ft. per sec.	9.1	12.2	13.2	14.1	14.5	
3. Area of valve opening, sq. in. = port width × valve opening	6.50	5.08	4.05	2.90	1.40	
4. Ideal steam velocity, ft. per sec. = (Item 2)/(Item 3) × piston area	110	189	256	382	802	
5. Coefficient of discharge (see Fig. 19)	0.62	0.62	0.63	0.64	0.72	
6. Corrected steam velocity, ft. per sec. = (Item 4) ÷ (Item 5)	178	305	410	600	1115	
7. Corresponding pressure drop, lb. per sq. in.	1.05	3.10	5.6	12.0	41.5	

Points representing piston positions should be taken close together near cut-off, and much farther apart at other positions. The angular velocity of the engine is assumed to

be practically constant, hence piston speed is represented by the ordinate of the semicircle. as AC, Fig. 20, for a mean between head end and crank end. Area of port uncovered by the valve at each piston position should be plotted as at AB in the upper part of figure. It is most conveniently found from a valve diagram; see page 7–33. Item 4, ideal steam velocity (as DE, Fig. 20) is (piston area ÷ area of valve opening) × piston velocity, ft. per sec. Coefficient of discharge for sharp-edged orifices varies with the ratio $p_2 \div p_1$, in this case (pressure in cylinder) ÷ (pressure in steam chest), as shown in Fig. 19. For low steam velocities, Item 6, use the expression $p' = c^2/9274\, v$, where p' = pressure drop, lb. per sq. in.; c = steam velocity, ft. per sec.; v = specific volume of the steam, cu. ft. per lb. (see Steam Tables, p. 5–04), for the pressure and temperature existing in the valve chest. For higher steam velocities, find the corresponding pressure drop from the Total-heat-Entropy chart, page 5–19.

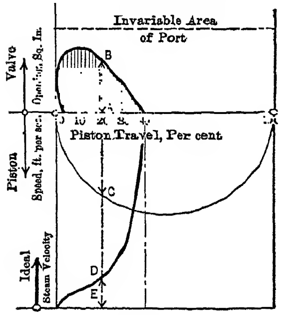

FIG. 20

A quick method of locating the point of tangency of the expansion hyperbola to the admission line is shown in Fig. 18. Draw vertical and horizontal lines from trial point A, to the intersections E and H with the lines of zero pressure and zero volume, and draw a line connecting E and H. If the tangent to the admission curve at A is parallel to EH, it also will be tangent to an hyperbola through A; hence the latter is the desired point. The horizontal axis must be the zero of absolute pressure, and the vertical axis the zero of cylinder volume, including clearance volume.

4. Friction through steam port. As a rule this is negligible, compared to pressure drop through the valve, except for long cut-off (approaching 50% of stroke). It can be computed from the formula for pressure drop through pipes and ducts. (See page 5–20). See also Bonin, *Zeits. f. ang. Math. u. Mech.*, v. 6, p. 491.

EXPANSION LINE.—The curve does not follow a simple law, but is complicated by partial re-evaporation (continuing as the pressure falls) of the film of water on the cylinder walls. It varies to some extent with all of the elements which affect cylinder condensation (see below under Steam Engine Economy). For all practical purposes, the curve pv = *constant* is sufficiently accurate for saturated or moderately superheated steam, while $pv^{1.06}$ = *constant* holds for steam superheated as much as 150° F. above saturation temperature. In duoflow engines, curves departing very far from these two indicate

In uniflow engines, condensation and subsequent re-evaporation are reduced, and $pv^{1.1}$ = *constant* is more nearly correct for saturated or slightly superheated steam. With steam superheated more than 150° F., there is very little cylinder condensation in either type of engine and the expansion curve can be taken directly from the Total-heat-Entropy chart (page 5–19) and the Pressure-Volume-Entropy charts or else $pv^{1.3}$ = *constant* can be used.

EXAMPLE.—To find the expansion curve of steam at 190 lb. per sq. in. absolute pressure, 300° F. superheat. The specific volume of steam at the initial temperature and pressure is 3.55 cu. ft. per lb. These conditions are represented on the Total-heat-Entropy chart by the intersection of the 300° F. superheat line and the 190 lb. pressure line. To find volume at, say, 110 lb. per sq. in. pressure, a line is dropped vertically from the initial point on the Total-heat-Entropy chart to 110 lb. pressure line, which gives the superheat, 205° F. By referring to the Pressure-Volume-Entropy chart, for that superheat and pressure, the specific volume is found to be 5.35 cu. ft. per lb. Then if the cylinder contains at cut-off a certain volume of steam, V_1 (including clearance volume), at 190 lb. pressure, that volume must expand to $5.35/3.55 = 1.507V_1$ when the pressure decreases to 110 lb. per sq. in. absolute.

EXHAUST TOE.—The curve KM (Fig. 18), represents free expansion (throttling) through the exhaust valve opening, but is complicated by evaporation of the film of water on cylinder walls. As long as the pressure in the cylinder is in excess of 1.5 × exhaust pressure, it may, with sufficient approximation, be found from the equation:

$$\left(\frac{P_r}{P}\right) = \log_{10}\left(\frac{c+x}{c+R}\right) , \quad \frac{0.892\, P_r V_r}{s}\int a\, dt$$

in which P = absolute pressure, lb. per sq. in., at any piston position x (fraction of stroke, see Fig. 21); P_r = pressure at release, lb. per sq. in., absolute; c = ratio (clearance volume ÷ displacement volume) and R = release ratio, both fractions of the stroke; P_r and V_r are, respectively, absolute pressure, lb. per sq. in. and specific volume, cu. ft. per lb., at point of release; s = stroke, ft.

The factor a is a function of the area of port opening, which varies with the piston position and is found by the method indicated in Fig. 22. The area of the exhaust valve opening (most conveniently obtained by means of the valve diagrams, Fig. 70-73), is plotted against time, zero of time being the point of release. This area can be determined by use of a planimeter or by averaging ordinates. The curve A (Fig. 22) of port openings thus obtained is distorted by multiplication of each value with the corresponding value of the expression, $1/(c + x)P$, where P = piston area, sq. in., if valve opening is taken in sq. in. Area under distorted curve a, for any piston position, is the value of $\int a\,dt$.

The numerical value of $(0.892\ P_rV_r)$ usually can be taken as 350, when time is taken in seconds. c, x and R are fractions of s.

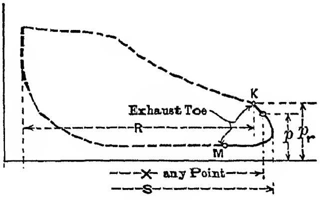

FIG. 21

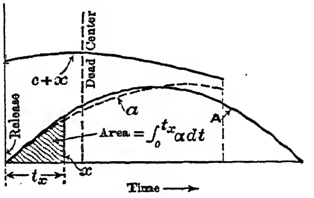

FIG. 22

This method assumes that all of the pressure loss is velocity-head, and none friction head. As the port opens widely, friction in the ducts becomes a noticeable proportion of the total pressure drop, and may be allowed for roughly, by somewhat decreasing the height of curve A near its maximum point.

For the section of curve in which the pressure in the cylinder drops from 1.5 × back pressure down to back pressure, no simple formula or graphical construction exists, but the curve easily can be sketched in from the shape of toe merging into the back-pressure curve (exhaust line), when the steam no longer flows out of the cylinder by its own free expansion, but is moving out under the displacing action of piston motion.

THE EXHAUST LINE is determined: 1. By back pressure in exhaust chest. 2. By pressure drop through exhaust valves and ports. Pressure in the exhaust chest depends upon the type of engine (compound, condensing, or non-condensing). For the receiver pressure of multi-stage engines, see the latter heading; for most suitable vacuum, see Steam Engine Economy and Condensation (page 7-22). The pressure in the cylinder must be higher than that in the exhaust chest, because of pressure drop due to flow of steam through exhaust valves and ports. Methods of finding excess pressure are identical with those described above under "Admission." Throttling through the valve when nearly closed toward beginning of compression causes compression to begin in the indicator card before the exhaust valve actually closes, the average point being 5 to 6% of stroke.

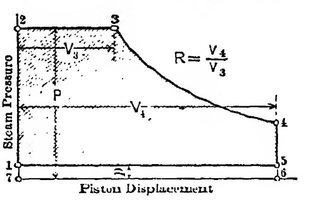

FIG. 23

THE COMPRESSION CURVE is not a simple one. As a rule, it first rises faster than the adiabatic, because the walls are hotter than exhaust steam, and then drops below the adiabatic at higher pressures, because compressed steam becomes hotter than the cylinder walls and begins to condense on them. For most cases $pv = constant$ is sufficiently accurate and is most commonly used; $pv^{1.1} = constant$ is more accurate under average conditions. See also Schüle, *Zeit.*, V. d. I., Nov. 24 and Dec. 8, 1906; Schneider, *Zeit.*, V. d. I., Feb. 9, 1907; Heinrich, *Zeit.*, V. d. I., 1912, page 1191.

MEAN EFFECTIVE PRESSURE FROM IDEAL CARD AND DIAGRAM FACTOR. —(Method 3). The ideal hyperbolic diagram without clearance and compression is represented by 1-2-3-4-5-1, in Fig. 23. The average ordinate, or mean effective pressure, lb. per sq. in., of this diagram is

$$\text{M.E.P.} = P\{(1 + \log_e R)/R\} - p, \qquad [7]$$

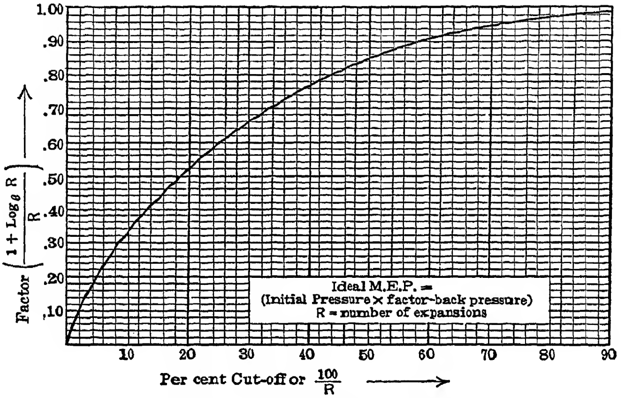
where P = initial steam pressure, and p = back pressure, both lb. per sq. in., abs.; $R = V_4/V_3$, which is called the ratio of expansion, or the number of expansions. For

this form of card it is the reciprocal of the cut-off ratio. The chart, Fig. 24, gives the ratio, (ideal M.E.P./P) for various values of R and for zero back pressure.

Example.—What is the ideal mean effective pressure of an engine with steam at 150 lb. per sq. in., gage, 25% cut-off, 24 in. vacuum, disregarding clearance and compression?

At 25% cut-off, the number of expansions is $1/0.25 = 4$. From Fig. 24, M.E.P./P for perfect vacuum = 0.597; then $0.597 \times (150 + 14.7) = 98.3$. Back pressure = 6 in. of mercury, or 2.95 lb. per sq. in. Hence, ideal M.E.P. = $98.3 - 2.9 = 95.4$ lb. per sq. in.

Fig. 25, shows the *ideal* mean effective pressure directly, for various expansion ratios and initial pressures, and for the two conditions of a back pressure of 15 lb. per sq. in., absolute, and of perfect vacuum. For the reasons explained above, the *actual* M.E.P.



. Factors for Calculating Mean Effective Pressure of Indicator Card

is less than that calculated by the formula and chart. The factor by which the ideal M.E.P. is multiplied to obtain the actual M.E.P. is called the *diagram factor*. Values which commonly apply (all referring to the ideal card without clearance or compression) are shown in Table 1.

This method of finding the M.E.P. is to be used for quick, approximate calculations only, and is not recommended for accurate work. Commercial mean effective pressures and overload capacities for different types of engines are shown in Tables 2 and 3. See also Foster, Manchester Association of Engineers, Jan. 23, 1915.

Table 1.—Diagram Factors

Average values for usual operating conditions, referred to ideal unmodified indicator diagram without clearance or compression (Fig. 23).

Type of Engine	Diagram Factor at Rated Load	Diagram Factor at Maximum Overload
Power Engines and Mill Engines: High Speed		
Single-valve engine, small size, simple	0.80	0.70
Piston-valve engine, simple	.82	.74
Piston-valve engine, compound	.70	...
Automatic four-valve engine, non-releasing valve gear, simple	.86	.82
Automatic four-valve engine, non-releasing valve gear, compound	.74	...
Releasing gear engine, simple	.90	.88
Releasing gear engine, compound	.76	.74
Releasing gear engine, triple-expansion	.70	.68
Uniflow poppet-valve engine, condensing	.78	.75
Uniflow, non-condensing, with large clearance	.62	.60
Uniflow, non-condensing with small clearance and auxiliary exhaust valv	.76	.75
Pumping Engines: Slow Speed		
Releasing gear compound, without jackets	.82	.81
Releasing gear compound, with jackets	.93	.92
Releasing gear triple, without jackets	.73	.72
Releasing gear triple, with jackets and reheaters	.85	.84

The factors are slightly less for non-condensing than for condensing engines of given type.

Influences which *reduce* diagram factors are: throttling due to small valve openings and steam passages or to very short cut-off; inter-related valve movements (single valve), which lengthen compression for early cut-off; late opening of exhaust valve; high piston speed; use of superheated steam.

Influences which *increase* diagram factor are jacketing and use of reheaters.

The *modified* ideal diagram, including clearance and compression, has, in general, an area somewhat less than that of the unmodified diagram, in approximately the following ratios for usual conditions: Releasing gear engine, 0.98; piston-valve engine, 0.96;

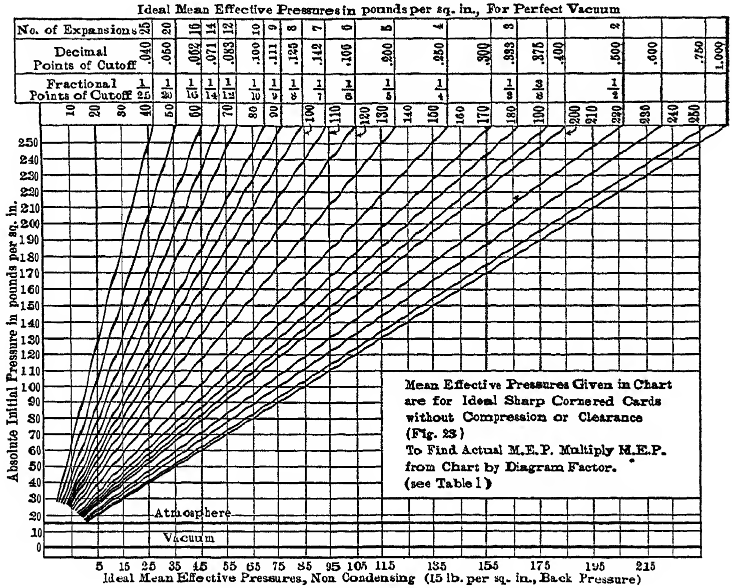


FIG. 25. Ideal Mean Effective Pressure Chart

Table 2.—Commercial Mean Indicated Pressures on Which Engine Ratings Are Based

Initial Steam Pressure, lb. per sq. in., gage	100	125	150	175	200
Engine Type and Operation	Rated Mean Effective Pressure, lb. per sq. in.				
Simple Engines					
Single-valve engine, condensing	45	49	53	57	62
Single-valve engine, non-condensing	51	58	64	71	77
Four-valve engine, condensing	42	46	50	54	58
Four-valve engine, non-condensing	48	54	60	66	72
Uniflow engine, condensing	35	42	48	52	55
Uniflow, non-condensing large clearance type	32	38	44	49	53
Uniflow, non-condensing, small clearance with auxiliary exhaust valves		44	51	56	59
Multi-stage Engines					
Compound condensing	25	28	30	32	34
Compound non-condensing	30	35	40	45	50
Triple-expansion, condensing		20	21	22	24

NOTE.—All engines for pressures above 200 lb. per sq. in. are special.

uniflow condensing, 0.91; uniflow non-condensing, large clearance type, 0.75, small clearance type, 0.95. Diagram factors applying to this form of diagram are the values of the table divided by the corresponding ratios.

EXAMPLE.—The diagram factor which should be used in calculating mean effective pressure from the modified diagram, for large clearance type of uniflow engines = 0.62/0.75 = 0.83.

Mean effective pressures in multi-stage engines are those referred to the low-pressure cylinder.

Most Economical Mean Effective Pressure is usually 65% to 75% of *rated* mean effective pressure (65% to 70% non-condensing uniflow, 70% to 75% in condensing uniflow).

The figures given in the table hold good irrespective of superheat, effect of which is discussed under Steam Engine Economy (p. 7–22).

Usual cut-off at rated load, for power engines under average operating conditions will range about as follows: *Simple engines*; four-valve engine, condensing, 17%, non-condensing, 25%; single-valve engine, condensing, 20%, non-condensing, 30%; uniflow, condensing, 15%, non-condensing, 20%. Compound engine, condensing, 33%, non-condensing, 40%. Triple-expansion, condensing, 35%. Cut-off refers to high-pressure cylinder and is the point of actual valve closing. Rolling-mill engines and blowing engines often work with longer cut-off than above.

CLEARANCE SPACE (as distinguished from linear clearance) includes all volume enclosed between piston and valves at one end of cylinder, when piston is at dead center at that end. Clearance is kept small as possible for the sake of steam economy, except in non-condensing uniflow engines in which it must be large (unless auxiliary exhaust valves are used) so that compression pressure will not rise above initial steam pressure. Increasing the ratio of cylinder diameter to stroke means larger clearance in percent of piston displacement. Low piston speeds permit use of small ports, and clearance can be reduced accordingly, while very high speeds mean large ports and valves and consequently large clearances (see also pages 7–13 and 7–29). See Table 4.

Table 3.—Overload Factors

The rated mean effective pressures of Table 2 are to be multiplied by the factors in this table in order to find the *maximum* M.E.P. which can be obtained.

Simple Engines	Initial Steam Pressure, lb. per sq. in.	Overload Factors: Condensing Operation	Overload Factors: Non-condensing Operation
Automatic engine; or single-eccentric releasing gear engine	100	1.86	1.45
	125	2.05	1.60
	150	2.25	1.75
	175	2.46	1.90
	200	2.67	2.06
Double-eccentric releasing gear engine	100	2.18	1.70
	125	2.43	1.87
	150	2.65	2.02
	175	2.84	2.15
Uniflow engine	100	1.63	1.30
	125	1.70	1.36 Large
	150	1.76	1.41 clearance
	175	1.81	1.44 type
	200	1.87	1.48

Compound Engines

MODIFIED HYPERBOLIC DIAGRAM.—Fig. 26 shows the sharp-cornered diagram 1–2–3–4–5–6–1, which includes the influence of clearance and compression, and hence more closely approximates the actual indicator card than does Fig. 23. The mean effective pressure is:

$$P\,(1 + c - cR) + \frac{P}{R}(1 + c)\log_e R - p\,(1 + c - cr) - pcr\log_e r. \quad [8]$$

where P = initial steam pressure and p = back pressure, both in lb. per sq. in., absolute; R = true ratio of expansion (*not* the reciprocal of the cut-off ratio, for this form of card), or $R = V_4/V_3$; r = compression ratio $= V_6/V_1 = p_1/p$; c = ratio of clearance $= V_1/(V_4 - V_1)$. V_1, V_3, V_6, etc., represent the volumes at the corresponding points on the card, Fig. 26.

For the actual engine with clearance, the *true* number of expansions $R = V_4/V_3 = P/P_4$, Fig. 26; whereas *apparent* number of expansions,

$$R_a = \text{reciprocal of cut-off ratio} = (V_4 - V_1)/(V_3 - V_1), \quad . \quad . \quad . \quad [9]$$

$$R = \frac{(c + 1)}{(cR_a + 1)} R_a. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [10]$$

The true number of expansions is always less than the apparent number of expansions.

Table 4 shows average clearance volumes for various types of engines in percent of piston displacement.

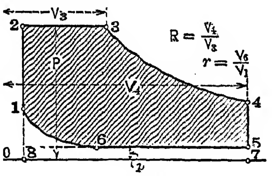

FIG. 26

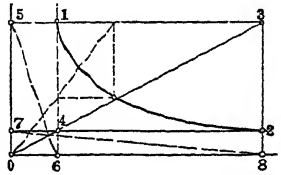

FIG. 27

LENGTH OF COMPRESSION AND FINAL PRESSURE OF COMPRESSION, p_1, depend on the clearance and the speed of the engine (see Table 4 and p. 7–14). For duoflow engines non-condensing, pressure p_1 (gage) varies from 70% *of initial gage pressure* in high-speed engines, down to 15% *of initial* gage *pressure* in low-speed engines; in condensing engines, p_1 seldom exceeds 15 lb. per sq. in. gage, unless the vacuum is poor or the clearance extremely small. For uniflow engines, the pressure p_1 is about 10 to 20 lb. per sq. in. less than the initial steam pressure in non-condensing, and 20 to 30 lb. per sq. in. less in condensing engines. Compression extends over 90% to 94% of the stroke in all uniflow engines, except in the non-condensing type with auxiliary exhaust valves, in which it extends over about 35% of the stroke.

QUICK CONSTRUCTION OF THE EXPANSION CURVE.—In Fig. 27 let 1 be the starting point; draw through it the vertical 1–6 and horizontal 1–3; to locate any other point, 2, draw vertical 2–3; through its intersection at 3 with the horizontal 1–3, draw diagonal to origin 0; through point 4 in which diagonal cuts vertical 1–6, draw horizontal

Table 4.—Clearance Volume of Steam Engines

4–2 to intersection with vertical 2–3, thus locating point 2. The area of rectangle 1–6–0–5 equals the area of rectangle 2–8–0–7; also the tangent to curve at 1 is parallel to diagonal 5–6, and the tangent at 2 is parallel to 7–8. The curve also can be constructed by the intercept method, as in Fig. 28, in which 1 is the starting point, and 1–3 = 2–4, 1–6 = 5–7, etc.

Construction of $pv^{1.06}$ = constant, is best accomplished by use of the log log slide rule. In the absence of such an instrument the following method may be used:

$$pv^{1.06} = pv \times v^{0.06} = pv \sqrt[16]{v} = constant. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [11]$$

The 16th root is found by extracting the square root four times. All other expansion

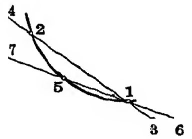

Fig. 28

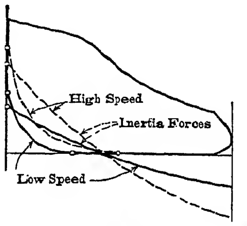

Fig. 29.—Effect of Speed on Compression

curves should be constructed by use of the Total-heat-Entropy chart or by use of the log log slide rule.

PISTON SPEED AND ROTATIVE SPEED.—The term piston speed commonly is understood to mean *average* piston speed, or 2 × stroke in ft. × r.p.m. High piston speeds are desirable for reducing floor space, weight, and cost of engine; high rotative speeds are desirable for engines direct-coupled to generators because size, weight, and cost of electric generators thereby are reduced. High piston speed, obtained by lengthening the stroke, rather than by increasing the revolutions per minute, does not cheapen the engine.

Economical piston speeds range between 500 and 1000 ft. per min., varying with the size of engine. (See Figs. 30 and 31.) Piston speeds up to 2000 ft. per min. are possible, but not economical for the following reasons: 1. High piston speeds cause excessive pressure drop through inlet and exhaust valves and ports. This either means increased steam consumption per horsepower-hour, or else large valves and ports, with resulting

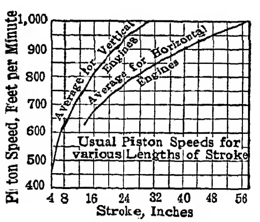

Fig. 30

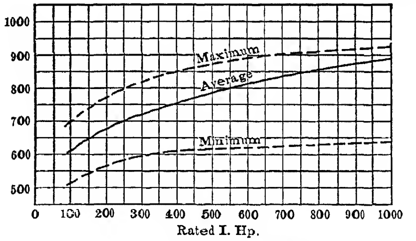

Fig. 31.—Piston Speeds of Engines

large clearances and waste spaces and, consequently, greater steam consumption (see Steam Engine Economy).

2. High rotative speeds produce great inertia forces. To prevent pounding in the main pins, the force must change slowly from tension to compression in the connecting-rod. This requires that change of direction of force shall occur before the steam valve opens. As a result, with high rotative speeds, longer compression is needed for a given clearance. (See Fig. 29.) Longer compression means somewhat greater steam consumption (see Steam Engine Economy). On the other hand, very low piston speeds cause increased cylinder condensation, because there is excessive time for such condensation. The two conflicting influences cause piston speeds to range as above given, and as shown in Figs. 30 and 31.

Valve gears impose limitations on rotative speeds. Releasing gears can be operated at speeds up to 150 r.p.m., but they offer no advantages above 100 r.p.m., and introduce difficulties above 120 r.p.m.

Direct coupling to compressors for air, gas, or ammonia limits the piston speed of engines.

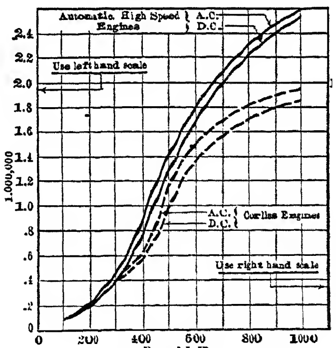

Fig. 35.—Weight of Fly-wheel Required

of engines. The floor space is the area of the rectangle enclosing engine and generator. These curves were plotted from data furnished by a number of builders of modern power engines, and show American practice in 1932.

Capacity of Compound Engines

The capacity of compound engines usually is figured by using mean effective pressure referred to the low-pressure cylinder, or *equivalent mean effective pressure.* The latter equals (M.E.P. of low-pressure cylinder + M.E.P. of high-pressure cylinder × ratio of high-pressure piston displacement to low-pressure piston displacement).

The best mean effective pressure is determined as a compromise between too great free expansion loss (high M.E.P.) and too great cylinder condensation loss (low M.E.P.). Commercial mean effective pressures are shown in Table 2.

The ratio of high-pressure piston displacement to low-pressure piston displacement is

influenced by various considerations, as: 1. Steam economy (meaning minimum heat interchange between cylinder walls and steam), would require that the expression (area of h.p. piston × steam temperature drop in h.p. cylinder + area of l.p. piston × steam temperature drop in l.p. cylinder) be made a minimum.

2. Equalization of forces in high-pressure and low-pressure rods and cranks (cross-compound only), would require that (h.p. piston area × pressure range in h.p. cylinder) and (l.p. piston area × pressure range in l. p. cylinder) be made equal.

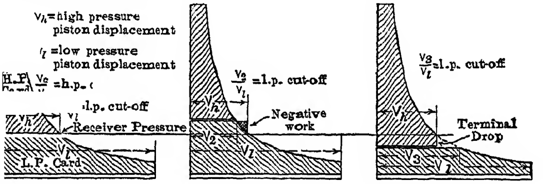
3. Equalization of work would require equality of work done per revolution in high-pressure and low-pressure cylinders.

4. Overload capacity would require the high-pressure cylinder to be of sufficient size to give ample overload capacity within the limits of cut-off in that cylinder.

Requirements (1) and (4) are contradictory. As a rule, a compromise is necessary in view of standard cylinder sizes being used.

Commercial cylinder ratios are shown in Table 5. For superheated steam somewhat lower ratios are used.

A rough rule for the size of non-condensing compound engine to give the same power as a simple engine of the same stroke and speed, is: High-pressure cylinder $0.75D$; low-pressure cylinder $1.3D$; where D = cylinder diameter of the equivalent simple engine. For condensing engines, high-pressure cylinder = $0.7D$; low-pressure cylinder = $1.4D$.



CORRECT L. P. CUT-OFF　　SHORT L.P. CUT-OFF　　LONG L. P. CUT-OFF

FIG. 36

RECEIVER PRESSURE can be varied by changing the low-pressure cut-off. The receiver is the space or container into which steam from the high-pressure cylinder passes before it enters the low-pressure cylinder. In many engines there is no separate receiver tank, the pipe connecting the high-pressure to low-pressure cylinder being made of sufficient diameter to give the required volume. In the Woolf type tandem-compound (now obsolete) the receiver was dispensed with entirely.

Fig. 36 is an ideal indicator diagram for an engine with a very large receiver (ideal case of uniform receiver presure) neglecting clearance and compression. For this ideal case, receiver pressure, $P_r = RP/n$, where P = initial steam pressure; R = cylinder ratio or V_l/V_h; n = number of expansions = V_l/V_c. Hence, neglecting clearance, P_r = initial steam pressure × cut-off (fraction of stroke in high-pressure cylinder). Pressures are absolute.

Table 5.—Commercial Cylinder Ratios of Multi-stage Engines

Cylinder ratios represent compromise between steam economy and good overload capacity.

	Condensing Engines					Non-condensing Engines				
Initial Steam Pressure, lb. per sq. in., gage	100	125	150	175	200	100	125	150	175	200
Type of Engine:										
Automatic compound for electric power generation, or blowing engines	3.5	3.9	4.3	4.7	5.1	2.3	2.6	2.9	3.3	3.7
Automatic compound for large overload capacity (mill engines)	3.0	3.3	3.6	4.0	4.4	2.0	2.2	2.5	2.8	3.1
Compound engine with releasing valve gear (rocking or poppet valves)	4.0	4.4	4.8	5.2	.....	2.6	2.9	3.2	3.6	
Triple-expansion engine: h.p. int. l.p.	....	1: 3.2: 7.0	1: 3.3: 7.7	1: 3.5: 8.4	1: 3.7: 9.0					

NOTE.—For higher pressures, cylinder ratios are not standardized, since engines for these pressures are built only to special order.

For the actual case, receiver pressure is less than that given by the above expression, since some *terminal drop* usually is allowed for the purpose of equalizing the work done by the two cylinders. Average receiver pressure may be found by constructing the indicator diagram, Figs. 39 and 40, if high-pressure and low-pressure cut-off are known. The following empirical expressions give approximate results, which may vary 10% from actual.

$$P_r = 0.58P \qquad [12], \qquad\qquad 0.9P \qquad [13],$$

in which P_r = receiver pressure, and P = initial steam pressure, both in lb. per sq. in., absolute; C_h and C_l = the cut-off in high- and low-pressure cylinders, respectively; R = ratio of low-pressure to high-pressure piston displacement; n = true number of expansions, considering clearance. Formula [13] may be used with the usual cylinder ratios and valve settings. Average values of receiver pressure may be taken at about 22 lb. gage for condensing, and 40 lb. gage for non-condensing engines with 150 lb. per sq. in. initial pressure (gage).

EFFECT OF CHANGING LOW-PRESSURE CUT-OFF.—If the high-pressure cut-off remains constant, lengthening the low-pressure cut-off reduces the work done by the low-pressure cylinder, and increases the work done by the high-pressure cylinder, because lengthening the low-pressure cut-off reduces the receiver pressure. (See Fig. 36.)

ACTUAL INDICATOR CARD.—Methods of constructing the ideal card and diagram-factors are similar to those used for simple engines. Features peculiar to the compound engine card are to be gained by study of the combined indicator card, in which both high-pressure and low-pressure diagrams are reduced to the same scale of pressure and volume. There are two methods of combining (also called "Rankinizing"), *viz.*, 1. By putting the clearance lines together as in Fig. 37. 2. By making the high-pressure and low-pressure

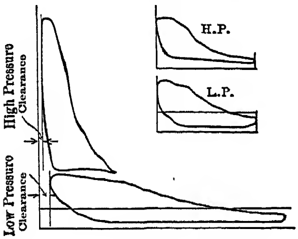


Fig. 37

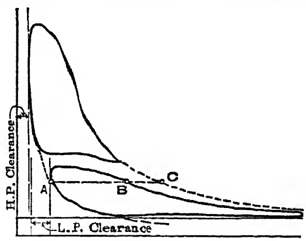

Fig. 38

Methods of Combining Indicator Cards

compression lines extensions of each other, as in Fig. 38. As a rule AB is only 80% to 85% of AC, thus showing the effect of cylinder condensation in the low-pressure cylinder. AB can be made equal to AC by reheating receivers and jackets on the low-pressure cylinder, but this is seldom done. (See Steam Engine Economy.)

Volume of Receiver.—The shape of the card is affected by the size of the receiver. As a rule, its volume should be $1\,^1/_2$ times the high-pressure piston displacement. It can be less for tandem than for cross-compound engines. Small receiver volume increases the temperature range in each cylinder, thereby reducing the economy. A very large receiver volume interferes with the regulation of the engine, if the high-pressure valve gear only is controlled by the governor.

Figs. 39 and 40 show a method of constructing the ideal combined indicator card for cross-compound engines and tandem-compound engines, respectively, and illustrate the effect of small receiver capacity. In these figures, abscissas represent volumes; ordinates, in the upper part of the figures, are portions of one revolution, and steam pressures in the lower part; V_h and V_l are high-pressure and low-pressure piston displacements, and C_h and C_l are high-pressure and low-pressure clearance volumes, respectively, while R is the volume of the receiver. The helices at the top show simultaneous positions of the high-pressure and low-pressure pistons. In cross-compound engines, the low-pressure crank is usually 90° (sometimes as much as 105°) ahead of the high-pressure crank in the direction of rotation. The effect of finite connecting-rod length is not shown in the diagrams, but can be taken care of by drawing arcs as shown under Valve Diagrams, Figs. 70 and 73. The variation introduced is unimportant, unless the cranks are 180° apart. At the right in Fig. 39, the high-pressure diagram is shown in dotted lines above

the low-pressure diagram. In the following discussion p_1, p_2, V_1, V_2, etc., refer to pressures and volumes at the points 1, 2, etc., on the diagram.

To lay out the diagram of Fig. 39, which is for a cross-compound engine, draw from the point of high-pressure cut-off, with point 18 as origin, the hyperbola 13–9 (volume 1–15 = volume 16–13) and locate point of low-pressure cut-off, 8, which is shown in this case as 50% of the stroke. This gives also pressure p_8 of the receiver into which the high-pressure cylinder later discharges its steam at 2. From the known point of beginning of low-pressure compression, draw hyperbola 11–12, which determines the pressure p_{12}, of the clearance space into which steam from the receiver at pressure p_4 flows at low-pressure admission, point 7.

Having drawn expansion hyperbola 1–2 with point 17 as origin, find pressure at 3 from the equation $p_2(V_2 + C_h) + p_8R = p_3(V_2 + C_h + R)$. Both V_2 and V_3 are the same as V_h. From 3 to 4, the high-pressure cylinder is exhausting into receiver, and $p_3(V_3 + C_h + R) = p_4(V_4 + C_h + R)$. At 4, steam from the receiver is admitted to the low-pressure cylinder, in which the clearance steam is at pressure p_{12}. Find the pressure at 5 from $p_4(V_4 + C_h + R) + p_{12}\, C_l = p_5(V_5 + C_h + R + C_l)$ and $p_5 = p_7$.

The line 5-6 of the high-pressure diagram corresponds to 7–14 on the low-pressure diagram, steam flowing into the receiver from the high-pressure cylinder, and out of it into the low-pressure cylinder, $p_5(V_5 + C_h + R + C_l) = p_6(V_6 + C_h + R + C_l + V_{14})$; also $p_6 = p_{14}$. At point 6 (determined from valve diagram), compression begins in the

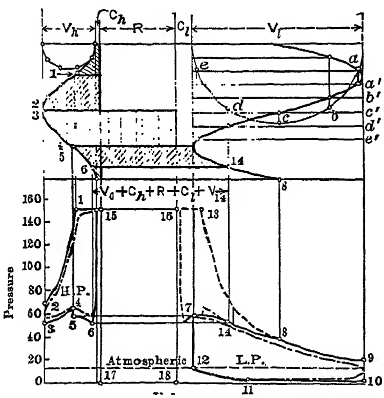

Fig. 39. Cross Compound Engines

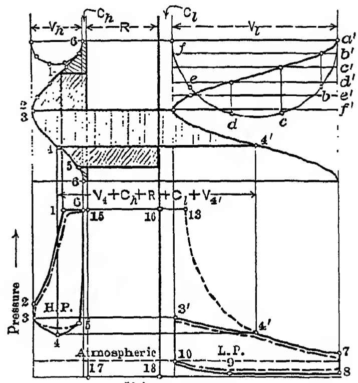

Fig. 40. Tandem Compound Engines

Methods of Constructing Ideal Combined Indicator Cards for Compound Engines

high-pressure cylinder. From 14 to 8 steam is expanding from the receiver into the low-pressure cylinder, and $p_{14}(R + C_l + V_{14}) = p_8(R + C_l + V_8)$. Volumes are represented by the horizontal lines in upper part of figures and may be scaled off directly from them for all points. The actual diagram will differ from the ideal diagram, due chiefly to the rounding of corners by throttling through valves and ports, and to cylinder condensation. The actual form is shown by the dot-dash lines.

Diagrams for tandem-compound engines can be constructed by the same methods. They have a form entirely different from those of the cross-compound, as shown by Fig. 40.

3. TRIPLE-EXPANSION ENGINES

The field of the triple-expansion engine is very limited. It is essentially a constant-load machine, as the small size of the high-pressure cylinder does not allow much overload capacity.

In marine service, the geared steam turbine and the turbo-electric drive are competing with the triple-expansion engine, with the result that the principal use of the latter is

to-day, in water works pumping engines. The overall efficiency of the triple-expansion engined pump is considerably better than that of a turbo-driven centrifugal pump, but the first cost of the reciprocating set is much higher, with the result that relative first costs and fuel costs decide which type is to be used.

4. EXTRACTION OR BLEEDER-TYPE ENGINES

In plants with engines operating condensing, where steam at 5 to 15 lb. per sq. in. gage pressure is needed for heating or chemical processes, it may be obtained from the receiver of compound engines, or tapped from the engine cylinder of simple engines, through a check valve and port which is uncovered by the piston some distance before the end of the stroke. In uniflow non-condensing engines, steam can be extracted during the compression stroke through a separate valve in the piston. This has advantage of decreased compression, permitting the use of a smaller clearance volume. (*Zeit.*, V. d. I., Dec. 20, 1913; Stumpf, Uniflow Steam Engine, 1922.)

5. STEAM ENGINE ECONOMY

References.—Heck, Steam Engine and Turbine, 1911; Foster, Manchester Association of Engineers, Jan. 23, 1915; Heilmann, *Zeit.*, V. d. I., June 10, 1911, and Oct. 31, 1911; Barrus, Engine Tests; Stumpf, Uniflow Steam Engine, 1922; Gebhardt, Power Plant Engineering, 1917; Fernald and Orrok, Engineering of Power Plants, 1916.

The economy of steam engines is expressed in pounds of steam per indicated horsepower-hour; pounds of steam per brake horsepower-hour; British thermal units per indicated horsepower-hour; B.t.u. per brake horsepower-hour; or by these same values per kilowatt-hour; or by the Rankine Cycle Ratio.

STEAM CONSUMPTION GUARANTEES.—In practice, it is customary to base steam consumption guarantees on the performance of similar engines working under similar conditions of steam pressure, superheat and back pressure. If such data are not available, an analysis of the following type becomes necessary.

FACTORS DETERMINING EFFICIENCY.—The ideal cycle for both steam engines and turbines is the Rankine cycle, Fig. 41. See also Steam Cycles, p. 5–14. The highest useful steam pressure is determined by the cost of engine and boiler plant in relation to cost of fuel. Back pressure is determined by the use of exhaust steam for heating purposes or chemical processes, or in condensing operation, by the relation of the gain in steam economy by increasing vacuum, to the cost of vacuum (see Fig. 46 and pages 7–22 to 7–25).

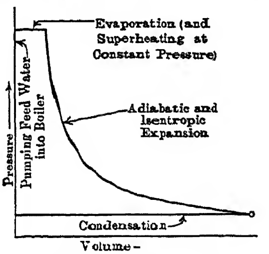

FIG. 41. Rankine Cycle

The steam consumption of a perfect engine following the Rankine Cycle, in lb. of steam per Hp.-hr. is (2546 ÷ B.t.u. available per lb. of steam). The divisor is found directly from the total-heat-entropy chart. The ratio

$$\frac{\text{Steam per brake-Hp.-hr. consumed by perfect Rankine Cycle engine}}{\text{Steam per brake-Hp.-hr. consumed by actual engine}}$$

is called the Rankine Cycle Ratio, Cylinder Efficiency or Relative Efficiency. The Rankine Cycle Ratio is depressed below 100% by the following factors: 1. Friction of steam in passages and ports; 2. Friction of moving parts of engine; 3. Cylinder condensation; 4. Leakage; 5. Losses by free expansion. Items 3 and 5 are the most influential factors. For engines with back pressures of 5 lb. per sq. in. or more above atmospheric pressure, expansion can be carried to back-pressure, and yet the loss by cylinder condensation is small. While steam consumption per Hp.-hr. is high, and the thermal efficiency, therefore, low, the Rankine cycle ratio is very high (about 90% if referred to indicated Hp.-hr.).

The Rankine Cycle Ratio of simple condensing engines is very low when saturated steam is used, because of excessive cylinder condensation, if expansion is carried to or near back-pressure; this also means a very large and expensive engine. Consequently, considerable free expansion loss is allowed. The proper size of cylinder is a compromise between excessive condensation loss (large engine for a given power) and excessive free expansion loss (small engine for a given power).

AVERAGE RANKINE CYCLE RATIOS.—Table 6 gives typical Rankine Cycle Ratios based on indicated Hp.; steam consumption per I.Hp.-hr., and overall thermal efficiencies based on brake Hp., for various types of engines working at or near full load, and with various steam and back pressures. Table 7 gives results of economy tests of various types of steam engines. The *water rate obtained under test conditions cannot be duplicated under ordinary continuous operating conditions* and Table 6 rather than Table 7 should be used for estimating steam consumption for every-day operation.

EXAMPLE.—To find the Rankine Cycle Ratio of uniflow engine, condensing, of 1200 Hp., working with 150 lb. saturated steam. From Table 6 the efficiency of a 500-Hp. engine under the same conditions = 64%. Substituting in formula to find the value of A, $64 = A + 11\sqrt[6]{500}$. $A = 33$. Efficiency of 1200-Hp. engine $= 33 + 11\sqrt[6]{1200} = 68\%$. The sixth root may be found by taking the cube root of the square root or by use of the log log slide rule.

FACTORS INFLUENCING CYLINDER CONDENSATION.—1. Temperature range of steam cycle in cylinder. 2. Area of surface on which steam can condense, in relation to volume of steam admitted. 3. Physical condition of entering steam (wet, dry satu-

NOTE.—For larger sizes and for higher superheats, the values of Rankine Cycle Ratio become greater than those given in the table. Variation of Rankine Cycle Ratio with size between the limits of 100 Hp. and 1500 Hp. is shown with moderate accuracy by the empirical formula:

$$E = A + 11\sqrt[6]{\text{I.Hp.}}, \text{ for condensing engines, and } E = A + 8\sqrt[6]{\text{I.Hp.}},$$

for non-condensing engines; value of factor A changes with the type of engine.

rated, or superheated). 4. Time during which steam can condense. 5. Space relation between entering and discharging steam (wiping heat on and off the walls of cylinder and ports). 6. Length of time of compression during which steam temperature exceeds temperature of cylinder walls. 7. Temperature of cylinder walls (steam jacketing).

All the above factors are at present beyond the range of any rational formula. It is necessary, then, to pile up a great mass of test data, or else to use an empirical formula, such as Heck's, given below, which, by a number of coefficients, furnishes sufficiently accurate results for most practical purposes.

References.—Heck, Steam Engine and Turbine; Callendar and Nicholson, *Proc.*, Inst. Civ. Eng., 1897, Vol. 131; Clayton, University of Ill. Bulletin No. 58; Duchesne, *Revue de Mécanique*, Vol. 19, 1906; Barrus, Engine Tests; Nusselt and Nagel, Forsch. Arb. V. d. I., Heft 300.

DETERMINATION OF STEAM CONSUMPTION FROM INDICATOR CARDS.—The initial steam consumption per indicated horsepower-hour may be determined from an actual indicator card, or from a probable indicator card as developed on p. 7–07, by means of the formula

$$W = \frac{\text{density at } E \times e}{\text{M.E.P.} \times L}, \quad . \quad . \quad . \quad [14]$$

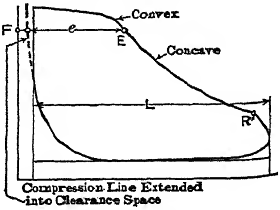

Fig. 42

where W = ideal steam consumption, lb. per I.Hp.-hr.; M.E.P. = mean effective pressure, lb. per sq. in.; L = length of stroke, ft. The value of e and position of E are given in Fig. 42. Point E is located near the cut-off a little below the inflection point from convex to concave. The quality of steam at E is unknown and therefore, it is customary to assume dry saturated steam at E, and take care of the variation of steam density by an initial condensation formula. (See below.)

FORMULA FOR INITIAL CONDENSATION.—The following formula was devised by R. C. Heck (Steam Engine and Turbine, paragraph 22),

$$m = (C/\sqrt[3]{N}) \times (\sqrt{sT/pe'}), \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [15]$$

in which m = fraction of initial condensation, or ratio of missing quantity to (ideal steam + missing quantity); N = rev. per min.; s = area of nominal cylinder surface, sq. ft., divided by the piston displacement, cu. ft., or

$$s = (24/D) \times \{(D/L) + 2\}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [16]$$

where D = diameter, in., and L = stroke of piston, in.; hence s is inversely a measure of the cylinder size; T is an empirical function of the temperature range in the cylinder, and is found from Fig. 43, by reading off T_1, corresponding to the highest pressure in the cylinder, and T_2 corresponding to the lowest pressure; then $T = T_1 - T_2$; p = absolute pressure at point E, Fig. 42, just at cut-off; e' is the ratio

$$\left(\frac{\text{cut-off, \%} + \text{clearance, \%}}{100\%}\right).$$

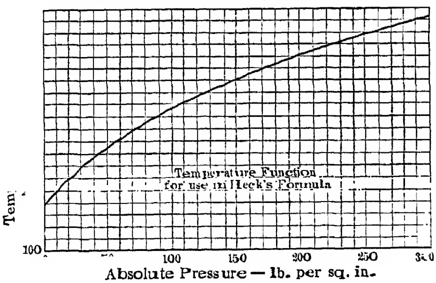

Fig. 43

In Fig. 42 it is represented by $FE'L$. C is a coefficient which takes care, in a measure, of the space relation between ingoing and outgoing steam, and hence must be somewhat with the type of See Figs. 14 to 16. A good average for C, for 4-valve using saturated steam, is 0.27. For single-valve engines, C is about 0.33. the speed exceeds 125 rev. per min., instead of $C/\sqrt[3]{N}$ use $^2/_3\,(C/\sqrt[4]{N})$. For effect of changing clearance volume, see p. 7–23.

The formula does not apply to low-pressure cylinders of compound engines, unless the water is separated from the steam in a large receiver and drained out, nor to en using superheated steam or steam jackets. It refers to engines which show inapprecia steam leakage when tested standing still.

To extend the range of usefulness of Heck's formula to the uniflow engine and to

use of superheated steam, the coefficient C must be modified. For duoflow engines, the value $C - \sqrt{\dfrac{\text{Superheat, deg. F.}}{4500}}$ may be substituted, and for uniflow engines, the value $0.45C - \sqrt{\dfrac{\text{Superheat, deg. F.}}{10{,}000}}$.

This modification necessarily must be only approximate, for the reason that the amount of cylinder condensation depends somewhat upon the point of cut-off. Condensation may for a given degree of superheat, be wholly absent at long cut-off and still be present at short cut-off.

EFFECT OF CHANGE OF INITIAL STEAM PRESSURE on engine economy is more important for high than for low ratios of expansion. For power engines operating with saturated steam, and with the usual expansion ratios, the relative steam consumption at various initial pressures is shown in Fig. 44, for both condensing and non-condensing operation.

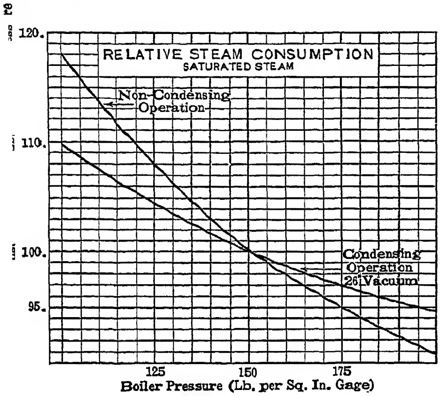

Fig. 44.

EFFECT OF SUPERHEAT on engine economy is double: (1) It reduces the weight of steam per unit volume; (2) It reduces cylinder condensation. If superheat is high enough, the missing quantity as calculated by the above given method, becomes negative, because the weight of steam admitted was computed upon basis of saturated steam. The worse the engine with regard to cylinder condensation, the more beneficial is the effect of superheat. Engines operating with high superheat show a flat load-steam-consumption curve (similar to that of the uniflow engine, Fig. 51). A rough-and-ready rule for single stage expansion engines is that each 10° F. of superheat, reduces steam consumption 1%. Fig. 45 shows the percentage saving in steam consumption due to superheat in various types of engines. Difficulties with packing and lubrication limit the total steam temperature, at present (1935) to 750°, or at most, to 800° F.

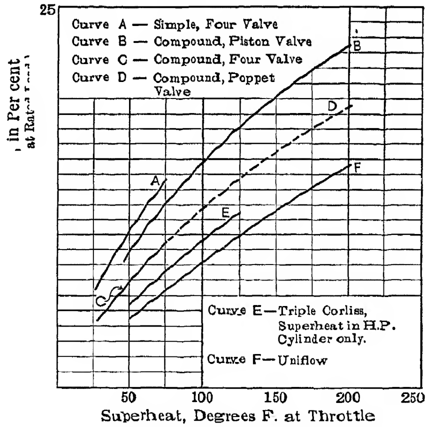

Fig. 45. Saving Effected by Superheat in Percent of Saturated Steam Consumption

EFFECT OF BACK PRESSURE OR VACUUM.—The harmful effect of back pressure is best seen from the lowered thermal efficiency of the Rankine cycle. It is not harmful if all of the exhaust steam is required at the high back pressure for heating or chemical processes. The engine then acts simply as a reducing valve and the power is a by-product.

The effect of vacuum varies with the type of engine. It is least effective in simple engines using saturated steam, with long cut-off, and most effective in multi-stage engines using superheated steam with short cut-off, provided compression need not be high. To make high vacuum effective, release must occur

comparatively early in the stroke (at R, in Fig. 42) and valve passages must be large. Under average conditions each added inch of vacuum reduces the steam consumption 1%. This percentage does not grow with increasing vacuum, but rather tends to decrease. In this respect the engine differs materially from the turbine. Fig. 46 shows the saving due to vacuum, for various types of engines.

References.—Heilmann, *Zeit.*, V. d. I., June 10, 1911; Barrus, Engine Tests; Fothergill, *Power*, Jan. 16, 1912.

CLEARANCE VOLUME is harmful to economy for two reasons: 1. Because it directly increases the surface on which steam condenses; 2. Because it increases free expansion loss, since the true expansion ratio for a given piston displacement at cut-off is less than if no clearance space were present. The effect of surface of clearance space on condensation cannot be expressed in a simple manner. A rough approximation may be gained by increasing C in Heck's formula (see above), in the proportion of

$$\sqrt{(\text{Clearance surface} + 2 \times \text{piston area}) \div (2 \times \text{piston area})}$$

The effect of clearance surfaces evidently varies with the type of engine, temperature range, superheat, etc.; that is, with all those factors which influence cylinder condensation.

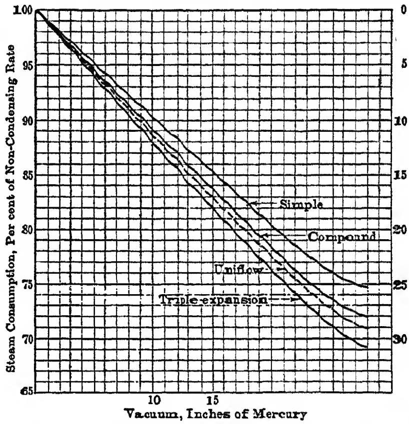

FIG. 46. Saving in Steam Consumption by Increase of Vacuum

The clearance volume as such is harmful, since it causes a given quantity of steam to do less mechanical work than it would do in an engine without clearance. Thus in Fig. 47 the same quantity of steam a does the work of the indicator card outlined in solid lines, in an engine with clearance, and does the additional work of the section-lined area enclosed in the dotted lines, in an engine without clearance. Fig. 47 is a particularly simple indicator card; conditions usually are more complicated. The effect of clearance space as such (neglecting surface action) can be counteracted by carrying compression to initial steam pressure. See Fig. 48. The card in solid lines (with clearance) and the card in dotted lines (no clearance) have the same area. The larger cylinder required for a given power, the surface of the clearance space, and the additional cylinder condensation during compression, render this method of compensating for clearance space valueless.

Taking into account only the harmful effects of *volume* of clearance space, and not those of its surface, a geometrical construction shows that, on an average, each additional 1% of clearance volume in single expansion engines increases the steam consumption 2%. See references below. Heat interchange between the steam and the surface of the clearance space, as a rule, still further increases this loss. In compound and triple-expansion engines, the effect of clearance is not quite so harmful.

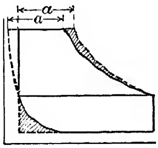

FIG. 47.

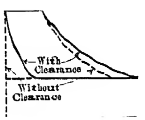

FIG. 48.

The smallest possible clearance space calls for valves in the cylinder head, with consequent reduced accessibility of the interior of the steam cylinder.

Non-condensing uniflow engines, on account of their long compression must have a large clearance volume, to prevent the compression pressure from rising above the steam pressure, or else they must have auxiliary exhaust valves which delay compression until more than half of the return stroke has been completed; see p. 7–39. Of the two, the latter design has been shown by several tests to have the better economy at mean effective pressures above 25 lb. per sq. in.

EFFECT OF COMPRESSION.—Taking into account only the volume of the clearance space, the starting point of that compression which results in greatest area of indicator card for a given quantity of steam, is given by the construction of Fig. 49. Joining

the cut-off point B to point A, extending the line to intersect clearance line at C; joining C with admission point D and extending the line to intersect the back-pressure line, we find point E at which compression should start (J. Stumpf, Uniflow Steam Engine, 1922). This construction results in short compression for long cut-off and long compression for short cut-off, a condition realized in most linkages and shaft governor valve gears. It shows that there is a most favorable compression for any given case.

In reality, matters are much more complicated on account of cylinder condensation during compression. Toward the end of long compression, the steam temperature exceeds the wall temperature, and cylinder condensation is not delayed until fresh steam is admitted, but actually begins during compression; the total time for cylinder condensation is increased and steam consumption rises. Steam-jacketed cylinders can economically carry earlier compression than non-jacketed, because wall temperature is higher. Tests by Heinrich (Mitteil. ü Forsch., 1914) have shown that between 2% and 50% compression, with cut-off constant, the steam economy does not vary more than 4% (Fig. 50). The test engine had 8 2/3% clearance volume.

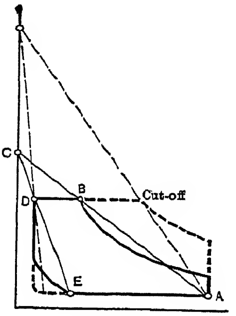

FIG. 49

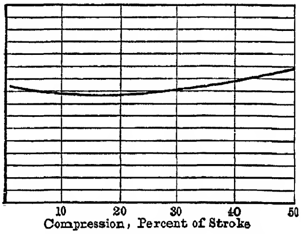

FIG. 50. Effect of Compression on Steam Consumption.

Compression earlier than that indicated by conditions of steam economy may be necessary for quiet operation of engine. See page 7–29.

References.—Heinrich, Mitteilungen über Forschungsarbeiten, *Zeit.*, V. d. I., Heft 146, June, 1914; Klemperer, *Zeit.*, V. d. I., 1905, p. 797.

EFFECT OF LEAKAGE.—Leaky pistons and valves can waste more steam than the best valve gear can save. Unsuspected leakage will readily lose as much as 10% of the total steam. (Barrus, Engine Tests.) No standard methods exist for determining the leakage of engines separately from losses by cylinder condensation. For approximate experimental determination, see A.S.M.E. Power Test Code. A valve may be perfectly tight when standing still, but leak badly in operation. For example, in piston valves, when not moving, steam works behind the rings and sets them out against the bushing, making a tight fit; but when moving, there is not sufficient time for steam to attain much pressure behind the rings, and the fit of the rings against the bushing depends largely upon the elastic pressure of the rings themselves; also on the surfaces of the valve and bushing which are exposed alternately to high and low pressures, steam condenses, the surfaces then slide over each other without removing the water film, and the latter flashes into steam when exposed to the low pressure and thus escapes to the exhaust.

Leakage affects the steam consumption per Hp.-hr. more at light loads than at heavy loads. Leakage through slide valves is never less than 4%, and often exceeds 20% of the total steam consumption at rated loads. Tests of slide valves (Callendar and Nicholson, *Proc.* Inst. C. E., 1897) show that the leakage Q in pounds per hour is given by the formula

$$Q = (C \times p \times B) \div l, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [17]$$

in which C = constant (about 0.02 for well fitted valves); p = pressure difference, lb. per sq. in.; B = perimeter of valve, in.; l = average overlap, in. The same value of C seems also to apply fairly well to piston valves without rings.

Tests made by the Penna. Railroad at Altoona, Pa., with a piston valve 12 in. diam., showed the following average leakage at *each end* of the valve, in pounds per hour per inch of circumference (leakage length); with one ring, 16.4 lb.; with two rings, 7.2 lb.; with three rings, 6.0 lb. These figures were obtained with steam at 185 lb. per sq. in. gage pressure, and atmospheric pressure at the other end of the valve. With 100° F. superheat, the leakage was about 15% greater, but with 200° F. superheat, it was only 7% greater than that of saturated steam. The leakage was inde-

pendent of speed and length of stroke. Within the range of usual pressures it is probably proportional, approximately, to the pressure difference.

Leakage is of greatest importance in a single-valve engine, since steam can leak directly into the exhaust without entering the cylinders. It is not so serious in an engine having separate valves for inlet and exhaust, since leakage steam must enter the cylinder, and do some work. It is still less wasteful in the uniflow engine. As it is shut off from the exhaust ports by the piston during 90% of the stroke, nearly all leakage steam must do work. Furthermore, a slight leakage raises the compression pressure considerably, causing the inlet valves to clatter so that leakage cannot occur unnoticed.

EFFECT OF CHANGE OF LOAD. WILLANS LAW.—The combined influences of cylinder condensation, leakage and free expansion losses (the relative effectiveness of each factor varies with type of engine), result in *variation* of steam consumption *with load* as shown in Fig. 51 (pounds of steam per I.Hp.-hour) and Fig. 52 (total steam consumption per hour). The dot-and-dash lines in Fig. 52 illustrate *Willans Law*, which states that total steam consumption, at any load, of an engine controlled by throttling is $C_1 + C_2 \times$ (indicated horsepower), in which C_1 and C_2 are constants for a given engine; C_1 represents steam consumption at no load, or steam lost by cylinder condensation and leakage; C_2 is the steam used per hour to produce one indicated horsepower. This holds almost exactly for throttling engines and for turbines, but cannot be applied to engines controlled by varying the cut-off.

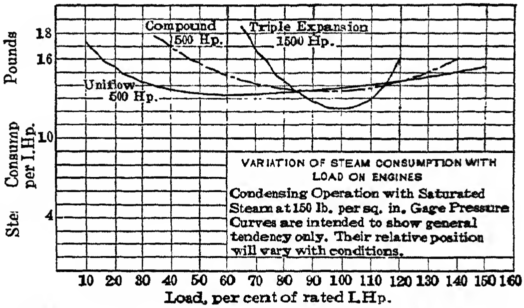

Fig. 51. Variation of Steam Consumption with Load on Engine

EFFECT OF VALVE GEARS AND OF METHOD OF CONTROL.—Narrow, long ports and slowly opening and closing valves result in wire-drawing through such ports and valves. For calculation of this effect, see Capacity of Steam Engines, p. 7–07. The loss of area of the indicator card divided by the area of the ideal card, furnishes directly the loss due to such wire-drawing. The arrangement of valves and ports likewise affects economy through its effect upon cylinder condensation.

EFFECT OF MOISTURE IN STEAM.—Tests by Marks and by Denton show that increase in the amount of moisture in steam at the throttle, up to 40%, has practically no effect upon the dry steam consumption; the water remains inert, passing through the cylinder without helping or hindering. (*Trans.* A.S.M.E., vol. xv., 1893.)

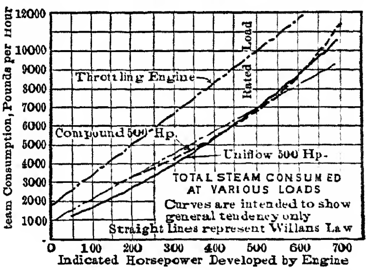

Fig. 52.

EFFECT OF REHEATING RECEIVERS.—Reheating receivers dry or superheat the steam going to the low-pressure cylinders of compound or triple-expansion engines, and also to the intermediate cylinders of triple-expansion engines. Reheating receivers, if made large enough, eliminate cylinder condensation, but require an equivalent amount of live steam in the reheaters. Hence, no gain results from their use alone. In compound engines, however, the *combination* of a reheating receiver having 1/4 sq. ft. of heating-surface per horsepower, and of jackets on the low-pressure cylinder, has shown a slight gain, while each of the two expedients by itself produced a loss. In triple-expansion pumping engines, reheaters are successfully used in combination with jackets on all cylinders.

EFFECT OF STEAM JACKETING.—Steam jackets raise the average temperature of the cylinder walls and prevent deep-reaching temperature fluctuations in them but they cannot prevent "skin deep" temperature fluctuations. In consequence they are of no effect in high-speed engines, as much steam being lost by condensation in the jackets as is saved by decreased condensation in the cylinder. They are, however, beneficial in slow-speed engines, such as pumping engines, in which the time for cylinder condensation is so great as to produce deep-reaching temperature fluctuations if no jackets are used.

EFFECT OF UNIFLOW PRINCIPLE.—The effect of the uniflow principle has been discussed under Cylinder Condensation. An additional effect, favorable to economy, is caused by the sudden and short exhaust. Heilmann, *Zeit.*, V. d. I., June 10, 1911, and Doerfel (private report) contend that the explosion-like exhaust mechanically sweeps the water off cylinder walls and does not give the heat in the cylinder walls sufficient time to evaporate the water. Hence, the average wall temperature is higher and initial condensation is reduced. Tests demonstrating this action are lacking. The clearance volume can be made very small in the condensing uniflow engine; this favorably influences the efficiency.

EFFECT OF ENGINE FRICTION.—Engine friction appears as the difference between indicated horsepower and brake horsepower. Both are easily determined, but since the power absorbed by friction is, in a given engine at constant speed, almost constant at all loads, increasing only very slightly as load increases, it is more usual to take a "friction card," showing the indicated horsepower when the engine is delivering no power at the shaft, and all of the work shown by indicator card is being absorbed by engine friction. In blowing engines, pumps and compressors, engine friction appears as the difference between indicated steam horsepower and indicated pump horsepower. Thurston makes the following approximate distribution of the total losses due to friction: Main bearings, 47%; piston and rod, 33%; crank-pin, 7%; crosshead and wrist pin, 5%; valve gear, 8%.

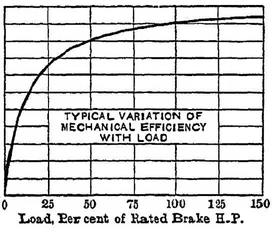

Fig. 53.

The ratio of brake horsepower (or indicated pump horsepower, respectively) to indicated steam horsepower is the *mechanical efficiency*.

Mechanical efficiency $= \frac{\text{I.Hp.} - \text{friction Hp.}}{\text{I.Hp.}} = 1 - \frac{\text{friction Hp.}}{\text{I.Hp.}}$. As friction horsepower is nearly constant, the mechanical efficiency varies with the load. Fig. 53 is a typical curve showing such variation. Mechanical efficiency depends upon the type and effectiveness of lubrication, upon the quality of workmanship and correctness of alignment of the engine, and upon the degree of cleanliness of the place in which the engine is to work.

It becomes lower as the initial pressure and number of cylinders are increased, and rises with increasing ratio of M.E.P. to initial pressure and with increasing size of engine. It is seldom below 85% at full load, while the highest record is about 97 1/2%. The mechanical efficiency of vertical engines is higher than that of horizontal engines of similar

Table 8.—Mechanical Efficiency of Steam Engines

Average values for every-day operation at rated load. Engines in good condition.

		Percent
Simple Engines:	Portable engine, 50 Hp	83
	Horizontal automatic engine, 150 Hp	90
	Horizontal Corliss engine, 300 Hp	91
	Horizontal uniflow engine, 400 Hp	90
	Locomotive	85
Compound Engines:	Horizontal automatic engine, 300 Hp	90
	Horizontal Corliss engine, 500 Hp	89
	Horizontal blowing engine, automatic, 2000 Hp	88
Triple-Expansion Engines:	Vertical power engine	90
	Vertical pumping engine, slow speed, 1500 Hp	94

type. Other factors being equal, the variation of mechanical efficiency with size of engine is expressed by

$$E_m = A + 2\sqrt[4]{\text{I.Hp.}} \qquad [18]$$

For a horizontal simple engine, constant A = about 79, so that for such an engine

$$E_m \text{ (percent)} = 79 + 2\sqrt[4]{\text{I.Hp.}} \qquad [19]$$

Table 8 shows average mechanical efficiencies obtained at full load, under ordinary conditions of operation, with engines in fair shape.

6. QUIET OPERATION OF STEAM ENGINES

Vertical single-acting steam engines run quietly as long as the forces on the piston act always downward. This condition usually exists at low and medium speeds. At high speeds or low back pressure, the compression of steam in the cylinder is not sufficient to keep the moving parts in compression at all times, because upward inertia exceeds the compression force, and knocking results. Noisy operation in single-acting engines may be caused by piston slaps or by alternating forces in the valve gear. A table of inertia factors is given in Vol. 3.

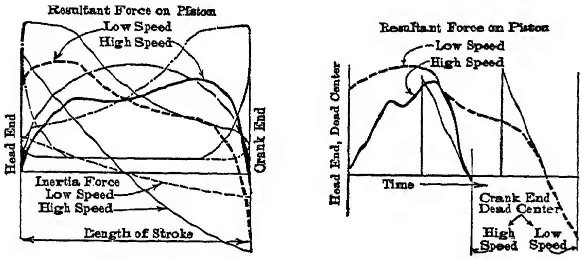

Fig. 54.

In double-acting engines, forces must change sign (tension to compression or *vice versa*) in every stroke. A knock occurs whenever the force changes sign suddenly and there is clearance in the joints. Play in the joints can be taken up, to a certain extent, by adjustment of brasses in main bearings, crank-pin and crosshead-pin. It can never be entirely eliminated, because pins wear oval, and deflect in operation; also because room must be allowed for an oil film and for unequal heat expansion. (For amount of clearance, see section on Machine Design, vol. 3 of this series.) This clearance can be filled with oil under pressure (forced lubrication; highly developed in British "quick revolution" engines), and knock can, thereby, be practically eliminated. Complete quietness is obtained by keeping the *rate of change* of force low, at the time the force changes sign. See Fig. 54. For a given shape of indicator card and a given engine, the rate of change of force increases with the revolutions, which is one reason why high speeds tend to produce pounding.

A second reason is due to the fact that the higher the speed and the greater the inertia forces the more is the position where the force changes sign moved toward the dead center. See Fig. 54. If the force changes sign *after* compression has been completed and when steam is being admitted, a knock occurs, unless steam is admitted gradually by a V-lead, or holes in the valve or valve seat. (See Valve Gears, Fig. 62.)

Long compression, with large clearance space, enables high-speed engines to operate very quietly. For detrimental effect on steam consumption of these features, see Steam Engine Economy, p. 7-23.

Direct-connected crank-and-flywheel pumping engines (steam engines with steam piston and pump piston on one common rod) including blowing engines and compressors, produce knocks in mid-stroke, because the forces change sign in mid-stroke. The knock is made more severe by the cross-heads vibrating from one side to the other.

Loose pistons are occasionally the cause of knocking and pounding. In high-speed releasing gears, the sudden contact of the lift arm with the valve arm produces knocking.

7. VALVE GEARS

References.—Dubbel, Steuerung der Dampfmaschinen, 1913; Furman, Valves, Valve Gears and Valve Diagrams; Zeuner, Treatise on Valve Gears; (see also Ninde, Ripper, Heck, Unwin and Allen).

Steam engines which operate pumps or compressors directly without a shaft, derive their valve motion directly from the motion of the piston. Steam engines turning a shaft derive the valve gear motion from cranks, eccentrics or cams on the main engine shaft or on a "lay" shaft driven by the main shaft. In the selection of valve gears, the possibility of enclosing the mechanism should be given careful consideration. Unenclosed valve gears throw oil, collect dust and dirt, and may injure attendants. In some cases the steam engine has been displaced by the small turbine because the advantage of complete enclosure could be shown for the latter.

VALVE GEARS OF DIRECT-ACTING STEAM ENGINES.—The piston, a short distance before the end of its stroke, operates a small pilot valve which admits steam to operate the main slide valve (Fig. 55). A time lag between the two valve movements allows the piston to complete its stroke. The diameter of the plug valve is usually 0.30 that of the steam piston. The size of slide valves and ports is based on a nominal steam velocity of 6000 ft. per min., and an exhaust velocity of 4000 ft. per min.

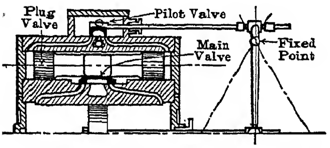

Fig. 55. Valve Gear of Direct-acting Engine

If two cylinders lie side by side as in a duplex pump, each piston in mid-stroke can reverse the motion of its neighbor, it being premised that the second half of the stroke will be completed in less time than the first half. If friction upsets this premise, one of the pistons "short-strokes," that is, does not complete its stroke.

VALVE GEARS OF CRANK-AND-FLY-WHEEL ENGINES.—In engines with revolving shafts, and valves operated by crank or eccentric, the fraction of the crank circle circumference during which the valve is open determines the ratio of opening travel to idle travel of the valve-moving mechanism. See Fig. 56. The idle travel may be reduced by linkages, as in Fig. 57, or eliminated by cams as in Fig. 58. The latter method is necessary on all non-releasing poppet-valve gears.

In Fig. 59, if the valve is to open when the piston stands at (3), and is to close with the piston at (4), both points being the mean between head end and crank end, then the valve opens when the engine crank is at (1) and closes with it at (2). The valve is wide open

Table 9.—Steam Velocities in Ports and through Valve Openings

Higher steam velocities reduce economy by excessive pressure drop. Lower steam velocities reduce economy by necessitating increase in clearance volume.

Type of Valve and Engine	Nominal Steam Velocity, Feet per Second		
	In Ports, Smallest Section	Through Greatest Valve Opening	
		Inlet	Exhaust
Slide-valve, slow-speed engine	70	90	70
Slide-valve, high-speed engine	130	175	130

Uniflow engine exhaust ports	....	....	60 to 120

* Velocities for double-beat poppet valves are based on nominal area—that of two circles having average diameter of valve seats. Velocities through greatest free opening, usually twice the above values.

The lower values apply to small engines, the higher values to large engines and superheated steam.

Length of port, for slide valves = 0.6 to 0.8 piston diameter; for rocking valves, 0.8 to 1.1 piston diameter, depending on valve diameter, which is usually 0.25 of the piston diameter when length = piston diam.

when the crank is at (5), half-way between (1) and (2). This condition determines the location of the valve-operating crank or eccentric on the main shaft or lay shaft. In particular, if the valve moves parallel to the piston, the eccentric is $(90 + \beta)$ degrees ahead of the crank or $(90 - \beta)$ degrees behind, depending upon opening direction of valve. The angle β is the angle of advance.

SIZE OF PORTS.—(See also Steam Engine Capacity.)—Port area commonly is determined by the equation *Port area* $\times$ *steam velocity* = *piston area* $\times$ *piston velocity*. In this equation the term "steam velocity" is only a conventional coefficient, as the

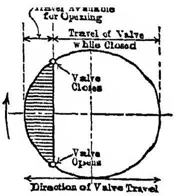

FIG. 56

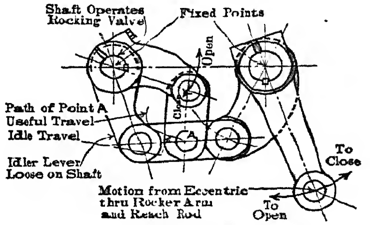

FIG. 57. Valve Gear Linkage

actual steam velocity varies continually because of the variation of piston velocity and of port area. See Fig. 60. In the use of so-called "steam velocities" from tables, care must be exercised because "piston speed" may mean either instantaneous or average piston speed. Table 9 is based upon *average* piston speed, extended over the whole stroke.

TYPES OF VALVES.—There are two broad classes of valves: 1. Sliding valves; 2. Lifting valves.

Slide Valves

DEFINITIONS.—Travel is total distance moved by the valve.

Throw of the Eccentric is eccentricity of the eccentric = distance from the center of the shaft to the center of the eccentric disc.

Lap of the Valve, also called outside lap or steam-lap is distance the outer or steam edge of the valve extends beyond or laps over the steam edge of the port when the valve is in its central position.

Inside Lap, or Exhaust Lap is distance the inner or exhaust edge of the valve extends beyond or laps over the exhaust edge of the port when the valve is in its central position. The inside lap sometimes is made zero, or even negative, in which latter case the distance between the edge of the valve and the edge of the port sometimes is called exhaust clearance, or inside clearance.

Lead of the Valve is the distance the steam-port is opened when the engine is on its center and the piston is at the beginning of the stroke.

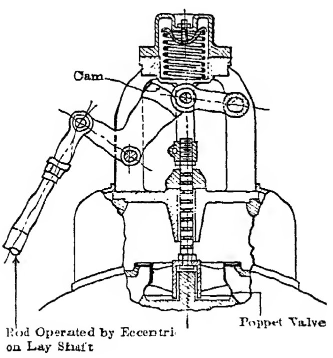

FIG. 58. Double Beat Poppet Valve

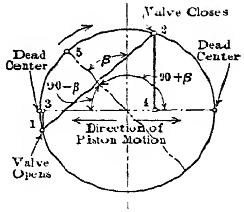

FIG. 59

Lead-angle is the angle between the position of the crank when the valve begins to be opened and its position when the piston is at the beginning of the stroke.

The valve is said to have lead when the steam-port opens before the piston begins its stroke. If the piston begins its stroke before the admission of steam begins, the valve

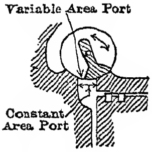
is said to have negative lead, and its amount is the lap of the edge of the valve over the edge of the port at the instant when the piston stroke begins.

Lap-angle is the angle through which the eccentric must be rotated to cause the steam edge to travel from its central position the distance of the lap.

Angular advance of the eccentric is (lap-angle + lead-angle).

Lineal advance is (lap + lead).

EFFECT OF LAP, LEAD, ETC., UPON STEAM DISTRIBUTION.—If a valve had neither lap nor lead, the center of the valve eccentric being 90° ahead of the crank center, then steam would be admitted to the engine throughout the full length of the stroke.



G. 60. Rocking Valve

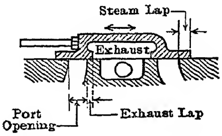


Fig. 61. D-Slide Valve

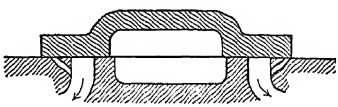

Fig. 62. Valve for Gradual Admission.

To enable steam to be cut off before the end of the stroke, and thereby allow expansion, lap is added to the valve. To enable steam to be admitted at the beginning of the stroke, as before lap was added, the eccentric is advanced on the shaft an amount equal to the lap angle. Advancing it still further by an amount called the lead angle causes admission to begin before the beginning of the stroke.

The four events, admission, cut-off, release or exhaust-opening, and compression or exhaust-closure, take place as follows: Admission, when the crank lacks the lead-angle of having reached the center; cut-off, when the crank lacks two lap-angles and one lead-angle of having reached the center. The greatest port opening is equal to half the travel of the valve less the lap. Therefore, in order not to reduce the port opening the valve travel must be increased if lap is increased. Adding exhaust lap to the valve delays release and hastens compression by an angle of rotation equal to the exhaust-lap angle, which is the angle through which the eccentric rotates from its middle position while the exhaust edge of the valve uncovers its lap. The above discussion of the relative position of crank, piston, and rod for the different points of the stroke is accurate only for a connecting-rod of infinite length. In practice, rods have a finite length, but the use of the infinite rod in laying out the valve diagram has the advantage that a mean between head and crank ends is obtained.

For actual connecting-rods the angular position of the rod causes a distortion of the position of the valve, causing the events to take place too late in the forward stroke and too early in the return. The correction of this distortion may be accomplished to some extent by setting the valve so as to give equal lead on both forward and return stroke, and by altering the exhaust-lap on one end so as to equalize the release and compression. F. A. Halsey (Slide-valve Gears) describes a method of equalizing the cut-off without at the same time affecting the equality of the lead. In designing slide-valves the effect of angularity of the connecting-rod should be studied on the drawing-board, and preferably by the use of a model. In the section on Machine Design, vol. 3, of this series, is a table which gives the crank-angles for various fractions of the stroke.

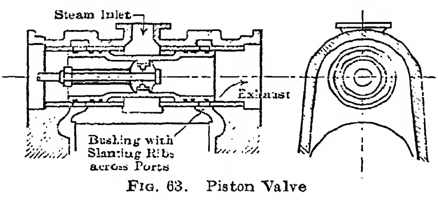

Fig. 63. Piston Valve

SLIDING VALVES.—The simplest form of *sliding valve* is the common flat slide valve, or D-valve, Fig. 61, which controls both steam admission and exhaust. It is much used for small portable engines working with saturated steam, but is not suitable for high steam pressures or for high superheats on account of distortion and rapid wear. It acts as a relief valve if the compression becomes too high or if there is too much water in the steam. It can be balanced by a pressure plate or by exposing part of the top of the valve to exhaust pressure. Steam can be admitted gradually at one end of the stroke by a V-lead or by holes in valve or valve seat as in Fig. 62.

The *piston valve* is perfectly balanced, and can be used with the highest steam pressures

and superheats, if the wearing parts of valves and valve bushings are free from the distorting influence of ribs, as is the valve in Fig. 63, and if the rings are protected against being set out by steam pressure. An example is the lock-ring type. The principal drawback of the piston valve is its large clearance volume. Clearance can be reduced by placing piston valves in cylinder heads (Van den Kerchove type).

The *rocking valve*, also called the Corliss valve, is single ported as in Fig. 60, for the slow speeds of pumping engines and ammonia compressors and double ported (Fig. 64) for piston speeds above 600 ft. per min. Separate valves are used for admission and for exhaust, the form of the latter being shown in Fig. 64. The rocking valve is a desirable

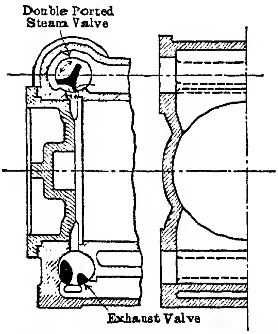

FIG. 64. Double-ported Corliss Valve

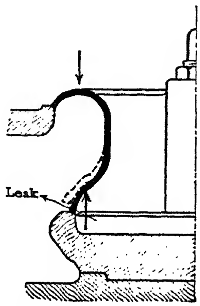

FIG. 65. Leakage of Poppet Valve

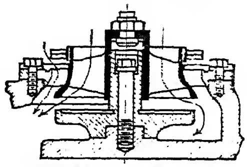

FIG. 66. Stumpf Valve

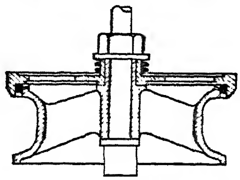

FIG. 67. Skinner Valve

form for use with saturated steam and for pressures up to 160 lb. per sq. in. gage. High steam pressures, or superheats exceeding 50° F., produce much friction, the first by squeezing the oil out of the space between the valve and valve seat, the second by distorting the valve and valve chamber. The general use of the rocking valve in the United States considerably retarded the introduction of high steam pressures and superheat, and paved the way for the steam turbine.

All sliding valves can be made *multi-ported*, to admit and shut off steam more quickly. For effect of multi-porting on economy and on shape of indicator card, see below.

LIFTING VALVES.—Single beat poppet valves, or mushroom valves, are sometimes used in the heads of low-pressure cylinders of triple-expansion pumping engines, to minimize clearance.

Double beat poppet valves, Fig. 58, have two seats of narrow width. They are very nearly balanced and can be entirely balanced if desired.

Steam pressure compresses the valve as indicated in Fig. 65 and tends to produce leakage. Unequal expansion, due to different metal or to differences of temperature (valve and one seat exposed to high temperature steam, other seat exposed only to low temperature steam) also causes leakage. To overcome this trouble, valves must either be ground in while under steam pressure (in which case they are tight for that particular pressure but leak if the pressure or superheat changes), or must be made flexible, as in the Stumpf valve, Fig. 66, or the Skinner valve, Fig. 67. Poppet valves can be used with the highest steam pressures and superheats. They have the disadvantage that the valve must be operated either by cams, rollers, or a pair of wiper cams.

In recent practice, cams and valve operating parts are hardened and ground, enclosed and lubricated by continuous oil streams. For speeds below 100 r.p.m., poppet valves may be operated by a releasing gear without a cam, although drop piston valves are preferred with this type of mechanism because quick closing is obtainable without slamming.

Valve Gear Diagrams

VALVE GEAR DIAGRAMS.—The diagram of valve opening at any piston position, Fig. 68, can be obtained from existing engines by placing the engine piston in different positions and measuring the valve opening for each position with various positions of the cut-off control mechanism, by blocking the governor at different heights. In engine design, the diagram can be taken by doing the same thing with a model, or by finding

various valve positions from a drawing. If the area of the valve opening exceeds the constant port area, the latter determines the steam flow. Constant port area is indicated by line AB, Fig. 68.

For steam admission valves, the foregoing diagram shows the range of cut-off; point

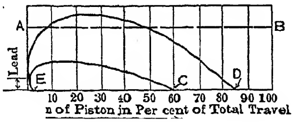

Fig. 68

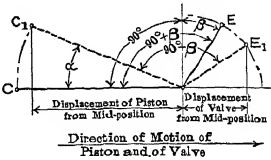

Fig. 69

of admission before dead center; lead, or linear valve opening at dead center, expressed in inches; maximum valve opening at short cut-offs; and wire drawing effect of valve. (See also Steam Engine Capacity, Fig. 20.) For exhaust valves, it shows the point of release, valve opening at dead center, and point of compression.

The interdependence and limitations of admission and exhaust events is shown by a different type of diagram, such as the Sweet, Zeuner, or Bilgram diagram, in which one variable indicates the positions of both valve and piston, for any crank position. The various valve diagrams differ by the choice of that variable. The use of one or the other is largely a matter of personal preference.

SWEET DIAGRAM, Fig. 70. (Also called Mueller diagram or Reuleaux diagram.) —The basis of the diagram is as follows: 1. Crank is turned ahead through angle $(90 + \beta)$. 2. Engine stroke is drawn to a reduced scale so that it coincides with valve travel. Then if the crank has turned through angle α from dead center position, DE indicates distance of valve from mid-position, while AC indicates the distance (average between head end and crank end), which the piston has traveled from end of stroke, expressed as a fraction of the whole stroke AB. By striking arcs EF and EG with radii $HE = IE$ so that HE/AB = ratio of connecting-rod length to engine stroke, we obtain AG = piston travel from head end, AF = piston travel from crank end dead center.* In the same manner, valve displacement DE can be corrected for finite length of connecting-rod, but as a rule the correction is negligibly small. DE is the valve displacement for all gears in which the valve is driven directly from an eccentric, without distortion by linkage or cams. Fig. 71 shows diagram derived from this principle, and the ideal indicator card (mean between head and crank end), with direction of *valve* motion horizontal, while Fig. 72 shows diagram with direction of *piston* motion horizontal and indicator cards for both head and crank ends. In both illustrations, the circle, drawn with any convenient diameter, represents both valve travel and piston stroke. If admission (point A) and cut-off (point B) are selected, the angle of advance is fixed. Either release or compression then can be selected, and the other one of the two is given, because CD is parallel to AB (same angle of advance).

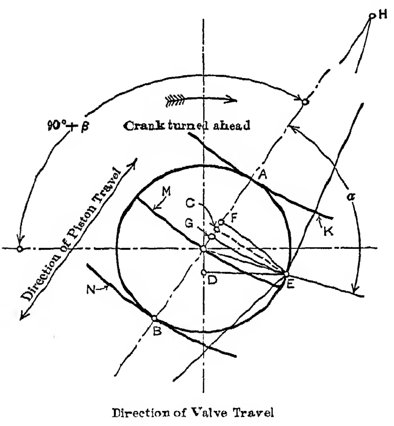

Fig. 70. Sweet Valve Diagram

The maximum port opening A, Fig. 71, is fixed by so-called mean steam velocity (see

* Instead of drawing arcs, as EG or EF, from each crank position, the arcs K, M, and N, drawn with radii = HE, may be used as reference lines representing ends and middle of stroke. Distance of piston from center of stroke when crank [illegible] distance parallel to AB from point E to arc M. With arcs as shown, A is head end dead center.

p. 7–30), and by available length of port. The ratio of travel to width of port is available from the diagram, and the valve travel can be found from the value of A. In using the diagram, the following precautions are to be observed: Admission must be $1/2\%$ to $1\ 1/2\%$ of stroke ahead of dead center, depending upon piston speed, compression, and

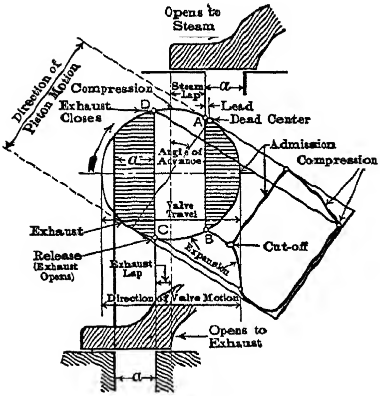

Fig. 71.

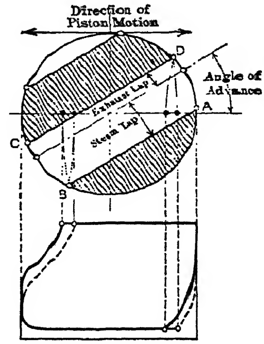

Fig. 72.

clearance volume. Cut-off in the actual indicator card is 10% to 20% earlier in the stroke than that determined from valve diagram, depending upon the so-called average steam velocity. For factors determining release and compression, see pages 7–13 and 7–23. Compression in the actual card begins 4% to 7% earlier than in the valve diagram. See p. 7–09. Release occurs from 5% ahead of dead center for low piston speeds, up to 25% for high piston speeds. If cut-off and compression are to be made more nearly equal for head and crank end, the valve must be moved toward the head end so that the head end lap is greater than the crank end lap. Complete equalization by this method is not desirable, because admission and release become unequal at the two ends.

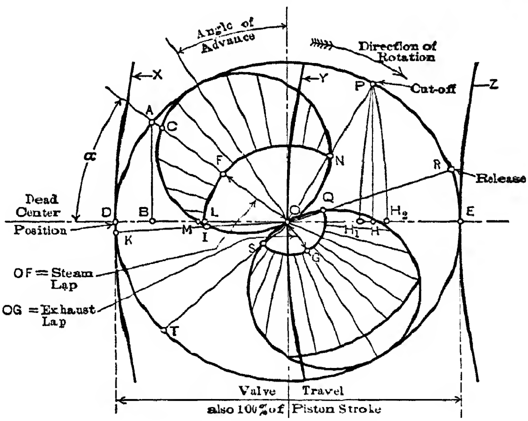

Fig. 73. Zeuner Valve Diagram

Piston valves usually have steam admission at the center, and exhaust at the outer ends of the valve. The valve phase is shifted 180° as compared to the plain slide valve. The valve diagram is the same as for the slide valve, with the following exceptions: Eccentric, instead of being (90° + angle of advance) ahead of crank in direction of motion, is (90° − angle of advance) behind crank. To equalize the cut-off, valve must be shifted toward the crank end.

ZEUNER DIAGRAM.—For finite length of rod, $R \cos \alpha$ = piston displacement from mid-position, if R = crank radius, α = angle through which crank has turned from dead center; $r \cos (\alpha + \beta)$ equals valve displacement from mid-position, if $2r$ = valve travel, and β = angle of advance. Any geometrical construction which, by one variable, gives

value of both $R \cos \alpha$ and $r \cos (\alpha + \beta)$ is a valve diagram. Zeuner, of Dresden, Germany, constructed a diagram, Fig. 73, by using rectangular co-ordinates for the piston travel, and polar co-ordinates for the valve travel.

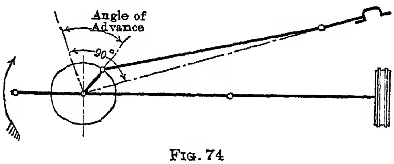

Fig. 74

For any crank-angle α, and crank position A, DB = piston travel (for DE = stroke), and OC = valve displacement from mid-position. At I, valve displacement = steam lap. Hence admission of steam occurs at K. Lead = LM. Cut-off occurs at N and P. Piston stroke at cut-off = DH for an infinitely long rod, = DH_2 at head end, = DH_1 at crank end.*

Release occurs when valve displacement equals exhaust lap (at Q and R). Compression occurs at S and T. The Zeuner diagram, although formerly very popular is now used less than the Sweet diagram.

LIMITATIONS OF VALVE-GEAR DIAGRAMS.—If the center line of the valve motion is not parallel to the center line of piston motion (see Fig. 74), the angle of advance marked in that illustration must be used. If valve motion is in any way distorted by linkages, cams, or skew drives, the simple valve diagrams cannot be used.

References.—Halsey, Slide-valve Gears; Fessenden, Valve Gears; Peabody, Valve Gears for Steam Engine; Spangler, Valve Gears.

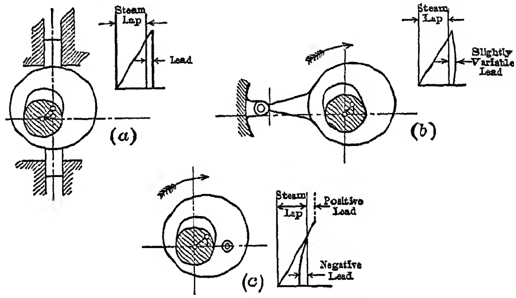

Fig. 75. Movable Eccentrics

SINGLE ECCENTRIC, VARIABLE CUT-OFF GEARS.—If the cut-off is to be variable with a single valve, and if admission and release are to remain correct over a wide range of cut-off, both valve travel and angle of advance must be varied in such a manner that the *lead* remains almost constant. This is accomplished by moving the eccentric " across the shaft," either in a straight line, as in Fig. 75 (a) or in the arc of a circle, as in Fig. 75 (b) and (c). In the former case, lead remains constant, while in the latter it is variable. Variability can be kept within narrow limits by proper location of the pivot. The pivot frequently is put on the center line of the crank [Fig. 75 (c)] to facilitate change of direction of rotation. It is desirable to reduce the lead to zero or to a negative value at minimum valve travel, in order to control the engine without load.

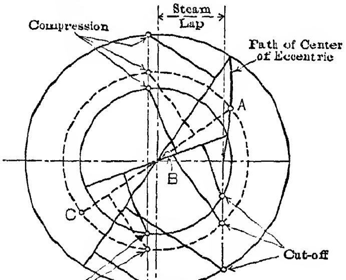

Fig. 76. Sweet Diagram for Slide or Piston Valve

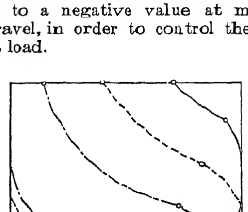

Fig. 77. Ideal Indicator Card for Slide or Piston Valve

* Instead of arcs PH_1, PH_2, etc., arcs XY and Z may be used as reference lines for the ends and middle of stroke, as explained for the Sweet diagram. With arcs as shown, D is the crank end dead center.

The Sweet diagram for a slide or piston valve, operated by a movable eccentric, is shown in Fig. 76, while the resulting ideal indicator cards, neglecting the effect of throttling, appear in Fig. 77. As the eccentric is moved closer to the center of the shaft, the valve travel is reduced, and with it the length of line representing 100% piston travel.

EXAMPLE.—$(AB/AC) \times 100$ = percent cut-off for position A of eccentric. As cut-off is shortened, release occurs earlier and compression becomes longer. Actual indicator card shows considerable throttling at early cut-off, on account of insufficient valve opening. (See Capacity of Steam Engines.)

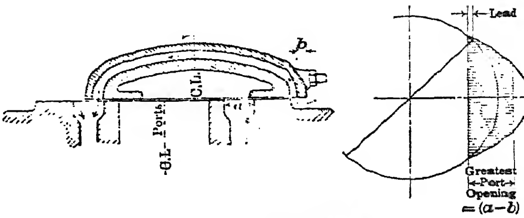

FIG. 78. Allen Valve

Single valves, driven by eccentrics which swing across the shaft, are much used in high-speed engines of office building power plants.

Excessive throttling is avoided by double admission valves, whose principle is shown by the Allen valve, Fig. 78. This valve admits steam directly and also through the valve from the other end. Port openings are doubled throughout, if the inlet port is made wide enough to accommodate the valve port and bridge. The Allen valve increases the clearance during a part of compression.

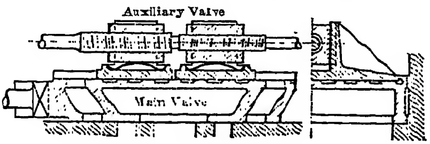

FIG. 79. Meyer Valve

RIDING CUT-OFF VALVES.—A single valve cannot vary the cut-off without change of compression. It is limited in its drive to shaft governors or to valve link-drive. Both of these drawbacks are avoided by *riding cut-off valve gears,* such as the Meyer valve, and others, illustrated in Fig. 79. The main valve controls admission, release and compression, while the auxiliary valve varies the cut-off. The latter is done either by changing the lap of the cut-off valve, or by varying the time of its motion by shifting the eccentric around the shaft, or by a combination of the two.

Relations can be read from the modified Sweet diagram in Fig. 80. The auxiliary or cut-off valve diagram determines cut-off only, the main valve diagram which is the same as for a single valve, determines admission, release, and compression. MA = 100% piston travel for the main valve diagram. EC = 100% piston travel for cut-off valve diagram. With the crank horizontal as shown, OM = main eccentric, OC = cut-off eccentric; then triangle OMC revolves about O, and MC = relative eccentric. The valve travel is horizontal, with CE as the direction of piston travel. The cut-off valve closes after the crank has turned through the angle C–5. $(CF/CE) \times 100$ = cut-off in percent of piston stroke. The greater the negative lap of the cut-off valve, the later in the piston travel does it close. If negative lap almost equals radius of relative eccentric, the cut-off valve reopens before the main valve has closed (with angles, etc., as shown in the diagram)

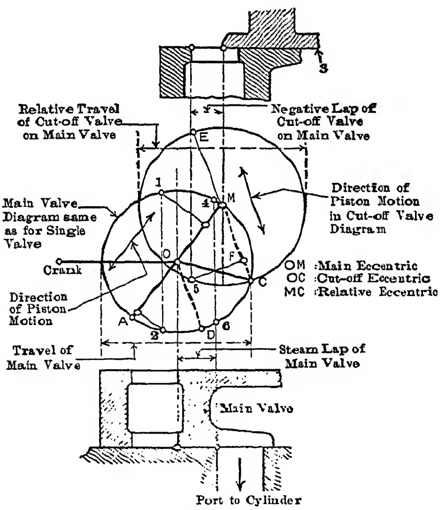

FIG. 80. Valve Diagram for Riding Cut-off Valve

MC must not be taken so large that there is not room on main valve for cut-off valve plus change of lap. Edge 3 of the cut-off valve must not be allowed to open when the main valve is open. The radius of the relative eccentric, *MC*, is usually made 1.6 to 2.0 times port width. The proportions in Fig. 80 give good results for average conditions. The angle of advance of main valve is from 30° to 35°. The distance between cut-off valves

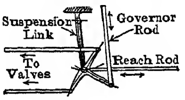

Fig. 81

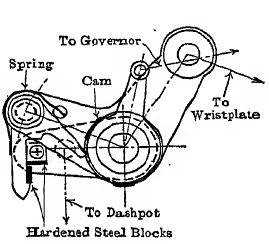

82. Releasing Gear for Rocking Valves

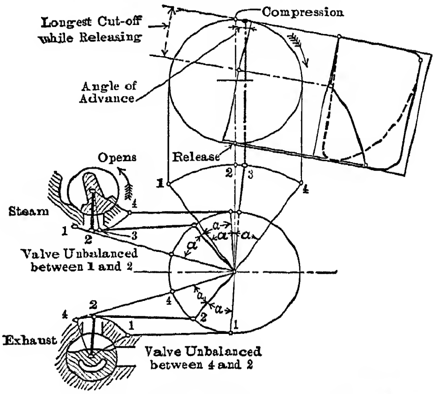

Fig. 83. Wrist Plate Linkage for Rocking Valves.

is adjusted by a right- and left-hand screw, or by a swinging bell crank as in Fig. 81; *MC*, Fig. 80, becomes both cut-off eccentric and relative eccentric, if its motion is superposed on that of the main valve as in the Buckeye engine, or if the cut-off valve operates in a separate fixed valve chamber.

VALVE GEARS WITH SEPARATE ROCKING VALVES FOR STEAM AND EXHAUST.—Rocking valves offer large unbalanced surfaces, if subdivided as in the four-valve type. Wasted friction work and wear are reduced by keeping the valves almost stationary when they are unbalanced. Such motion is obtained by " wrist plate " linkages, Fig. 83. Releasing cut-off is very limited in single eccentric gear as shown by the modified Sweet diagram in the upper part of the illustration. No intermediate cut-off is possible between 45% and 95%, because the valve gear moves away from the releasing cam, Fig. 82, in that interval. To make the releasing cut-off long, the angle of advance is made small (about 5°). This causes late release and short compression, and hence is suitable only for engines with small clearance and slow speed, such as ammonia compressors, slow-speed pumping engines, etc. For higher speeds, the releasing cam is made oscillating to overtake the gear on its return stroke, or else separate eccentrics are used for steam and exhaust, as in Fig. 84, which is a modified Sweet diagram (mean between head end and crank end). With double eccentrics, 3/4 cut-off can be obtained. The steam valve must be released, even with the governor in lowest position, otherwise the steam valve will be open at the same time the exhaust valve is open. The steam valve is moved directly, without distorting of motion by the wrist plate. The exhaust valve is driven through the wrist plate.

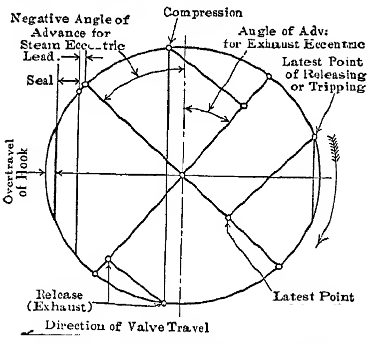

Fig. 84. Sweet Diagram for Double Eccentrics

Four-valve non-releasing gears usually have separate eccentrics for steam and exhaust. Valve diagrams are the same as for single valve gears but the travel of valve after closing is very much reduced by linkage as in Fig. 57.

Reference.—Moss, Layout of Corliss Valve Gears.

POPPET-VALVES AND GEARS.—If D = valve diameter, the free area on account of obstruction by the hub, ribs, and annulus of valve ranges from 0.65 ($\frac{1}{4}\pi D^2$) for small valves, to 0.85 ($\frac{1}{4}\pi D^2$) for large ones. The width of seat ranges from $^3/_{32}$ to $^3/_{16}$ in. For balancing purposes, the difference of diameters of upper and lower seats is small as possible, except in uniflow engines in which the top seat frequently is made considerably larger than the bottom seat for the purpose of making the valve relieve excessive compression in case of the failure of vacuum. In that case compression must be carried up almost to initial steam pressure, to relieve strains on the valve. The maximum valve lift is usually $^1/_8 D$.

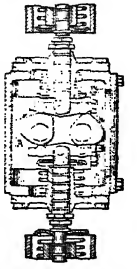

FIG. 85. Cam Mechanism for Double-beat Poppet Valve

In engines up to 500 or 600 Hp., the valves commonly are operated directly from a shaft governor on the main shaft. In larger engines, they are driven from a lay shaft parallel to the cylinder axis. Between 600 and 1000 Hp., releasing gears almost invariably are used; although occasionally, linkage gears with variation of linkage by a spindle governor are built. Poppet-valve gears have been brought to a high state of perfection by European engineers. Their number is so great that they cannot be described in this volume. See Steam Engine Valve Gears by Dubbel (German), published by J. Springer, Berlin.

Poppet-valve gears, as valve gears, are subject to the same limitations as Corliss valve gears, with the added complication that there is no over-travel possible after the valve has closed. Consequently, non-releasing poppet-valves all are moved by cams. The cam, as a rule, only lifts the valve, while a spring returns it to its seat. If double-acting cams are used, a rather stiff, but elastic member must be introduced to keep the stresses from becoming excessive.

All "automatic" valve gears, whether operated by shaft governor or by linkage, result in very small valve openings at short cut-offs, just as in slide valve gears. In releasing gears, separate eccentrics for steam and exhaust are necessary, just as in Corliss valve gears.

A great difficulty of releasing poppet-valve gears lies in the fact that valves either hammer or else leak, correct seating seldom being obtained. Air dash-pots close properly at some lifts, but not at others. Oil dash-pots work well at all lifts, at certain oil temperatures. When the oil is cold, the valves do not seat; when it is hot, the valves slam.

A double-cam mechanism for poppet valves is shown in Fig. 85.

In some European engines, hydraulic (oil-pressure-operated) valve gears have been used with success, also compressed-air-operated valve gears. (See *The Engr.*, 1928, p. 134.)

VALVE GEARS OF UNIFLOW ENGINES.—Exhaust slots must be long enough to allow the exhaust pressure to drop down to condenser pressure with the latest cut-off (30 to 33%). As a rule the length of slots equals 10% of the stroke. The cylinder must

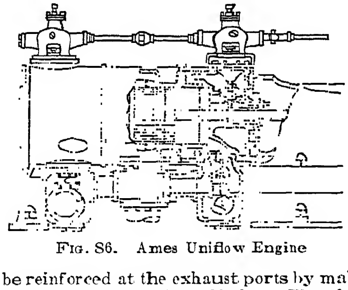

FIG. 86. Ames Uniflow Engine

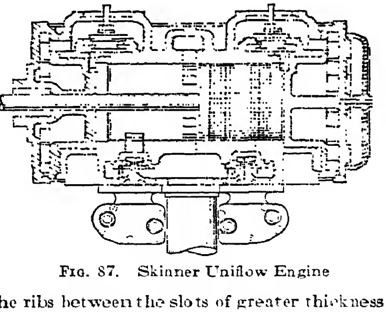

FIG. 87. Skinner Uniflow Engine

be reinforced at the exhaust ports by making the ribs between the slots of greater thickness than the body of the cylinder. The clearance volume should be such that the compression rises to within about 20 lb. per sq. in. of the steam pressure; with good vacuum, however, this is not possible. For the exponent of the polytropic curve, and for increase of compression by throttling, see p. 7-09.

Inlet valves, almost exclusively, are of the double-beat poppet type, in order to allow the use of the engine with high steam pressure and high superheat. For greatest economy, involving high vacuum, the inlet valves are in the cylinder heads; for moderate economy and lower vacuum (24 to 25 in.) valves may be in the top of the cylinder. Uniflow engines, which always operate condensing, except in emergency cases, are equipped with auxiliary clearance volume in the cylinder heads, which is added to the working space by the engine in case of emergency. Engines which always or frequently operate non-

condensing usually are equipped with auxiliary exhaust valves. Fig. 86 represents the exhaust valves of the Ames engine and Fig. 87, those of the Skinner engine. For European designs of auxiliary exhaust valves, see Dubbel, Valve Gears; also, *Power*, Feb. 13, 1923. The auxiliary exhaust is adjustable to adapt the engine to different back pressures with constant clearance volume. For other data on inlet valve gears, see above under

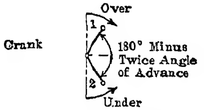

Fig. 88. Two Eccentrics

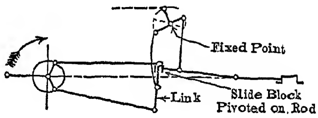

Fig. 91. Allen

Reversing Gears

Poppet-valve Gears. Cut-off usually is limited to 30 or 35%, in order to get sufficient valve lift at normal cut-off. In condensing engines it ranges from 8 to 15%.

REVERSING GEARS.—Reversal of the direction of rotation is obtained in the most perfect manner by operating the valves from an eccentric which is (180° − 2 × angle of advance) out of phase with the other eccentric. See Fig. 88. In a crude manner, the engine can be reversed by interchanging the steam inlet and exhaust or by reversing the motion of the valve, which is equivalent to driving it by an eccentric which is 180° out of phase.

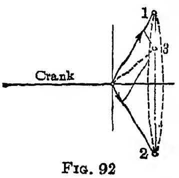

Fig. 92

Changing from eccentric (1) to eccentric (2) can be effected by actually shifting the eccentric, or by using two eccentrics. In the latter case the eccentric rods either can be provided with gab-hooks and can be made to alternately engage the valve rod at the will of the engineer, or they may be connected to a link. The former method is still in use on paddle-wheel steamers. Linkage reversing gears are the preferred form, because the change of position of the block in the link allows various combinations of motion of the two eccentrics. For arrangements of link gears see Figs. 89 (Stephenson), 90 (Gooch) and 91 (Allen). The general effect of a reversing gear link is illustrated by Fig. 92. Shifting the relative position of block and link results in using fractions of the motion of each eccentric and in combining these

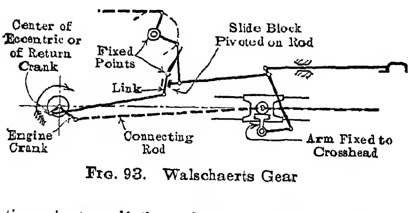

Fig. 93. Walschaerts Gear

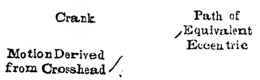

Fig. 94

motions just as if the valve were driven directly from an equivalent eccentric (3). This means that center of the equivalent eccentric "is shifted across the shaft" and that cut-off, compression and release vary as above described under the heading of single-eccentric variable cut-off gears. Fig. 89 shows "open rods." If, with the crank in the position shown, the rods are crossed, the arrangement is known as "crossed-rods."

The path of the equivalent eccentric is, as a rule, curved, as indicated by the dotted lines in Fig. 92, depending on the relative length of link, eccentric throw, eccentric rods, on the suspension and guiding of link as well as on the location of rod pivots and of the block in the link. Accurate determination may be made by means of models or of point-by-point construction on the drawing board. For the effect of the above-mentioned details, see Halsey, Slide Valve Gears; Furman, Valves, Valve Gears and Valve Diagrams.

WALSCHAERTS GEAR (Fig. 93).—If one of the eccentrics is replaced by the main crank of the engine, the Walschaerts gear results. The mechanism utilizes a constant fraction of the crosshead motion, but by means of the linkage the motion, derived from an eccentric keyed on the shaft at right angles to the crank, is made adjustable and reversible. See Fig. 94. The result is a straight line path of the equivalent eccentric, with the exception of the error caused by the obliquity of the connecting-rod. The Walschaerts is a very desirable valve gear for locomotives, despite the large number of joints. The eccentric is replaced by an outside return crank when used on locomotives. Its advantages are: Low friction work; all parts lie outside and are accessible for inspection and repairs. For other details see Halsey, Slide Valve Gears; Furman, Valves, Valve Gears and Valve Diagrams. See also p. 14–38.

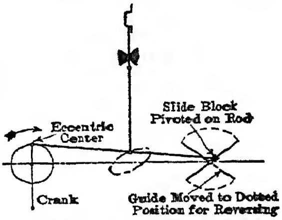

FIG. 95. Radial Valve Gear

Reversing gears are of the greatest importance in locomotives, where only those reversing gears are useful in which the up-and-down motions of the steam cylinder relative to the wheels do not materially affect steam distribution. This consideration is absent in reversing gears for marine engines, which allows the use of so-called "radial" valve gears. Only one eccentric is used, and a point of the eccentric rod is guided in an adjustable direction. Each point of the eccentric rod describes a different curve, which varies with the inclination of the guide point. Motion is taken from the eccentric rod at right angles to its mid-position. The various radial valve gears differ with regard to the relative positions of the eccentric point, guide point and valve operating point, and also with regard to the method of guiding the guide point. See Fig. 95. In the position of the eccentric shown in the illustration, the valve position is independent of the direction of the guide and lead is constant. Radial valve gears are described in detail in books and periodicals on marine engines.

References.—General references for valve gears, in addition to those given above are: Auchincloss, Link and Valve Motions; Durand, Practical Marine Engineering; Dalby, Valves and Valve Gear Mechanisms; Hiscox, Modern Steam Engineering.

8. OPERATING DATA

REGULATION TROUBLES.—See Governors, vol. 3 of this series; also Trinks. Governors, and Governing of Prime Movers. If regulation is not close enough (too much difference between full-load speed and no-load speed), use a smaller fraction of governor travel, or alter the governor, for instance by making the spring more flexible. This can be done by grinding off some of the outer part of the spring wire, making it thinner, or by reducing the width in the case of a leaf spring.

Racing of engine may be due to many causes, such as no oil, or not sufficiently heavy oil in the governor gag pot; excessive friction in the governor; too much steam admission at no load; too much steam volume beyond control of governor; leakage in the pilot valve of relay governor; lost motion of relay mechanism; dull edges of catch hooks in releasing gears; improperly adjusted or worn vacuum pots of releasing gears; too close setting of governor; insufficient capacity; improperly designed or poorly adjusted linkages between governor and control valve; reaction of valve gears upon governor.

HOT BEARINGS result from many different causes, such as insufficient oil; dirty oil, even a powder so fine as not to cause any gritty feeling being sufficient to heat a bearing; water in oil; use of oil that is too light or too heavy; undue tightness of bearing; wrong shape or location of oil-grooves; improper bedding of bearing, or contact in spots; binding, due to lack of alignment; improper bearing material; too high rubbing speed or pressure (product of *bearing pressure* × *revolutions per minute* is excessive); insufficient opportunity to get rid of friction heat; poor finish of journal or box.

In each individual case of a hot bearing, a search must be made for any of the above-mentioned causes.

KNOCKING AND POUNDING.—See Quiet Operation of Engines, p. 7–29. In addition to the reasons therein mentioned, excessive water in the steam will produce severe knocking.

STARTING.—Warming up before starting is advisable. Four-valve engines usually are equipped for hand operation of the valves for warming up purposes. A single valve engine should be started slowly with the drain valves wide open. In engines which have to be started suddenly against full load, relief-valve springs are set rather loosely.

VALVE SETTING should be checked regularly, say, every two weeks, with the indicator. Common defects and their cause are indicated in Fig. 96.

WEAR OF CYLINDERS AND OF PISTON RINGS.—Under average conditions, a set of piston rings travels 330 million feet before removal becomes necessary. Steam cylinders last for 2450 million feet of piston travel, before re-boring becomes necessary. Cylinder walls are made thick enough for two reborings. For day and night operation, this means that a set of rings lasts 14 months, and that the cylinder must be rebored every 8 years, and must be replaced after 25 years. Both figures are influenced by the quality of material of the rings or of the cylinder and by the effectiveness of lubrication. Thus a set of rings sometimes is worn out in two months, but in some cases will last two years. If cylinders are made of ordinary soft cast iron, the wear may be five times as rapid as indicated by the above figures, which apply to castings of hard cylinder iron. After a

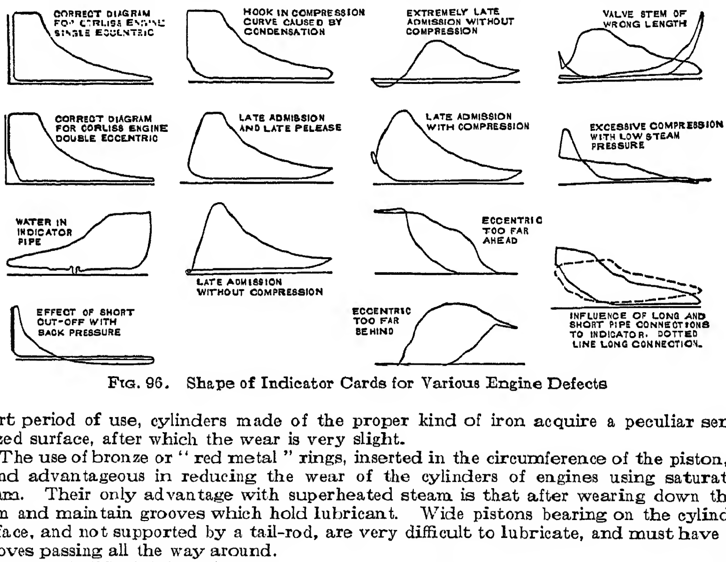

Fig. 96. Shape of Indicator Cards for Various Engine Defects

short period of use, cylinders made of the proper kind of iron acquire a peculiar semi-glazed surface, after which the wear is very slight.

The use of bronze or "red metal" rings, inserted in the circumference of the piston, is found advantageous in reducing the wear of the cylinders of engines using saturated steam. Their only advantage with superheated steam is that after wearing down they form and maintain grooves which hold lubricant. Wide pistons bearing on the cylinder surface, and not supported by a tail-rod, are very difficult to lubricate, and must have oil grooves passing all the way around.

BALANCING OF ENGINES.—In all steam engines, except very slowly moving pumping engines, it is desirable to balance the rotating parts (crank, crank-pin, and about 60% of connecting-rod) by counterweights. The balancing of reciprocating parts by rotating parts causes unbalanced forces at right angles to the inertia force of the reciprocating parts. For that reason the reciprocating parts of vertical engines are very seldom balanced. In horizontal engines, up to 40% of the reciprocating parts are balanced by rotating parts. According to Radinger, if W = weight of reciprocating parts, lb., and A = piston area, sq. in., $W = 3A$ for low-pressure cylinders and $4A$ for high-pressure, both for strokes below 30 in. From 30 in. up, $W = A \times S$ to $1.8A \times S$, where S = stroke, ft. These are average values which can be somewhat reduced by careful design and excellent materials.

In horizontal-vertical engines (angle engines) a counterweight opposite the crank can be made to balance the reciprocating parts of both engines, with the exception of the deviation caused by the finite length of the connecting-rod. That deviation equals $\times a$, where a = the sine harmonic acceleration and n = the ratio of the connecting-

rod length to crank radius. The deviation can be balanced by counterweights on two shafts, rotating in opposite directions at twice the engine speed.

9. STEAM ENGINE PARTS *

PISTON RINGS.—Concentric rings are preferable to eccentric ones on account of strength, if they are made right. Several makers machine them to fit the cylinder and then give them their spring by peening, or by annealing when sprung open. Others machine them while the ends are sprung closed. Or the rings may be cast out of round, in such shape that they exert uniform pressure when sprung in. (Reinhardt, *Zeit.*, V. d. I., 1901, pages 232–373; also *Auto. Engr.*, London, Sept., 1919.) Rings for large low-pressure cylinders are sectional.

The thickness of eccentric snap rings of ordinary cast iron is $^1/_{32}\,D$ at the heavy side, and $^1/_{50}\,D$ at the split, D being the cylinder diameter, in. They are turned $^1/_{72}\,D$ larger than the cylinder. The pressure between ring and cylinder is 2 lb. per sq. in. Concentric snap rings which are to be sprung over, made of high class cast iron of 40,000 lb. per sq. in. tensile strength, may be made $^1/_{30}\,D$ thick, with a width equal to the thickness. Rings must travel only a fraction of their width into the counterbore, otherwise the steam pressure collapses and breaks them.

PISTONS AND TAIL-RODS.—Most pistons work without tail-rods. The clearance between cylinder and piston should be 0.001 in. per inch of diameter up to 20 in. diam. of cylinder. From 20 in. diam. the clearance should be 0.0005 in. for each additional inch of diameter.

Example.—Piston diameter for a 40-in. cylinder

$$= 40 \text{ in.} - (20 \times 0.001) - (20 \times 0.0005) = (40 - 0.030).$$

The bearing surface of pistons, in horizontal engines, is the surface between piston rings only. Any bearing surface outside of the rings is unbalanced and causes excessive wear. Circular oil grooves are desirable between the rings to prevent oil being squeezed out by the weight of the piston.

Pistons in vertical marine engines frequently have tail-rods, to avoid the use of oil in cylinders, without unduly increasing friction. These vertical cylinders (using saturated steam) are first " run-in " with graphite and beeswax, and thereafter are lubricated only by the water which condenses on the cylinder walls. The rubbing parts acquire a hard smooth " water polished " surface.

Pistons of uniflow engines from 500 Hp. up usually are equipped with tail-rods. These long pistons must be loose to avoid sticking in cylinder. They wobble if not guided at both ends. European builders make the tail-rod serve as a guide only, but American builders prefer to make it also carry a large part of the weight of the piston; for high-temperature steam, due to the difficulty of lubricating the piston, the tail-rod and cross-head slides are made to carry the entire weight of the piston, and the only pressure on the cylinder walls is that of the piston rings.

Low-pressure pistons of large engines, such as blowing engines, are made of the cone type (umbrella type, Swedish type, or marine type), and their weight is carried outside the cylinder, on slides. The clearance between the cylinder and piston should be $^1/_{16}$ in. to $^3/_{32}$ in. all around, because contact between a steel piston and a cast-iron cylinder must be avoided. The piston and tail-rod usually are in one piece, and frequently are made hollow. They are turned about two sets of centers, with the axis of the tail-rod portion at a slight angle to the axis of the piston-rod portion, so that the rod is bent when not loaded, but becomes approximately straight, when supported on the slides at the two ends and loaded with the weight of the piston. Tail-rods also can be turned " cambered " by being loaded with a weight equal to the piston, and fixed at the ends while a revolving tool turns them. The rod also can be sprung in a revolving steady rest in the lathe, and thus be turned cambered.

The clearance between piston and head is ($^1/_{32}$ in. + $^1/_{150}\,S$) for slow-speed engines and ($^1/_{16}$ in. + $^1/_{150}\,S$) for high-speed engines, S being the stroke, in.

CRANK-PINS AND CROSSHEAD-PINS.—In some side-crank engines, in order to obtain the advantages of a cast-iron (semi-steel) wearing surface, the pins are cast integral with the crank disc or crosshead, but are reinforced by a steel pin through the middle. In most modern engines, however, the pins are of forged carbon steel, case-hardened to eliminate wear.

* Only those parts peculiar to steam engines, and not discussed in the general subject of Machine Design (Vol. 3 of this series) are treated under this heading.

STANDARD PROPORTIONS OF STEAM ENGINE PARTS.—Proportions found by long usage to give satisfactory results were compiled by Trooien (*Bull.* Univ. of Wis., No. 252; *Am. Mach.*, April 22, 1909) and are expressed by the formulas given below in standard type. They are correct for a steam pressure of 125 lb. per sq. in. above exhaust. As operating pressures have steadily risen since the time of compilation, Trooien's proportions must be adapted to the increased steam pressure. The formulas given in italics may be used for this purpose.

The wide variation in the " constant " in some of the parts is doubtless due to variations in design which cannot be explained in detail in a brief tabulation.

Notation.—D = diameter of piston. A = area of piston. L = length of stroke. L_c = length of connecting-rod. Hp. = rated horsepower. N = rev. per min. C and K = constants, and d = diam., l = length of element under consideration. H.S. = high-speed engines, L.S. = low-speed or long-stroke engines. All linear dimensions are in inches. p = initial pressure, absolute, minus back-pressure, absolute, lb. per sq. in.; p_1 = initial gage pressure, lb. per sq. in.

Piston-rod.— $d = C\sqrt{DL}$. H.S.: C = 0.15 (min. 0.125, max. 0.187); L.S.: C = 0.114 (min. 0.1, max. 0.156). *Uniflow Horizontal, C = 0.22; vertical, C = 0.17 (150 lb. per sq. in. steam pressure).* $d = C\sqrt{DL}\sqrt{\frac{p}{125}}$. *Occasionally, the diameter of the body of the rod is determined by the character of the fastening, either at crosshead or at piston end.*

Cylinder.—Thickness of wall, $t = CD + 0.28$. C = 0.054 (min. 0.035, max. 0.072). $t = (p_1CD/125) + 0.28$. Thickness of flanges = 1.12 to 1.20 × wall thickness. No. of stud bolts = 0.72 D for H.S.; 0.65 D for L.S. Diam. of stud, $d = 0.04\,D + 0.375 > 3/4$ in. $d = (0.04D\sqrt{p_1/125}) + 0.375$. *Spacing* $< 6\,d$. *Values given by these formulas are very safe, being based on considerations, not only of strength, but of tightness of joint. Other authorities recommend that the nominal stress in the studs should not exceed*

Ratio (C) of Stroke to Cylinder Diameter (L/D).— C = L/D; for N > 200, C = 1.07 (min. 0.82, max. 1.55); for N = 110 to 200, C = 1.36 (min. 1.03, max. 1.88); for N =< 110, C = (L − 8)/D = 1.63 (min. 1.15, max. 2.4). *These ratios do not hold for uniflow engines.*

Piston.—Width of face, f = CD + 1 in., C = 0.32 for H.S. (0.26 for Corliss). Thickness of shell, t = thickness of cylinder wall × 0.6 for H.S. (0.7 for L.S.).

$$f = C(\sqrt[3]{p/125})\,D + 1 \text{ in.}$$

Crosshead.—Area of shoes, sq. in. = CA (C = 0.53 mean; min. 0.37, max. 0.72). Maximum pressure, based on full steam pressure at mid-stroke, 40 lb. per sq. in. H.S. (min. 28, max. 57), 43 lb. per sq. in. Corliss (min. 32, max. 61). *Area* = $CAp/125$.

Crosshead-pin or Wrist-pin.—Diameter = CD (C = 0.25 mean, min. 0.17, max. 0.28). Length of bearing surface = 1.25 × diam. (min. 1.0, max. 1.5) for H.S.; 1.43 × diam. (min. 1.0, max. 1.9) for Corliss. *1.8 for Uniflow. Diam.* = $CD\sqrt{p/125}$.

Connecting-rod.—For high-speed engines, rod of rectangular section, thickness at middle = $C\sqrt{L_c \cdot D}$. (C = 0.073 mean; min. 0.055, max. 0.094). Width at middle = thickness × 2.28 (min. 1.85, max. 3.0). For low-speed engines, rod of circular section, diam. = $C'\sqrt{L_c \cdot D}$. (C′ = 0.092 mean; min. 0.081, max. 0.104). L_c = length, center to center of bearings.

Thickness, H.S., = $C\sqrt{L_c \cdot D}\,\sqrt[4]{p/125}$; *diameter, L.S.* = $C'\sqrt{L_c \cdot D}\,\sqrt[4]{p/125}$. *Area of smallest section (neck), 0.70 × area at middle.*

Modern experience teaches that finished connecting-rods are safer than rough-forged or cast-steel rods, on account of the stress-concentrating action in the latter of nicks, laps, cracks, seams, or other flaws.

Crank-pin.—Diam. for H.S. = CD. (C = 0.40 mean, min. 0.28, max. 0.52); diam. for side-crank Corliss = C′D. (C′ = 0.27 mean; min. 0.21, max. 0.32). *For Uniflow at 150 lb. per sq. in. pressure, C = 0.40.* Length for H.S. = diam. × K. (K = 0.87 mean; min. 0.66, max. 1.25); for Corliss = diam. × K′. (K′ = 1.14 mean; min. 1.0, max. 1.3). *Diam., H.S.* = $CD\sqrt{p/125}$. *Diam., Corliss* = $C'D\sqrt{p/125}$.

Main Bearings of Crank-shaft.—For H.S. center-crank engines, diam. = $C\sqrt[3]{\text{Hp./N}}$. (C = 6.6 mean; min. 5.4, max. 8.2). For Corliss side-crank engines, diam. = $C'\sqrt[3]{\text{Hp./N}} - 0.3$. (C′ = 7.2 mean; min. 6.4, max. 8.0). Length, H.S. = 2.1 × diam.;

length, Corliss = 1.9 × diam. Diam. × length = 0.48A, for H.S.; = 0.60A for Corliss. *In engines carrying armatures of electric generators on the shaft, the diameter of the latter in the main bearing is determined primarily by rigidity requirements. Bearing pressure due to combined weight and steam force seldom exceeds 250 lb. per sq. in. In recent high-speed engines, use of force-feed lubrication, oil filtering and cooling has permitted bearing pressures to be increased and size of crank-pin and crosshead-pin to be reduced.*

Fly-wheel.—Diam., in., = 4.4 × length of stroke (min. 3.4, max. 5.0). Rim speed, for H.S. = 70 ft. per sec. (min. 48, max. 70); for Corliss = 68 ft. per sec. (min. 40, max. 68). *For (weight × diameter²), see Fig. 35. In recent practice, fly-wheel weights have been increased, particularly for driving a.c. generators, so that no trouble is now encountered in synchronizing.*

Weight of Reciprocating Parts.—(Piston + piston-rod + crosshead + $^1/_2$ connecting-rod.) W = weight, pounds = $(D^2/LN^2) \times 2{,}000{,}000$. (min. 1,370,000, max. 3,400,000). Balance weight opposite crank-pin = 0.75W.

This formula gives the weight of reciprocating parts which should not be exceeded, to ensure quiet and safe operation of the engine. Average values of reciprocating weights are given by Unwin as 2 to 3 lb. per sq. in. of piston area, for simple engines; 5 to 7 lb. per sq. in., for compound engines, high-pressure side; 2.1 to 2.5 lb. per sq. in., for low-pressure side.

THICKNESS OF STEAM CYLINDERS.—If t = thickness of cylinder, in.; D = cylinder diam. in.; p = admission pressure, pounds per sq. in.; $t = 0.0004\,Dp + 0.3$. Large horizontal low-pressure cylinders should be made somewhat thicker to prevent them becoming oval on account of their own weight. Recently, special mixtures of cast iron, which resist wear and "growth" under temperature, have been used for cylinders, also nickel-cast-iron for valves.

The following proportions and allowable stresses were taken from various authorities, the selection in each case being that which agrees best with modern conditions.

CYLINDER HEADS.—Cylinder heads are usually either the box form, or the ribbed type. For the latter, the thickness = 1.0 to 1.2 × cylinder wall thickness t; for the box type, thickness of each wall = 0.85 t. Flange thickness = 1.12 to 1.25 t. Ribs are used to give the necessary stiffness, but in the single-wall type, if improperly designed, they may actually weaken the head by cooling strains which result in cracks. Overall depth of head = $0.04\,D\sqrt[3]{p_1} + 1.5$. This dimension varies considerably, depending upon the type and location of valves.

PISTON-ROD ENDS.—Nominal stresses in lb. per sq. in., based on the maximum steam pressure acting on the piston under usual operating conditions, should not exceed the following values, unless the parts are made of high quality steel. At section through key slot, 5500 lb. per sq. in.; shear in key, 5000 lb. per sq. in.; bearing pressure of key, 15,000 lb. per sq. in. Bearing pressure of rod on piston or crosshead should not exceed 15,000 lb. per sq. in., steel on cast iron; 20,000 lb. per sq. in., steel on steel. Tensile stress at root of thread, 7000 lb. per sq. in. Care must be taken to avoid sharp corners, which cause extreme magnification of stress. At a change of section from diameter d_1 to a larger diameter d_2, least radius of fillet = $0.15(d_2 - d_1)$. Fine threads, or threads with rounded corners frequently are used.

CONNECTING-ROD ENDS.—Average tensile stress in side members of connecting-rod ends between 3500 and 6000 lb. per sq. in. The high value is safe, if the end member and bearing brasses are rigid. *Closed-end type:* If d_p = diam. of crank-pin (or wrist-pin, respectively), width of eye = $1.15\,d_p + {}^1/_8$ in. Width of side = $0.30\,d + 0.1$ in. Width at end of eye = $0.33\,d_p + 0.1$. Thickness of sides and end = $0.9\,d_p$. These proportions are based on correctly-selected dimensions of crank-pin. *Marine type:* Allowable stress in bolts, based on nominal diameter d_b, is $\left(9000 - \dfrac{3200}{d_b} - \dfrac{600}{d_b^2}\right)$. One bolt is taken as carrying 60% of the total load. In rods with forked ends (4 bolts), the allowable stress is 20% less. Stresses 15% to 20% higher are permissible with high-class material, or in bolts whose average cross-section is reduced below the section at root of the thread. For high-speed engines, connecting-rod bolts are now (1935) made of heat treated alloy steel of high tensile strength, as are valve rods.

ECCENTRIC.—Diameter depends on shaft diameter and on throw. Width, in., = (average force, lb. × r.p.m.) ÷ 70,000. So-called "eccentric strap" should be designed as a beam rather than as a strap, to avoid locally concentrated pressures.

ENGINE FRAMES are, almost without exception, of cast iron and of the bored guide type. The moving parts should be wholly enclosed by the frame, leaving covered holes which can be opened for inspection. It is desirable to have a partition near the

stuffing box for separating the drips from lubricating oil. Frames must take up the engine forces without harmful deformations.

The average static stress is 600 to 800 lb. per sq. in. in designs where bending moments can be kept small. Where the moments are likely to be large, the average tensile stress in the smallest section should not exceed 350 lb. per sq. in. In general, rigidity rather than strength determines the dimensions, and the permissible stress becomes less in large engines.

Fig. 97 is a Corliss engine frame, and represents the typical American design for horizontal engines. Fig. 98 is a typical European design, in which the oil shield is entirely separate from the bedplate. Fig. 99 is a vertical power engine frame, and Fig. 100 a

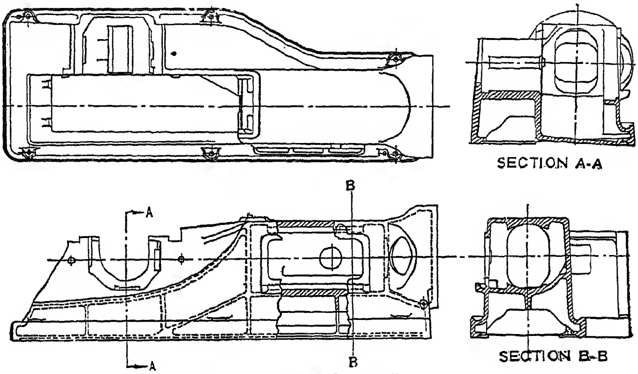

Fig. 97. Corliss Engine Frame

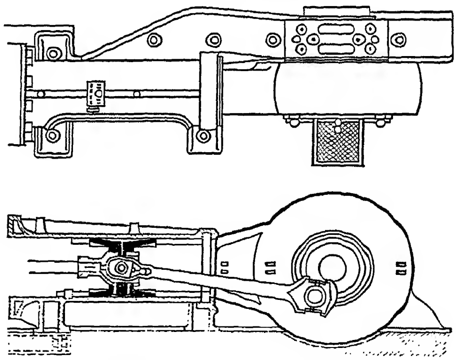

Fig. 98. European Engine Frame

marine engine frame. In the latter, the two front rods can be removed, leaving the cylinder supported on the back frame, so that the crank-shaft easily can be removed and replaced.

10. LUBRICATION

The lubrication of reciprocating engines divides itself into three types: 1. Drip lubrication; 2. Stream lubrication; 3. Forced lubrication. If oil is allowed to be splashed around or to run into the foundation, only drop-by-drop lubrication is possible. Types 2 and 3 require catching and filtration of the oil. Some engines are equipped with self-contained lubricating systems, using no other filter than a strainer in the crank case.

Wear is inevitable in such a system. Wear can be wholly avoided by the use of stream lubrication or forced lubrication in conjunction with a close-mesh cloth filter. See Vol. 3 of this book for additional information.

On engines with complicated valve gears, such as Corliss or poppet-valve gears, automatic lubrication is very difficult. In purchasing engines, the lubrication problem should be carefully considered.

In engines operating with steam at high temperature (either at high pressure or highly superheated), proper lubrication of cylinders is difficult. In the present state of the art (1935), the limiting steam temperature is about 700 to 750° F. although one installation is stated to operate at 800° F. For these conditions, the "hydrostatic" lubricator is replaced by mechanically-operated lubricators injecting oil into the steam line near the throttle, but closer to the inlet valves as the steam temperature increases. For very high temperatures, oil is injected directly above each inlet valve and also into the cylinder itself, at points about 1/3 of stroke from each end and at top or at several points around the circumference, with an auxiliary feed to the piston-rod packing case. Injection into the cylinder increases the oil consumption but is especially necessary in designs of uniflow engines in which the jackets trap out the oil in the steam. For extreme temperatures the

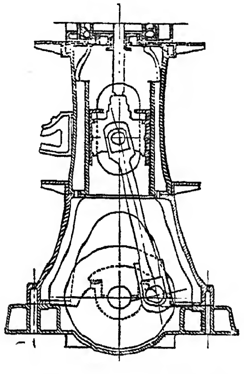

FIG. 99. Vertical Power Engine Frame

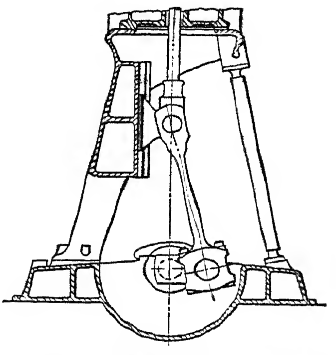

FIG. 100. Vertical Marine Engine Frame

injection into the cylinder is *timed* to occur when the piston reaches a given point in the stroke.

The lubrication of steam cylinders and sliding valves (including piston valves and rocking valves) never can be perfect, as the rubbing surfaces cannot be completely separated by a film of oil. The contact will be partly metallic, and wear cannot be entirely avoided.

In operation with saturated steam, the film of water on the walls washes off any mineral oils, unless they are blended with grease, usually 5% tallow. With superheated steam, the oils used are straight mineral oils (uncompounded), or else have only a very small amount of animal oil.

The cylinder oil consumption ranges from 0.1 pint to 4 pints per million sq. ft. of surface swept over by the piston (perimeter of piston × distance traveled), with an average of 0.8 pint per million sq. ft. The average consumption per million sq. ft. will be less in large poppet-valve engines than in small slide-valve engines. Even in engines of the same type and size, there is a wide variation in oil consumption, due partly to waste, to different methods of handling, and in steam and operating conditions, but chiefly to the difference in texture of cylinder and piston castings. In some cylinders, oil adheres strongly to the walls, in others it does not cling to the surface but is wiped off by the piston and by the moisture, and requires continual replacement. See also *Power*, Feb. 15, 1910.

In engines using high-temperature steam (700° to 800° F.), the cylinder oil actually is vaporized by the heat of the steam, but if the viscosity is high enough, some oil remains on the surfaces until a fresh supply is injected. If *too much* oil is supplied, it "cracks" and forms carbon deposits which cause increased heating and wear. In large engines, with steam at 700° F., 7 drops of cylinder oil per minute to each end of each cylinder.

6 drops in each valve, and 5 drops in each packing case have been found to give good lubrication while avoiding carbon.

From carefully recorded data furnished by the Vacuum Oil Co., the average cylinder oil consumption for usual steam conditions is found to vary with the size of engine according to the equation

$$Q = K\sqrt{\text{Rated Hp.}},$$

where Q = gallons per year of 3000 hours. The factor K ranges from a minimum of 1.2 to a maximum of 12, with an average of 4.8 in power plants, and from a minimum of 8 to a maximum of 53, with an average of 24 in steel plants where the consumption always is high.

The consumption of bearing oil varies over an even wider range, but averages 1 1/2 to 2 times the cylinder oil consumption.

Marine engines using superheated steam at 700° F., after initial treatment as described on p. 7–43, have been lubricated by injecting a spray of cold water into the steam near the throttle, together with a very small amount of oil.

SEPARATION OF OIL FROM EXHAUST STEAM.—Where exhaust steam from reciprocating engines is to be used for heating feedwater or in process heating, the oil carried in the steam must be removed. The oil may be removed either before or after condensation of the steam. In the former case, the steam is passed through oil separators, usually of the baffle type but occasionally of the centrifugal type; or where extreme freedom from oil is necessary, it is passed through a baffle separator in series with a closed feedwater heater, beyond which a cold water spray is injected into the exhaust pipe, and is finally passed through a second separator. To separate the oil from the water after condensation, skimming tanks, or sponge or towel filters may be used. The filters must be cleaned regularly.

Compounded oils are more difficult to remove than straight mineral oils.

On Mississippi River steamboats, aluminum sulphate and caustic soda are used to coagulate the oil, after which it is removed from the water by sand filters. In Europe, charcoal oil-separators have been used successfully.

11. COST OF ENGINES

Prices vary with the size, type of engine, and market conditions. Average costs in 1931, when basic pig iron cost $15.50 at Pittsburgh and common labor 39 cents per hr., are shown in Fig. 101. For comparison, the average prices in 1915, when basic pig iron cost $12.50 per ton at Pittsburgh and common labor 20 cents per hour, are also shown, in dotted lines.

These prices do not include generator or piping. The rated I.Hp. of an engine is usually 1 2/3 times the rated kw. of the generator which it is to drive. Compound engines average about 70% higher in cost than simple engines of the same type.

The cost of an engine also can be derived from the pound prices and from the weights of engines as shown in Fig. 32, bearing in mind, that, in general, the weight of the fly-wheel varies from about 25% of the weight of the engine without fly-wheel in 100-Hp. engines, to 30% in 800-Hp. engines. (In late practice, the fly-wheels of engines driving alternators are made considerably heavier.)

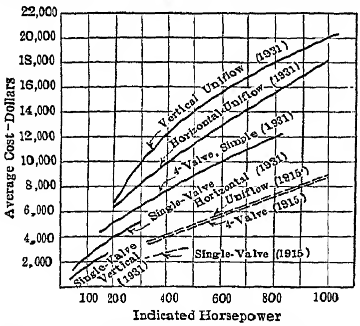

Fig. 101. Comparison of Engine Prices, Not Including Generator

The pound price, cents per pound, in 1931, averaged:

For vertical uniflow engines..........	18.4 + 640/rated I.Hp.
For horizontal uniflow engines........	9.1 + 1370/rated I.Hp.
For 4-valve and single-valve engines....	8.9 + 1370/rated I.Hp.

The cost of installation, varying with local conditions, averages about 17% of engine cost.

DEPRECIATION OF ENGINES ranges from 3% to 5% per year with slow-speed engines, to 5% to 10% with high-speed engines.

12. SELECTION OF TYPE OF ENGINE

The first question to be decided in selecting an engine usually is, whether to install a cheap engine of simple form or a more expensive highly developed type. For small sizes, driving auxiliaries, etc., where steam economy is not so important as reliable operation over long periods without attention, the simplest form of engine, such as the single-valve type, is installed, usually of the vertical enclosed, self-oiling type. Vertical single-acting engines are much used for driving stokers, as they need very little attention (see p. 7–29, Quietness of Operation). For the main engines of power plants, simplicity usually is less important than economy, and the 4-valve or uniflow engines are installed, except where more steam is needed for heating than for power.

Non-condensing engines are installed where the exhaust steam can be used for heating during a large part of the year, as in the power plants of office buildings, hotels, and hospitals. For such use, they should be of the most economical type, to save fuel in those periods in which all or part of the exhaust steam is not required for heating. If the steam needed for heating is considerably less than required for power, the bleeder or extraction type of engine can be used. This works condensing but takes steam for heating from the receiver, if of the compound type. In this case the high-pressure cylinder is made larger in proportion to the low-pressure cylinder than in the usual compound; or two smaller engines can be installed, one working non-condensing and furnishing steam for heating, and the other condensing, furnishing additional power. Heating systems now installed produce a back-pressure at the engine of 1 to 10 lb. per sq. in. above atmosphere; the recent tendency is to decrease this back pressure, due to increased use of vacuum heating systems in which the back pressure does not exceed 1 lb. per sq. in. gage.

The compound engine has been displaced by the uniflow, except, *a*, where the load is quite constant, and *b*, for compressors and blowing engines. For the latter, the distribution of forces during the stroke, in the uniflow type, is particularly unsuited to the requirements of the compressor, and as the load is reasonably constant, compound engines are almost universally used for this service. On account of its flat economy-load curve (p. 7–25) the uniflow engine is especially suited to the average plant where the load varies widely from day to day and throughout the day. In office building and hotel power plants, uniflow engines now are installed almost exclusively, usually operating with superheated steam. For high back pressure (ranging in process work from 20 to as high as 75 lb. per sq. in. above atmosphere) the uniflow is not suitable, on account of its long compression, unless the initial steam pressure is raised in proportion, and simple 4-valve or single valve engines usually are preferred. The compound principle is used in small marine engines and in large direct-acting boiler feed pumps. In locomotives, high superheat in simple engines has displaced the compound engine.

Triple- and quadruple-expansion engines are limited almost entirely to marine engines and pumping engines with absolutely constant load.

Slow-speed engines have longer life, are more reliable and usually somewhat more economical than high-speed engines, but the latter usually cost less for the unit including generator, and take up less floor space. For selection of piston speed and rotative speed, see p. 7-14.

Vertical engines have not been popular in the U. S., except in comparatively small sizes, where the handling of crosshead and connecting-rod in case of repairs causes no hardship. Large vertical engines are inaccessible to crane service, unless the steam cylinder is taken off the frame or the lower head can be pulled up through the cylinder. Tall vertical engines must have very broad bed plates and rigid housings, because of horizontal vibrations which are caused by pulsations in the steam pipes. Vertical engines are disliked by operators on account of the frequent climbing of stairs necessary in attendance and oiling. They are, however, necessary in marine work and in other places where the floor space is very limited. Recently, for engines driving generators, the trend has been to high-speed multi-cylinder vertical engines, on account of great reduction of floor space occupied, without excessive headroom requirement.

Horizontal engines are preferred by all operators, on account of their accessibility for attendance and repair. Side-crank engines are preferred to center-crank engines on account of the care required to keep three bearings in line. In general, single-crank engines are preferred to multi-crank engines, because of the smaller number of parts needing attention, but in many cases greater uniformity of torque is needed or there is a necessity for quick starting from any position, which requires more than one crank. Locomotives, marine engines, automotive engines, rolling mill reversing engines, etc., all require more than one crank. Reciprocating pumping engines are built with several

cranks, to give more uniform water delivery. The reasons for the trend toward multi-crank vertical engines already have been mentioned.

Angle engines occasionally are installed where space is limited or vibrations must be reduced to a minimum.

Corliss valves should not be used with superheated or high-pressure steam. Inlet valves of the poppet or drop piston types are used instead, in the h.p. cylinder.

For selection of valve gear for steam engines, see pp. 7–30 to 7–41.

13. TESTING OF STEAM ENGINES

Tests of steam engines are for the purpose of verifying guarantees given by the manufacturer of the engine or to determine its performance as regards: 1. Thermal-economy characteristics (heat value or steam rate or both). 2. Capacity in indicated horsepower, kilowatt output, or brake horsepower. Tests of engines also are made to determine special data or to verify particular guarantees.

All steam engine tests should be made in accordance with the A.S.M.E. Test Code for Reciprocating Steam Engines. An abstract of the 1935 Code is given on p. 16–26.

Barth.

A steam turbine is a form of heat-engine in which two distinct changes of energy take place. The available heat energy of the steam first is converted into kinetic energy by the expansion of the steam in a suitably shaped passage, or nozzle, from which it issues as a jet. A portion of this kinetic energy then is converted into mechanical energy by (1) directing the jet, at a proper angle, against curved blades mounted on a revolving disc or cylinder; or (2) by the reaction of the jet itself if the expanding channel can revolve.

The pressure on the blades, causing rotary motion, is purely dynamical and is due solely to the change of momentum of the steam jet during its passage through these blades.

Radiation and condensation losses in turbines are of a small order. Leakage losses occur through clearances over the ends of Parsons blades and through labyrinths and

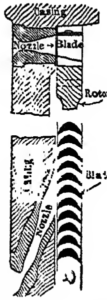

Fig. 1. Impulse

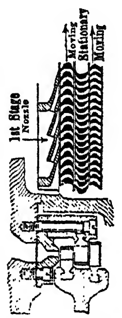

Fig. 2. Curtis.

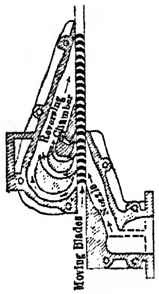

Fig. 3. Re-entry

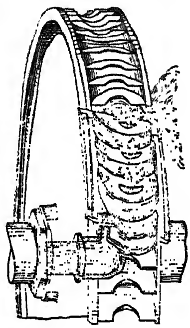

Fig. 4. Helical Flow

Types of Steam Turbines

glands. Friction of high-velocity steam jets through passages and across blades, together with the friction losses of high-speed revolving discs and idle blades in steam-filled chambers, have considerable effect on the ultimate efficiency of the turbine. The requirements of safe mechanical construction must be considered.

1. TYPES OF TURBINES

THE SIMPLE-IMPULSE TURBINE consists essentially of one or more nozzles supplied with high-pressure steam, with the discharge jet impinging, at a suitable angle, on a single row of blades on a revolving disc. The steam expands in the nozzle to exhaust pressure, its velocity increasing during expansion. The resulting kinetic energy is partly converted into mechanical energy during the passage of steam across the blades. The commonest type of simple-impulse turbine is the **DeLaval**, shown diagrammatically in Fig. 1.

For best efficiency of the simple-impulse turbine the ratio ρ of wheel speed to steam speed of the jet issuing from the nozzle ought to be about 0.53. This ratio can be obtained only with heat drops not exceeding 55 B.t.u. with the usual allowable blade speeds, or 100 B.t.u. for geared units. These drops may obtain when high back pressures are employed. Usually the heat drop exceeds these amounts, leading to a decrease in speed ratio ρ, with resultant lower efficiency. Simple impulse turbines usually are built for small output, although they have been used in units up to 3000 Hp.

VELOCITY-COMPOUNDED TURBINES utilize the high-velocity jet from the nozzle more efficiently than does the simple impulse turbine. The steam, after crossing the first row of moving blades, flows through stationary curved blades or passages. These reverse the direction of the jet and redirect it against a second row of moving blades. This reversal and re-impingement may occur several times before the steam finally escapes to the outlet. When velocity-compounding consists of several rows of revolving blades mounted on the same or parallel wheels, with intermediate stationary reversing blades, the form results in the well-known Curtis stage, Fig. 2. This also is called a *velocity stage*. In another form, the reversing passages redirect the steam back against the same row of blades that the jet first crossed. This is known as the *re-entry* type of turbine, Fig. 3.

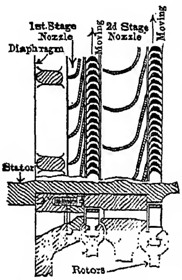

FIG. 5. Multi-stage Impulse Turbine

HELICAL FLOW TURBINES, Fig. 4, employ a forged steel wheel. Semi-circular buckets are milled in the circumferential rim at an angle of about 30° with the tangent. The steam expands to exhaust pressure in the nozzle which directs the steam into one side of the semi-circular bucket. The steam gives up part of its energy in its first reversal through 180° in the moving bucket but still retains considerable velocity. It then passes to a reversing chamber which redirects the steam into the wheel buckets. This is repeated several times in additional reversing chambers until as much energy as possible is delivered to the turbine wheel. The whole operation occurs in a single wheel which may be provided with several groups of nozzles and reversing chambers.

In all of these velocity-compounded turbines, part of the kinetic energy is absorbed each time the steam crosses a revolving blade or bucket. More work is thus obtained from a given quantity of steam flowing than in a simple-impulse turbine of the same blade speed. The friction losses, however, increase with the addition of the reversing blades or chambers. The various forms of velocity compounding are used for small steam turbines, particularly for non-condensing auxiliary services, such as driving pumps, blowers, exciters, stokers, etc. The Curtis stage forms one element of compound units.

A STAGE in steam turbines is a term used to signify that part of a machine in which a drop of pressure occurs with the generation of kinetic energy, together with such succeeding blades and passages where no further drop of pressure occurs. A stage, therefore, includes the nozzles, the moving blades and the reversing blades, or chambers, when used. Each of the preceding units consists of a "single stage."

THE MULTI-STAGE IMPULSE TURBINE consists of a series of simple-impulse turbines built on the same shaft. Each such simple turbine forms a stage. It is so designed that the steam expands through only a portion of the total pressure range in the nozzles of the first stage. On leaving the blades of the first wheel, the steam enters the second-stage nozzles, carried in the diaphragm forming the wall of the stage, and expands through a further pressure drop. This jet impinges on a second row of revolving blades. The operation is repeated in every stage until the steam is fully expanded in the final stage to the exhaust pressure.

With this construction, Fig. 5, it is possible to maintain the most efficient ratio of wheel

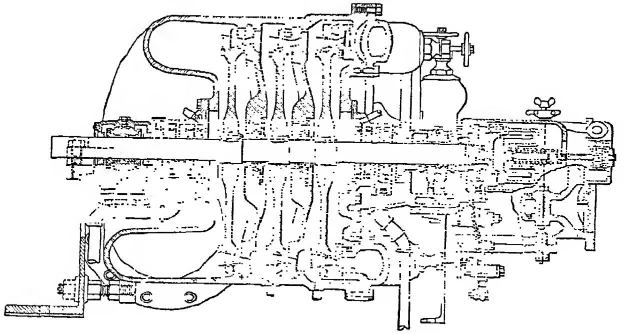

FIG. 6. Section of 3-stage Curtis Turbine

speed to steam speed by properly apportioning the total heat drop, from initial conditions to final pressure, between a suitable number of stages. Hence high efficiencies are possible with many of these turbines.

The total heat drop from initial conditions to final pressure is divided either equally or in a particular empirical manner, fixed by the manufacturer's construction, between the various stages. Steam speeds are calculated and wheel speeds selected to give the value ρ, *i.e.*, the ratio of wheel to steam speed, as high as commercially possible. Low-cost, few-stage units have low values of ρ and low efficiency. High-efficiency machines have high values of ρ and many stages. Multi-stage impulse turbines can be built for the largest output desired.

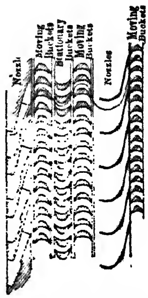

FIG. 7. Compound Impulse Turbine

Another form of turbine comprises a series of velocity-compounded or Curtis stages, known as 2-stage Curtis, 3-stage Curtis, etc. This construction is used on some of the smaller turbines. Fig. 6 shows a 3-stage Curtis turbine built by the General Electric Co.

The theoretically high efficiency of a small multi-stage impulse turbine with few stages is somewhat offset by the large whirling and friction losses of the discs and blades of the first stages, which revolve in dense media of high-pressure steam, and usually have nozzles delivering steam over only a portion of the periphery.

A velocity-compounded or Curtis stage often is substituted for several of the first simple stages in small and medium sized multi-stage impulse turbines. The resultant compound-impulse turbine, Fig. 7, is shorter, more compact, costs less, and

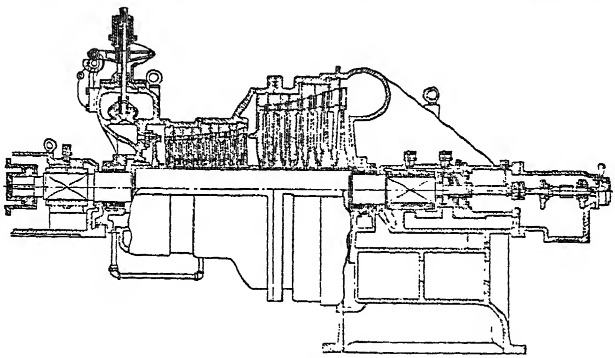

FIG. 8. DeLaval Multi-stage Turbine

is practically as efficient as the straight multi-stage impulse turbine of the same capacity. Fig. 8 shows such a compound unit built by the DeLaval Steam Turbine Co.

In impulse turbines the pressure on the two sides of the blade is substantially the same. All pressure drops occur in the nozzles between stages. Radial clearances of impulse blades, therefore, may be quite liberal, but suitable packing must be provided where the shaft passes through the diaphragm between stages.

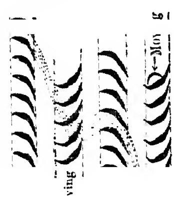

FIG. 9. Impulse-Reaction Turbine

No distinct line exists between impulse and so-called reaction turbines, as the majority of so-called impulse turbines have more or less reaction in the last stages. The term "impulse" applies to stages with no reaction or with only a small amount of reaction, say 10 to 15%, *i.e.*, 10 to 15% of the total heat drop per stage is expended, with a small pressure drop, in passing through the moving blade, thereby increasing the relative outlet velocity.

THE IMPULSE AND REACTION TURBINE, typified by the **Parsons turbine,** consists of one or more revolving drums placed inside a cylinder, with rows of blades attached alternately to the stationary cylinder and to the revolving drum. This is shown diagrammatically in Fig. 9. The passages between blades of all rows are designed to form contracting orifices; hence there is a drop in pressure and a subsequent expansion

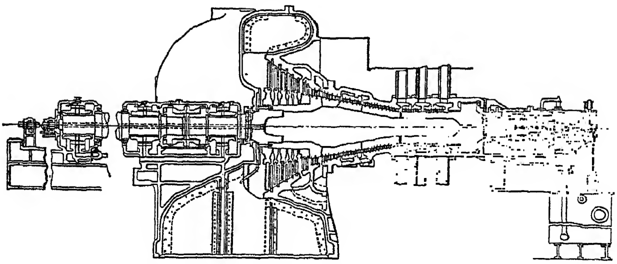

FIG. 10. Parsons Turbine (Allis-Chalmers)

of the steam through every row of blades. A row of stationary blades and its following row of revolving blades is known as a *stage* in a Parsons turbine. Fig. 10 shows a Parsons type of turbine as built by Allis-Chalmers Mfg. Co.

For best efficiency in a Parsons turbine, blade speed should be about 90% of steam speed. To obtain this efficiency, low steam speeds and many moving rows of blades, and a consequently long spindle must be used. In general, lower ratios of blade to steam speed prove more practical and commercial, giving fewer rows of blades and shorter turbines. In Parsons turbines, as in multi-stage turbines, clearances in the inter-stage seal must be small to prevent excessive steam leakage. With standard Parsons blading this necessitates small radial clearances over the ends of the stationary and moving blades. Many Parsons turbines are fitted with shrouds to provide axial, rather than radial, clearance which is accurately controlled by axial adjustment of the thrust bearing (end tightening).

On small Parsons turbines using high steam pressure, it is difficult to make sufficiently short blades for the first stages, and a Curtis stage often is substituted for several reaction stages at the high-pressure end. The resulting combination machine, Fig. 11, known as the Curtis-Parsons, is shorter and somewhat cheaper to build than the standard Par-

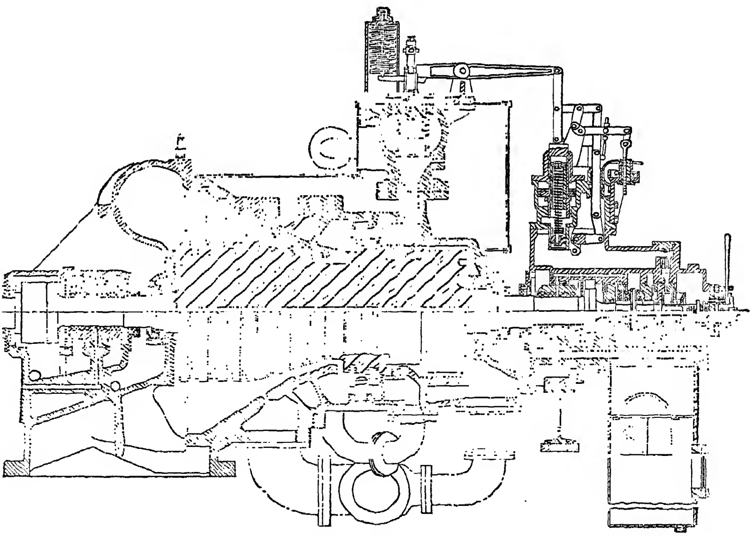

FIG. 11. Curtis-Parsons Turbine (Westinghouse)

sons. If a large pressure drop is allowed in the first nozzles, the temperatures in the casing are moderate and distortion troubles are lessened.

The Ljungstrom Double Rotation Turbine, Fig. 12, is a radial flow unit of the reaction type. It consists of intermeshed sets of blading, each rotating in the opposite direction. Two generators, tied together electrically, are required. The relative velocity of the two sets of blades is twice that obtainable with a fixed casing and a single revolving spindle. This construction leads to high capacity and high efficiency for a given diameter of blade ring. The unit is compact and usually is placed above, and supported by, its surface condenser. Its construction permits the use of high temperature steam and quick starting. The simple radial-flow design is applicable to back-pressure, non-condensing, and the smaller sizes of condensing units. Large condensing units have double flow axial blading in the exhaust end, as in Fig. 12, which is a 50,000 kw. unit built by S.T.A.L.

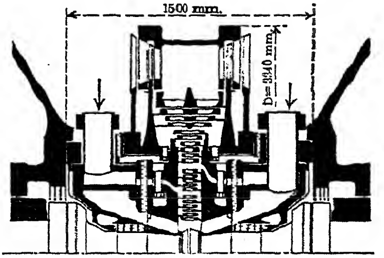

Fig. 12. Section of Blading of Ljungstrom Turbine

APPLICATIONS OF STEAM TURBINES.—The principal application of large turbines has been to drive alternating-current generators, to which they are connected by a solid or flexible coupling. Turbines of various sizes, also direct-connected, drive centrifugal pumps, small direct-current generators, fans, blowers, etc.

For a given blade speed, turbines with small diameters, operating at high r.p.m., are most economical. Such units may be connected through double helical reduction gearing to moderate speed machinery such as fans, propeller shafts, compressors, stokers, pumps, etc. Both driving and driven units then may operate under best conditions, and first cost of equipment is lower. In some cases, geared turbines have operated rope and belt drives for factory machinery, as cotton mills, rolling mills, etc. Geared turbines also have been used to drive locomotives.

Single-cylinder turbines are used (1935) in capacities up to 80,000 kw. at 1800 r.p.m. and 15,000 kw. at 3600 r.p.m. Fig. 13 shows an 80,000-kw. unit built by General Electric Co. Fig. 14 shows a 75,000-kw. unit built by Westinghouse Elec. and Mfg. Co. Unidirectional, double-flow turbines in one cylinder provide large areas for the last blade rows with low tip speeds. Larger units are multi-cylinder, of either the tandem or cross-compound types, with double-flow low-pressure cylinders to obtain the desired low-pressure blade area. Compound units also are used with reduction gearing in marine and other service. Vertical compound units have been installed to conserve engine-room space.

Impulse vs. Reaction Turbines.—Kraft (The Modern Steam Turbine) states that the impulse type is best suited for use in the high-pressure region and for small steam quanti-

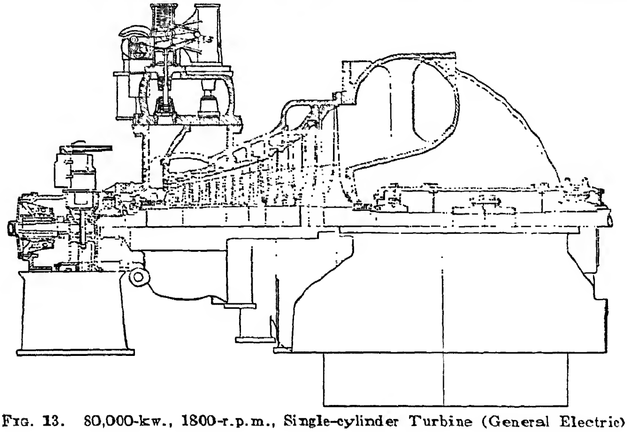

Fig. 13. 80,000-kw., 1800-r.p.m., Single-cylinder Turbine (General Electric)

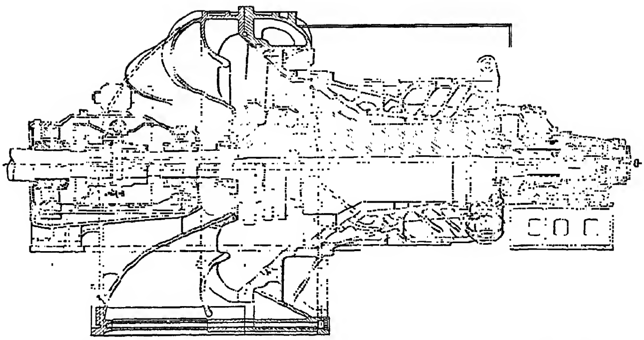

FIG. 14. 75,000-kw., 1800-r.p.m., Single-cylinder Turbine (Westinghouse)

ties. The reaction type has advantages for the lower pressure region and where large volumes of steam must be handled. Practice is tending toward the use of discs for low-pressure reaction blading at high blade speeds. In commercial practice, there is little difference in efficiency between the two types.

European builders have developed so-called *self-contained sets*. These consist of a turbine mounted directly on its condenser which may form the base-plate of the unit. The turbine often is connected to the generator through gearing. The exciter and condenser auxiliaries are driven direct from the turbine, through gearing or by connection to the main shaft. Erection costs are low and performance is good, as all auxiliary power is obtained at the steam rate of the main unit.

STEAM CONDITIONS.—Turbines can be built to operate at any steam pressure from a few inches of vacuum up to the highest steam pressures available. Central station pressures (1935) are generally in the range of 300, 400, 600, and 1200 lb. per sq. in. Industrial turbines operate at all pressures from 100 lb. to 1200 lb. per sq. in. Steam temperatures up to 1000° F. are in use, though usual practice is 700 to 850° F., with a trend towards higher temperatures. Vacuum of 29 in. can be maintained with 57° F. cooling water. With 70° F. cooling water a vacuum of 28.5 in. can be obtained.

OPERATING CHARACTERISTICS.—In the *straight condensing turbine* all the steam that enters the throttle, excepting some gland leakage in certain types, passes completely through the turbine to the condenser, in which a vacuum is maintained. Fig. 15 shows a straight condensing turbine built by the Elliott Co.

Extraction or Regenerative Turbines.—Steam is withdrawn from the turbine at intermediate stages of expansion and used to preheat the feedwater in open or closed heaters. The use of extraction turbines leads to higher station economy and they are preferred to straight condensing units. Since steam is extracted at various points, the quantity of exhaust steam decreases, and the size of condenser is smaller than otherwise. This likewise permits an increase in the rating of a given casing.

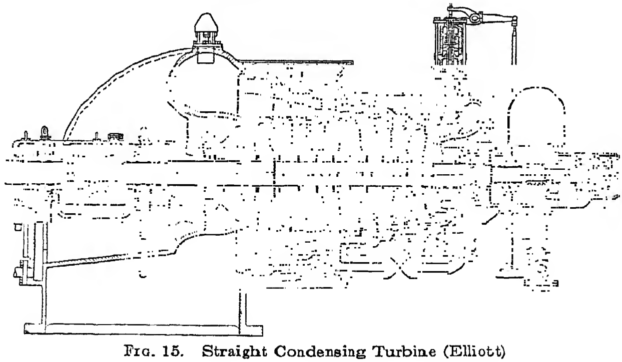

FIG. 15. Straight Condensing Turbine (Elliott)

Expansion at high efficiency from high pressures, with moderate steam temperature, to a high vacuum results in excessive moisture in the low-pressure stages. To avoid this, and to improve station economy, steam can be withdrawn from the turbine at an intermediate stage, reheated by flue gases, live steam, or other hot fluid, and then returned to the turbine. This results in a *reheating turbine*. Reheating turbines usually have extraction heaters to preheat the feedwater. This type is known as a *regenerative-reheating turbine*.

Non-condensing or High-pressure Turbines exhaust at atmospheric pressure or above. They form the high-pressure units of reheating turbines. They also exhaust to heating systems, to industrial processes, or simply to atmosphere in a few cases.

While many small non-condensing turbines for auxiliary use have comparatively low efficiencies, those used for power generation can be designed for higher engine efficiencies than the same size of condensing unit. Steam volumes are greater, leading to longer blades and lower percentage of leakage. Also the heat drop is confined almost wholly to the superheat field. See R. T. Luce, *Mech. Engg.*, April, 1931, p. 276.

In the *bleeder turbine*, steam is extracted at one or more intermediate stages, often at comparatively high pressures, for industrial use. Frequently the pressures at these bleeder stages must be maintained constant by a special regulating device forming a part of the turbine. The steam not withdrawn at the bleeder points expands through the remainder of the turbine to exhaust or to the condenser pressure. This type of turbine may operate at a given load with all the steam that enters at the throttle, flowing out of the bleeders, or with all throttle steam passing to the condenser when no steam is bled, or with any condition intermediate between these extremes. (See Burge and

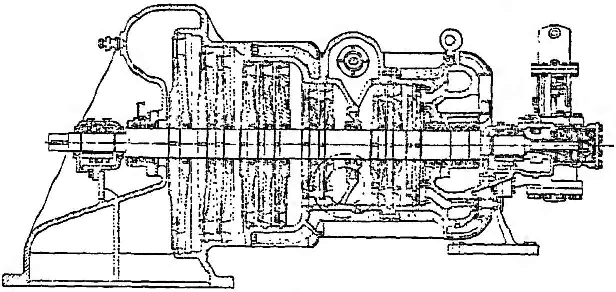

Fig. 16. Bleeder Turbine (Moore)

Chittenden, Steam Extraction Turbines, *The Engr.*, Dec. 19, 1924.) Fig. 16 shows a bleeder turbine built by Moore Turbine Corp.

LOW-PRESSURE TURBINES formerly were those that received steam at or about atmospheric pressure and expanded it to vacuum conditions. They were employed extensively to utilize the exhaust of non-condensing reciprocating engines or low-pressure steam from other sources. Certain of these types still are built, but the term "low-pressure turbine" now is frequently applied to the second cylinder of compound and of reheating turbines, where the inlet pressure to the low-pressure cylinder may be well above atmosphere. Certain of these units are made double flow to provide sufficient exhaust areas at the last blade rows.

MIXED-PRESSURE TURBINES are designed to receive steam at two or more pressures. Frequently such units serve as low-pressure turbines, receiving the exhaust of a hoisting, rolling mill or other engine which operates intermittently. These turbines have a high-pressure section to which live steam is admitted when there is a deficiency of low-pressure steam. In certain cases the unit is essentially a high-pressure turbine, receiving only such small quantities of low-pressure steam as are available, for instance, from non-condensing auxiliaries.

ACCUMULATOR TURBINES have been developed for service with steam accumulators, both of the low-pressure and of the Ruths or high-pressure types. The accumulators are large cylinders filled to 90% of capacity with water. During the charging period the pressure in the accumulator increases and the water absorbs the latent heat of the steam supplied. On discharge, this stored heat evaporates a portion of the water as the pressure falls. The pressure of steam from the accumulator falls through the whole dis-

(*Continued on page 12*)

Table 1.—Comparison of Turbine Characteristics

Classification	Type	Characteristics: Physical	Characteristics: Operating	Relative Advantages	Applications	Manufacturers
Impulse	Simple Impulse	1 nozzle or set of nozzles. Single disc with one row of blades. One passage of steam across blades. Simple casing construction.	Little heating necessary—quick starting. Clearances usually ample. Simple governing systems.	Low first cost. Comparatively small size. Heat drop limited to 100 B.t.u. for high efficiency; larger heat drops lead to decreased efficiency. Small floor space.	Certain high- or low-pressure units with small heat drops. Auxiliary drives. Turbo-blowers and compressors.	DeLaval Steam Turbine Co. Carling Turbine Blower Co.
Impulse	Simple Velocity Stage or Curtis	1 nozzle or set of nozzles. Single stage with two or more rows of revolving blades and necessary intermediate reversing blades. One passage of steam across each blade row.	Moderate wheel speeds. Large pressure drop in nozzle. Large end clearance for blades. Same pressure throughout stage. Simple governing systems. Can use comparatively large pressure drop.	Low first cost. Large power in small size. Moderate efficiency. Can utilize comparatively high heat drops. Strongly built. Small floor space.	Auxiliary drives, as stokers, pumps, exciters, small d.c. and a.c. generators, fans, blowers, etc. For emergency units requiring quick starting, as reserve boiler feed pumps, house turbines, etc. Non-condensing units for industrial plants in connection with process.	General Electric Co. DeLaval Steam Turbine Co. Moore Steam Turbine Corp. Allis-Chalmers Mfg. Co. Murray Iron Works Co. Elliott Co. Terry Steam Turbine Co. Coppus Engineering Corp. Carling Turbine Blower Co. Westinghouse Electric & Mfg. Co.
Impulse	Re-entry	1 nozzle or set of nozzles. Single row of buckets or blades. Reversing chambers to re-direct steam on buckets or blades one or more times. Simple casing construction.	Usually moderate wheel speeds. High wheel speeds used in some geared sets. Can employ comparatively large pressure drop. Simple governing devices.	Low first cost. May secure relatively good efficiency. Ruggedly built. Small floor space.	Auxiliary drives of all kinds. Geared sets. Emergency reserve units for quick starting. Paper mill drives. Small marine geared propelling units for tugs, etc.	Westinghouse Elec. & Mfg. Co. DeLaval Steam Turbine Co. Dean Hill Pump Co. Babcock-Wilcox-GoldieMcCulloch (Galt. Ont. Canada). L. J. Wing Mfg. Co.
Impulse	Helical Flow					Terry Steam Turbine Co. B. F. Sturtevant Co. DeLaval Steam Turbine Co. D. E. Whiton Machine Co.
Impulse	Multi-Stage Impulse or Rateau	Several simple impulse wheels in series, separated by diaphragms carrying nozzles or orifices. Usually many stages. Large clearances at ends of blades; small side clearance at nozzle.	Small heat drop per stage. Hence most efficient ratio of wheel speed to steam speed may be had. Fine clearances necessary at diaphragm glands. Throttling or nozzle governing, latter preferred.	High efficiencies possible. High blade speeds needed in last rows of large condensing units. Built in large as well as small sizes. Blade limitations in exhaust end of large units. Requires careful heating before starting.	Turbo-generator drive. Large auxiliary drive. Marine propulsion. Centrifugal pumping sets. Turbo-blowers and compressors. Bleeder and extraction units. Mill drives.	General Electric Co. Elliott Co. DeLaval Steam Turbine Co. Terry Steam Turbine Co. Moore Steam Turbine Corp.
Impulse	Velocity-compounded or Multi-stage Curtis	Series of simple Curtis stages separated by diaphragms carrying nozzles. Large end clearances on blades; small side clearance at nozzle. Relatively few stages.	Relatively large pressure drop per stage. Fine clearances at diaphragm glands. Can be started quickly. Few operating troubles. Usually nozzle governing.	Small floor space. Moderate efficiency. Rugged construction fit for hard service.	Non-condensing service with large auxiliaries, house turbines, exciters, etc. Condensing turbo-generator sets. Marine reversing turbines. Bleeder and extraction units.	General Electric Co. Bethlehem Shipbuilding Co. Terry Steam Turbine Co. Elliott Co. Moore Steam Turbine Corp.
		Series of alternate rows of converging fixed and moving orifices. Both diameters and blade lengths steadily increase. Steam flows axially. Fine clearances at ends of some types of blading. End-tightening used with certain blading. Usually many rows.	Small heat drop per row permits use of ratios of wheel speed to steam speed conducive to high efficiency. Usually throttle governing. Require extended warming-up period before starting.	Usually require large floor space. High efficiency possible in all sizes. Blade limitations in exhaust ends of large units. Easy to bleed for feedwater heating.	Turbo-generators. Marine propulsion. Geared drives. Extraction units. Mill drives.	Allis-Chalmers Mfg. Co. Westinghouse Elec. & Mfg. Co. American Brown Boveri Co. Bath Iron Works.
	Radial-flow Ljungstrom	Alternate series of radial rings carrying converging reaction blading arranged for radial steam flow. Low pressure stages are axial flow on large units. Alternate rings revolve in opposite directions. Hence two generators tied together electrically. Small clearances over blades.	High relative velocities lead to high efficiency with few blade rows. Radial rings require nearly constant blade length. Small leakage losses. Can be started quickly. Can use high temperatures. No critical speed through which to pass.	No foundation for unit which is supported by condenser. Quickly erected. High efficiency, particularly in high-pressure and in small size condensing units. No outer heat insulation needed.	Turbo-generators. Extraction units.	S.T.A.L. (Finspong, Sweden) Brush Engineering Co. (Loughborough, England) A.E.G. (Berlin, Germany) M.A.N. (Nürnberg, Germany) S.S.W. (Berlin, Germany) Brown Boveri & Co. (Baden, Switzerland)
	Velocity Multi-stage Impulse or Curtis-Rateau	1 Curtis stage followed by series of simple impulse stages with intermediate diaphragms carrying nozzles. Shorter than straight multi-stage impulse unit.	Only moderate pressures and temperatures in casing, due to large pressure drop in first nozzle. Favorable ratios of wheel speed to steam speed possible in both Curtis and other stages.	Compact and short. Efficiency practically the same as multi-stage impulse up to 5000 kw. and fair in larger sizes. Rugged construction in moderate sizes. Lower pressure on high-pressure gland packing box due to Curtis stage.	Turbo-generators. Auxiliary drives for larger units. Centrifugal pump drives. Turbo-blowers and compressors. Mill drive through gearing. Bleeder and extraction units.	Ingersoll-Rand Co. General Electric Co. DeLaval Steam Turbine Co. Moore Steam Turbine Corp. Terry Steam Turbine Co. Elliott Co. Murray Iron Works Co. B. F. Sturtevant Co.
	Velocity-reaction or Curtis-Parsons	1 Curtis stage followed by series of Parsons stages. Frequently of disc-and-drum construction. Larger clearances than in Parsons.	Pressure and temperatures in casing reduced by expansion in Curtis nozzle.	Shorter and more rugged than standard Parsons. Efficiency good in small sizes, and fair in large units.	Turbo-generators. Marine propulsion. High-efficiency marine geared auxiliary generator sets. Bleeder and extraction units. Mill drives.	Westinghouse Elec. & Mfg. Co. American Brown Boveri Co.

NOTE—Some manufacturers build several types of turbines and their names may have been unintentionally omitted from the above list for certain types.

The following firms are among the builders of turbines in Europe. Great Britain: *Impulse*, British Thomson-Houston Co.; Metropolitan-Vickers Co.; Frazer and Chalmers; Bellis and Morcom; John Brown and Co.; W. H. Allen and Son; *Parsons*, C. A. Parsons and Co.; Richardson, Westgarth and Co.; English Electric Co. Switzerland: *Impulse*, Escher, Wyss and Co.; Oerlikon Co.; *Parsons*, Brown Boveri and Co. Germany: *Impulse*, A.E.G.; M.A.N.; W.U.M.A.G.; Bergman E.W.; *Parsons*, S.S.W.; Guttehofnungshutte; Maffai-Schwartzkoff. Holland: Geb. Stork and Co. Czecho-Slovakia: Erste Brunner M.F.G. Italy: Franco Tosi. France: A.E. Sautter-Harlé; C.E.M.; S. G. Als-Thom.

charge period. A low-pressure turbine usually is employed with low-pressure accumulators, being fitted with a throttling governor. High-pressure accumulator turbines generally have a series of valves to admit additional steam to lower stages as the pressure falls in the accumulator. Turbines have been built to operate both as high-pressure and as accumulator turbines by means of suitable valve gear and nozzles to admit accumulator steam at the desired points.

Accumulator turbines have been used to supply steam for carrying peak or other sudden demands for power. The load curves for such peaks are generally triangular in form. This steam requirement can be found by means of a series of Willans lines (see p. 8–69) showing turbine performance at a series of pressures from full to discharge pressure. The pressure-discharge curve of the accumulator is plotted. The total steam demand over the peak is found from these two curves and from the load curve, by taking small increments of load and determining the total steam and the pressure drop for the duration of each. These steam quantities can be plotted and integrated.

When the total steam required from the accumulator is known, the amount of water in the accumulator to yield this steam is found approximately as follows: Let w' = total steam to turbine, lb.; h'_{fg} = latent heat at average pressure in accumulator, B.t.u. per lb.; w'' = storage water required in accumulator, lb.; h_{fc} = heat content of saturated water at full accumulator pressure, B.t.u. per lb.; h_{fd} = heat content of saturated water at completely discharged pressure of accumulator, B.t.u. per lb.; w_m = weight of 1 cu. ft. of saturated water at average accumulator pressure, lb.; $w' \times h'_{fg} = w'' (h_{fc} - h_{fd})$. C = storage capacity needed in accumulator, cu. ft. Hence

$$''_{fc} - h_{fd}) \times \cdot$$

Usually 3% additional water storage is provided to compensate for radiation. The shell volume is so chosen that the storage water occupies about 90% of the total volume when fully charged.

For data and illustrations of the largest installation at present (1932) of Ruths accumulators and turbines, at Charlottenburg, Germany, see *Engg.*, June 13, 1930; also see Christie, The Peak Load Problem in Steam Power Stations, *Mech. Engg.*, Dec., 1928; Taylor and Wettstein, The Ruths Steam Accumulator, *Mech. Engg.*, Aug., 1925.

TURBINE CHARACTERISTICS.—Table 1 classifies certain information regarding types, characteristics, advantages and disadvantages, services and manufacturers of the various forms of steam turbines.

TURBINE SPEEDS.—For 25 cycles, 1500 r.p.m.; for 60 cycles, 3600, 1800 and 1200 r.p.m. European turbines for 50 cycles, 3000 and 1500 r.p.m. There is a tendency to extend the capacity of the higher speed units by the use of multi-cylinders. Turbines direct-connected to pumps and blowers usually operate at the speed of the driven unit. Turbines for geared sets may run at any desired speed, and have been built for speeds of 6000 to 7200 r.p.m. in the smaller sizes. This leads to low first cost and increased efficiency.

2. STEAM TURBINE CYCLES

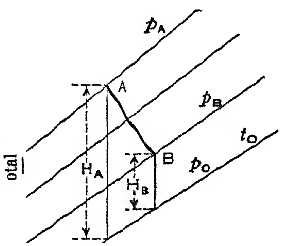
If steam could be expanded in a turbine with no friction or other losses, expansion would be isentropic. Theoretically, steam turbines operate on the Rankine Cycle, or its modifications such as the Regenerative, Reheating or Regenerative-reheating Cycles. Turbine problems involving energy transformations in the steam are based on isentropic adiabatic expansion with the necessary modifying factors. Since such adiabatic expansion occurs at constant entropy, these problems readily can be solved on a Mollier diagram. (See p. 5–18.)

In the **Rankine Cycle** (see p. 5–14), the steam is expanded isentropically from the initial steam condition before the throttle valve to the exhaust pressure. The heat drop measures the heat thus theoretically available for work (see p. 5–18). The **engine efficiency** expresses the ratio by which the actual turbine approaches the Rankine cycle in converting into work the energy available from adiabatic expansion. The numerator may be the heat equivalent of either internal, coupling or generator-output kilowatts. The denominator is the product of heat drop and total pounds of steam. It is necessary therefore to state whether the calculated ratio is "Engine Efficiency based on internal kilowatts," "Engine Efficiency based on coupling kilowatts," or "Engine Efficiency based

on generator output." 1 kw.-hr. = 3412 B.t.u. per hr. Let I kw. = internal kilowatts; h_1 = total heat per lb. of steam at initial conditions before the throttle; h_2 = total heat per lb. of steam after isentropic expansion to exhaust pressure; w = total lb. of steam per hr. Engine efficiency, based on internal kilowatts, = $(3412 \times I \text{ kw.})/w\,(h_1 - h_2)$. Similar expressions can be found for coupling kilowatts or generator output. Where turbines are sold to drive pumps, fans, or other equipment, the rating frequently is expressed as Brake Horsepower at the coupling. The numerator in the above equation then becomes $2543 \times$ B. Hp. Straight condensing, high-pressure and low-pressure turbines with no extraction or reheating, follow the Rankine cycle.

The Regenerative Cycle, the Reheating Cycle, and the combination of these in the **Regenerative-reheating Cycle** (see p. 5–15, Steam) are used extensively for steam turbines.

There are difficulties in applying the engine efficiency to turbines operating on certain of these cycles. G. Darrieus (The Rational Definition of Steam Turbine Efficiency, *Engg.*, Sept. 5, 1930) proposed a new standard which will apply to all turbines. The *Darrieus efficiency* is the ratio of the heat to work to the difference of isentropic drops of the steam entering and leaving the turbine, the isentropic heat drops being measured with relation to an arbitrary condenser pressure p_0, or to the temperature t_0 of the surroundings. Thus in Fig. 17 let A and B represent initial and final conditions, respectively, in a turbine, and let H_A and H_B be the isentropic heat drops from A and B respectively to the condenser pressure p_0. w = lb. of steam per hr.; kw. = output.



Entropy
FIG. 17

$$\text{Darrieus efficiency} = \frac{3412 \times \text{kw.}}{w\,(H_A - H_B)}.$$

This gives somewhat different values from the engine efficiency as calculated above.

The general expression of Darrieus efficiency is as follows: For any turbine to which w_A, w_B, w_C . . . lb. of steam per hour are supplied at the states A, B, C . . . , and from which w_x, w_y, w_z are extracted or discharged at the states x, y, z (where the total steam supplied = total steam withdrawn), and the heat equivalent of work done = $3412 \times$ kw., where kw. = kilowatts, internal, coupling, or generator-output, the Darrieus efficiency, internal, coupling, or generator-output respectively,

$$= \frac{3412 \times \text{kw.}}{w_A H_A + w_B H_B + w_C H_C + \ldots - w_x H_x - w_y H_y - w_z H_z}$$

where H_A, H_B, . . . H_z are the available isentropic heat drops at states A, B, . . . z referred to the surrounding temperature t_0, or to the corresponding saturation pressure p_0 of the condenser. See also A Steam Chart for Second Law Analysis, J. H. Keenan, *Mech. Engg.*, Mar., 1932, and Turbine Plant Efficiency Calculations, J. C. Smallwood, *Combustion*, July, 1934.

3. NOZZLES

CRITICAL PRESSURE.—The simplest form of nozzle consists of a circular hole with a well-rounded mouth on the upstream entrance in the side of a chamber containing high-pressure steam at absolute pressure p_1. As the pressure p_2 on the discharge side of the nozzle becomes less than p_1 the flow of steam increases until the so-called critical pressure is reached. The flow will not increase with any further decrease in the pressure on the discharge side of the nozzle. The critical pressure is $0.5457\ p_1$ for superheated steam, and $0.5774\ p_1$ for saturated steam. Its value under any conditions can be found from the equation,

$$\text{Absolute Critical Pressure, } p_c = p_1 \left(\quad \right)^{n/(n-1)}$$

where p_1 = initial pressure, lb. per sq. in., abs., and n = exponent for adiabatic expansion at constant entropy ($p\,v^n$ = constant) of the steam at the stated conditions. The value of n varies for differing steam conditions; for superheated steam, n varies with different steam tables. An average value is $n = 1.3$; for wet steam, $n = 1.035 + 0.1\,q$, where q = quality expressed as a decimal. The velocity at the critical pressure is substantially

that of sound in the gas or vapor at the pressure and density existing at the throat. See p. 3–78.

The steam jet leaves the nozzle in practically straight lines as long as p_2 equals or is greater than the critical pressure. Hence for these expansions, nothing more is needed in a turbine than a convergent passageway, with the discharge directed at the desired angle toward the revolving blades. The orifice must be convergent, for the rate of increase of velocity exceeds the rate of increase of volume, until the critical pressure is reached. If p_2 is less than the critical pressure, the pressure in the throat, or narrowest part of the orifice, remains at the critical pressure, and further expansion of the steam occurs after leaving the orifice. This causes the jet to expand in all directions. Walls are necessary to confine this further expansion with its accompanying increase in velocity and volume. To do useful work, the jet must be projected toward the blades in a fixed direction, usually at an angle of 12° to 30° to the axis of the blade row. The smaller angles should be used when high efficiency is desired. Below the critical pressure the volume increases at a greater rate than the velocity. A diverging section, therefore, is added to the throat, forming a convergent-divergent nozzle, with mouth dimensions suitable for the range of expansion. The total angle of the divergent walls varies from 6° to 12°. The smaller angles appear to give better expansion. If the nozzles are of rectangular cross-section, the sides continue to diverge for their full length. This also is done in some circular nozzles.

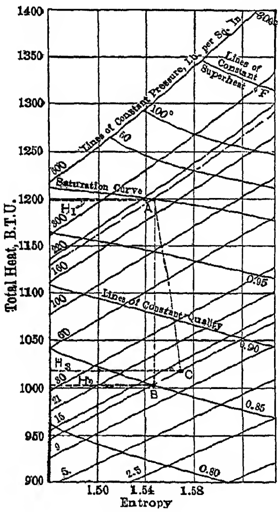


FIG. 18

THEORETICAL NOZZLE VELOCITY.—The heat drop $(h_1 - h_2)$ from any initial conditions to a final pressure can be found by the method shown on page 5–18.

As the steam expands in a nozzle, a portion of this available heat is transformed into kinetic energy and increases the velocity of the jet. The theoretical velocity V_0, ft. per sec., resulting from complete transformation of this heat drop is $V_0 = 223.8\sqrt{(h_1 - h_2)}$. This velocity is not obtained in an actual nozzle due to friction, eddy and other losses. Let η_n = efficiency of conversion into kinetic energy in a nozzle expressed as a decimal, or *nozzle efficiency*. The actual velocity V_1 of the steam jet leaving the nozzle is

$$V_1 = 223.8\sqrt{\eta_n\,(h_1 - h_2)}.$$

Another term used in considering nozzles is the velocity coefficient, k_n, which is the ratio of the actual velocity V_1 to the theoretical velocity V_0.

Nozzle losses appear as reheat. The total heat at the nozzle mouth,

$$h_3 = h_2 + (1 - \eta_n)\,(h_1$$

This is represented by point C on Fig. 18 on the pressure line p_2 of the mouth. The specific volume of the steam can be determined from conditions at point C.

In multi-stage turbines the steam may enter the nozzles of all but the first stage, with an appreciable velocity V_c, the carry-over from the preceding blade row, and with a kinetic energy $(V_c/223.8)^2$. The velocity of the steam leaving the nozzle becomes

$$V'_0 =$$

The total heat at the nozzle mouth is $h'_3 = h_2 + (1 - \eta_n)\{(\quad \cdot h_2) + (V_c/223.8)^2\}$. This exceeds h_3 above, by the amount $(1 - \eta_n) \times (V_c/223.8)^2$.

Carry Over is the portion of the absolute velocity leaving the preceding blade row which actually enters the nozzle in the proper direction. Formerly it was assumed that carry over only amounted to 50 to 75% of the absolute leaving velocity. Improvements in design of nozzle entrances, have increased this recovery to about 85 to 90% at most efficient load. Even higher recoveries are possible with further improvements in design.

Many data have been published on nozzle experiments. See Stodola, Steam Turbines; Goudie, Steam Turbines. Nozzle efficiency is greatly influenced by: *a*, form of approach to nozzle; *b*, con-

dition of steam entering nozzle; *c*, degree of roughness of nozzle; *d*, length of nozzle; *e*, thickness of partitions in groups of nozzles; *f*, conditions of outlet edges of partitions.

The Steam Nozzles Research Committee of the Inst. of Mech. Engrs. has published many valuable data on nozzle efficiency. (*Proc.*, Inst. Mech. Engrs., 1923, 1924, 1925, 1928, 1930). The following data show the performance of a set of converging impulse nozzles with partitions 0.04 in. thick, with 20° angle, and with a parallel portion beyond the throat equal in length to twice the width at the throat.

Theoretical velocity V_0 ft. per sec.	400	600	800	1000	1200	1400	1600	1800
Approximate corresponding heat drop, B.t.u. per lb.	3.2	7.2	12.8	20.1	28.8	39.2	51.2	64.8
Velocity coefficient, k_n	0.976	.955	.947	.946	.944	.944	.945	.946
Nozzle efficiency η_n	0.953	.915	.897	.895	.892	.892	.894	.895

The Nozzle Research Committee also noted that better coefficients were obtained when the nozzle partitions were well chamfered at the outlet edge. The angle of discharge is decreased by this chamfer and may be less than the nominal angle. These coefficients include any influences of supersaturation.

Kearton states that for curved nozzles used in multi-stage impulse turbines, velocity coefficients of 0.96 for velocities of 1000 ft. per sec., and of about 0.94 for velocities of 3000 ft. per sec. may be assumed. These correspond to nozzle efficiencies of 0.922 and 0.885. Superheating will increase and wetness will reduce these figures, the maximum variation being 2%.

Wirt (An Experimental Investigation of Nozzle Efficiency, *Trans.* A.S.M.E., xlvi, 1924) gives the results of tests of nozzles by means of impact tubes using air. Warren and Keenan (A Machine for Testing Steam Nozzles by the Reaction Method, *Trans.* A.S.M.E., xlviii, 1926) give results using steam, which indicate velocity coefficients of 98.3% with standard General Electric turbine nozzles, and with outlet velocities of 400 to 2000 ft. per sec., equivalent to a nozzle efficiency of 96.5% which is quite high. The results of these two papers are as follows:

Ratio of theoretical velocity to sound velocity	η_n, Reaction Test Steam (Warren and Keenan)	η_n, Impact Test, Air (Wirt)
0.86	96.8%	97.1%
0.67	96.8%	96.3%
0.50	97.4%	97.5%

Steam Shock leads to nozzle losses when the pressure at the mouth is greater than that for which the nozzle is designed. The steam appears to expand as though conditions at the mouth were those for which the nozzle was designed, until at a certain point in the nozzle the pressure becomes less than that at the mouth. Recompression then begins to the pressure at the mouth, and the volume decreases. This causes the jet to detach itself from the wall, and often results in setting up pressure pulsations. The detached jet may no longer be in the direction of the nozzle axis, and so will have an unfavorable angle of discharge. (See Stodola, Steam Turbines, p. 88 on Steam Shock.)

When steam expands rapidly from a slightly superheated condition, it does not begin to condense when the saturated condition is reached, but continues to expand as in the superheated region, thus becoming supersaturated. *Supersaturation* has been shown to exist in simple nozzles (Yellott, Supersaturated Steam, *Trans.* A.S.M.E., FSP-56-7, June, 1934). Supersaturation, with its lesser steam volumes, causes greater nozzle discharges than saturated steam. Supersaturation also tends to lessen the efficiency of nozzles due to energy loss when drops start to form and the steam mass seeks equilibrium. Supersaturation effects should be considered in nozzle design.

Commercial nozzles may not have as high efficiencies as given above, due to poor entry conditions, too wide flare beyond the throat, or too wide and unchamfered partitions at the mouth. Gains of 5% in nozzle efficiency have resulted from the redesign of nozzles in certain cases.

FLOW OF STEAM IN NOZZLES.—The design of all nozzles is based on the following formula of continuity:

$$W = A_t V_t \div 144 v_t = A_m V_m \div 144 v_m,$$

where W = weight of steam flowing, lb. per sec.; A_t = area at throat, sq. in.; V_t = velocity at throat, ft. per sec.; v_t = specific volume of the steam at throat conditions, cu. ft. per lb.; A_m, V_m and v_m are similar conditions at the mouth.

The pressure at the throat of a convergent-divergent nozzle is always the critical pressure. Hence, the flow of steam through this nozzle is constant, regardless of the value of p_2, the discharge pressure. The converging portion of such a nozzle is short, usually about 1/4 in., and the expansion here is assumed to take place with no losses if the approach is straight and has no obstructions. For this condition of flow, Goudie, in Steam Turbines, gives the following equations for the flow of steam through a convergent-divergent nozzle:

(*a*) Steam initially superheated: $W_s = 0.3155 A_t \sqrt{p_1 \div v_1}$, where W_s = lb. of superheated steam flowing per sec.; A_t = area of throat, sq. in.; p_1 = initial absolute steam

pressure, lb. per sq. in., v_1 = specific volume of steam at pressure p_1 and the stated superheat. Velocity in the throat, ft. per sec. = $V_t = 72.24\sqrt{p_1 v_1}$.

(*b*) With steam initially dry, Goudie holds that the steam remains supersaturated during its expansion from initial to throat conditions, *i.e.*, no condensation from adiabatic expansion takes place and hence the specific volume is less than if condensation does take place. The discharge W of a nozzle, lb. of steam per sec., is given by the same equation as for superheat. Some designers do not allow for supersaturation, and use a coefficient of 0.3004 instead of 0.3155 in the preceding equation.

Converging-diverging nozzles of curved form, as used in the low-pressure stages of impulse turbines, are designed with the nozzle efficiency applied to expansion up to the throat as well as to the complete expansion, owing to the loss from recompression in turning the steam around the curve. The throat velocity V'_t is then calculated from the formula $V'_t = 223.8\sqrt{\eta_n(h_1 - h_t)}$ where η_n = nozzle efficiency and h_t = total heat per lb. after isentropic expansion from initial conditions to throat pressure p_t. h_t is readily found on the Mollier diagram. If p_2 is greater than critical pressure, converging nozzles are used, usually of rectangular cross-section, and of the form shown in Fig. 5.

The area of the mouth of either convergent or convergent-divergent nozzles is given by the equation $A_m = 144\,Wv_m \div V_m$, where W = weight of steam flowing per sec., lb., v_m = specific volume at mouth conditions, found from the heat-entropy diagram; after allowing for reheat from nozzle losses, $V_m = 223.8\sqrt{\eta_n\{(h_1 - h_2) + (V_c/223.8)^2\}}$ = velocity at mouth, ft. per sec.; h_2 = total heat after isentropic expansion from initial conditions to mouth pressure p_m; V_c = carry-over velocity, ft. per sec.

When the mouth of the nozzle is too large the pressure in the nozzle falls below p_2 and the nozzle has "over-expansion." Serious eddies, shocks and other losses resulting from recompression are set up, and the loss from this cause may be serious. If the mouth is too small, the steam will not be fully expanded until after leaving the mouth of the nozzle, and is thus *under-expanded.* The loss from under-expansion is only about 30% of the loss from a similar amount of over-expansion, and hence is not of a large order of magnitude. Some designers provide for a small amount of under-expansion in all stages. This gives the best economy of the turbine at a load below maximum, and also a better range of high economy, and provides for low boiler pressure. The nozzle calculations given above may be used to design steam nozzles for uses other than in turbines.

ARC OF WHEEL COVERED BY NOZZLES.—To give the jet proper direction, a series of moderately small nozzles, spaced around the arc of the wheel, is used instead of one large nozzle. The partitions at the mouths of this group of nozzles are quite small, so that the clear opening is usually 0.88 to 0.94 of the pitch of nozzles. The length of circular arc occupied by nozzles of rectangular cross-section is given by the equation

$$ncP = A_m \div l_m \sin(\alpha - \phi/2),$$

where n = number of nozzles; P = pitch of nozzles, in.; c = thickness coefficient (0.88 to 0.94); A_m = calculated mouth area at right angles to axis of nozzle, sq. in.; l_m = radial depth of mouth, in., the minimum depth being 1.5 to 2% of mean blade ring diameter; α = angle of axis of nozzle to axis of blade row (12° to 30°); ϕ = angle of divergence of side walls of nozzle if any ($\phi = 0$ for convergent orifices). For complete admission

$$l_m = A_m / [\pi Dc \sin(\alpha - \phi/2)]$$

where D = mean diameter of the ring of nozzles, in. c is made as large as possible by chamfering off the outlet edge of the partition to a thin section.

If the nozzles of several succeeding stages do not cover the whole circumference of the wheel, the nozzle lead of succeeding sets must be calculated, as the steam is carried round the wheel a short distance in crossing the blades. The amount of lead is largely affected by the clearances between nozzles and blades on both inlet and outlet sides of the blade. The larger the clearance on the outlet side, the less important is the matter of lead. Another factor is the effect of increasing the nozzle arc of the succeeding stage to provide for the increased steam volume. This usually automatically takes care of the lead. Nozzle lead, as a rule, is a minor consideration in turbine design. See Goudie's Steam Turbines, pp. 273–275.

CROSS-SECTION OF NOZZLES.—Converging-diverging nozzles may be of circular cross-section at throat and mouth, or they may have rectangular cross-section throughout. The former are used on single-stage turbines, and sometimes in the first stage of multi-stage turbines of moderate efficiency. Frequently, these are pitched slightly towards the center of the shaft to cause the jet to enter the blades with less spilling at the shroud.

Simple converging orifices in diaphragms are of rectangular section throughout. These

orifices may be cast in place in the diaphragms or may be of built-up construction with machined surfaces and may be bolted or welded to the diaphragms in sections.

The discharge angle α of convergent orifices must frequently be increased in the last stage of impulse turbines to provide passageway for the large volume of steam present, without too high leaving loss. The pitch of nozzles is fixed arbitrarily. Usually it equals 3 to 4 times the blade pitch. Another rule is not to exceed 1 in. in width at the throat when measured at right angles to the axis of the jet.

Murray Iron Works Co. uses for converging-diverging nozzles a straight tube with rounded entrance, down the center of which projects a tapered needle valve controllable from outside the casing. This forms an annular throat between needle valve and pipe which expands at the angle of taper of the needle to a full clear mouth opening. The expansion ratio can be adjusted to suit the steam conditions by using the proper needle valve. Also the capacity of the unit can be adjusted by changing the throat area through shifting the position of the needle valve to give the necessary steam flow.

NOZZLE MATERIALS.—Most converging-diverging nozzles are made of cast brass or bronze, though some have been made of steel alloys and even of cast iron. One manufacturer uses for moderate superheat a bronze of about the following composition: Copper, 79; lead, 10; tin, 10; phosphorus, 1. Other metals, as Monel metal, Everbrite and stainless steel, have been used.

Convergent orifices usually are formed by casting sheet-metal partitions of nickel steel in the diaphragms. These contain from 3.5 to 5% nickel to increase their strength and resistance to corrosion. Chrome-vanadium steel also has been used for this purpose. When the nozzle block is of gun metal, phosphor-bronze or copper partitions are used. With built-up nozzles, Monel metal, stainless steel, and other alloys may be used.

In diaphragms with small nozzle height, the nozzle plates have been brazed or welded into diaphragms of cast or forged steel in hydrogen furnaces. They are easy to manufacture, cheaper than built-up nozzle plates, and give accurate nozzle forms.

4. BLADING

The steam leaving the nozzle in impulse turbines is directed against the revolving blades at an angle of from 12° to 16° with the plane of the blade for the early stages, increasing to 30° in some low-pressure stages. The relative entrance velocity of the jet and its entering angle can be found from the velocity diagram, as in Fig. 19. The exit angle of the blades is made the same as the entering angle in some small units, particularly those of the re-entry type, and also in the early stages of turbines.

LOSSES IN BLADING.—A portion of the energy of the steam jet is lost while crossing a blade passage, due to friction, compression and re-expansion and resultant eddies. Hence the relative velocity V_{ro} leaving the blade is less than the entering relative velocity V_{ri}. The ratio of leaving to entering relative blade velocities is called the **blade coefficient,** *i.e.*, $V_{ro}/V_{ri} = k_b$. This coefficient is influenced by the width of blade, the form of its rear flank, the total angle through which the steam is turned, the relative velocity of the steam and the smoothness of the blades. Kraft (The Modern Steam Turbine, pp. 25–26) states that higher efficiencies are obtained with increased radial length of nozzles and blades. He attributes this to the influence of losses due to disturbed flow in the region of the walls, and these losses increase with shorter blades. He shows that the stage efficiency η_s in an impulse turbine with $^3/_{16}$-in. blades is only about 42%, while with 4-in. blades $\eta_s = 85.2\%$, other characteristics of nozzles and blades remaining the same. Hence the importance of long blades.

RECOMPRESSION IN BLADE PASSAGES.—Stodola remarks that the greater part of blade losses result from compression and re-expansion in the curved passages. Belluzo (Steam Turbines, pp. 74–88) develops the principles of shock and recompression in curved passages. In the case of a curved passage, recompression results from the effect of centrifugal force upon the steam molecules which are traveling at a high relative velocity through the curved passage of the blades. If the curve of the blade passage is assumed to be an arc of a circle of radius R, ft., and of width, h, ft. (h is usually small), and if d_1 = density of steam, lb. per cu. ft., $g = 32.2$, V_r = mean velocity of steam crossing blade, ft. per sec., p_a = absolute pressure of steam at inlet and outlet of blade (stage pressure), lb. per sq. in., p_x = absolute pressure that the steam assumes as a result of recompression due to centrifugal force, lb. per sq. in., then

$$144\,(p_x - p_a) = \frac{d_1}{g} \times \frac{h}{R} \times V_r^2, \quad \text{or,} \quad p_x = p_a + \frac{d_1}{g} \times \frac{h}{R} \times \frac{V_r^2}{144}.$$

If recompression were the only consideration, wide passages with wide blades having curves of large radius would be best. Such blades have increased friction losses. Hence

blade widths have been a compromise, determined largely as a result of test and experience.

Zietemann (Dampfturbinen, p. 72) concludes that the blade coefficients are principally influenced by the total angle through which the steam is turned. He presents the following values for commercial blading where β_1 and β_2 are the entering and leaving angles of the blade.

$(\beta_1 + \beta_2)/2$.......	10	20	30	40	50	60	70	80
k_b...............	0.77	0.85	0.89	0.918	0.938	0.953	0.962	0.966

Zietemann's values depend only on the total angle of deflection. Stodola (Steam Turbines, p. 179) presents data from some Brown Boveri experiments which indicate that the maximum blade coefficient k_b, with blades having 30° inlet and outlet angles, varies with relative entering steam velocity V_{ri}. For a given blade, the coefficient curve is hyperbolic and the coefficient drops off with relative steam velocities above or below that at maximum value. The mean of the maximum values of k_b is as follows:

V_{ri}...............	400	800	1200	1600	2000	2400	2800	3200
k_b...............	91.2	91.	90.8	90.4	89.9	89.	87.8	86.2

In blading design, consideration should be given to these values as well as to Zietemann's in choosing k_b.

Aerodynamic methods are being applied to blade studies. As a result of these studies, the inconsistencies of earlier test data will be removed and correct expressions found for velocity coefficients, probably in terms of the Reynolds number and the Mach ratio.

For first approximations before the velocity diagram is completed, k_b may be assumed to vary proportionately from 0.94 at 100 ft. per sec. steam velocity to 0.885 at 1200 ft. per sec. velocity.

Fig. 19*A* is the velocity diagram for one stage of a multi-stage turbine, which stage

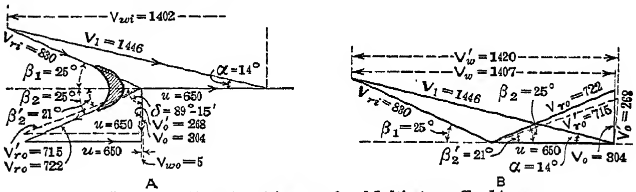

FIG. 19. Velocity Diagram for Multi-stage Turbines

operates under the following conditions: Pressure and temperature before nozzle (no carry over), 65 lb. per sq. in., abs.; 380° F.; expands to 38 lb. per sq. in., abs.; nozzle angle, $\alpha = 14°$; nozzle loss, 8%; wheel speed, $u = 650$ ft. per sec.; heat drop, $h_1 - h_2 = 45.4$ B.t.u. Velocity leaving nozzle $V_1 = 223.8\sqrt{0.92 \times 45.4} = 1446$ ft. per sec.

From the diagram, the relative entering velocity $V_{ri} = 830$ ft. per sec., and blade entrance angle $\beta_1 = 25°$. Assume $\beta_2 = 25°$ and $k_b = 0.87$. Relative leaving velocity $V_{ro} = 0.87 \times 830 = 722$ ft. per sec. Absolute leaving velocity $V_o = 304$ ft. per sec. The blade form can be drawn from this diagram.

The work done, in ft.-lb., is the product of the wheel speed u and the velocity of whirl V_w, divided by gravity g. The velocity of whirl is the sum of the co-ordinates of the absolute entering and leaving velocities in the direction of motion. This can be readily determined from Fig. 19*B*, which is the usual form of combined velocity diagram. The lower triangle of Fig. 19*A* is placed on the same base u as the upper triangle, and $V_w = (V_{wi} + V_{wo})$ can be determined graphically, as shown, and equals 1407.

Then work done in B.t.u. : g 36.5 Combined nozzle and blade efficiency = 36.5 / 45.4 = 80.4%.

ENTRANCE AND EXIT ANGLES OF BLADES.—The exit angle often is made 3° to 10° less than the entrance angle, as shown in the dotted lines, Fig. 19*A* and *B*, where $\beta'_2 = 21°$, a decrease of 4°. k_b becomes 0.862 and $V'_w = 1420$. The work done per stage now is 36.85 B.t.u., and the combined nozzle and blade efficiency becomes 36.85 / 45.4 = 81.2%.

The volume of steam can be assumed to remain constant during its passage across the blades. The length of blade on its inlet side is usually 1/16 in. longer than the width of the nozzle mouth. The outlet length of the blade should be increased over the radial length of nozzle mouth due to the decreased velocity V_{ro} at the blade outlet. If l_o =

outlet length of blade, and l_n = radial height of the nozzle, $l_o/l_n = V_1 \sin \alpha / V_{ro} \sin \beta_2$. When the angle has been closed a number of degrees, as shown above, this ratio may call for an excessive length on the outlet side of the blade. Some turbine builders vary the length of the shorter blades to meet these requirements. Others use only flat concentric shrouds for mechanical reasons, and make the inlet side somewhat longer than necessary. Frequently, some throttling exists on the outlet side and the blade functions partly as a reaction blade.

The dynamical thrust on the blades per lb. of steam $F = (V_{ri} \sin \beta_1 - V_{ro} \sin \beta_2)/g$. This is small in impulse turbines.

The theoretical required outlet length of blade is reduced approximately 1% for each 1% of reaction given to the blade. The usual limit of reaction in impulse blading appears to be about 10 to 15%. Most impulse blades on large units now are designed with a degree of reaction on the outlet side of the last rows of blading. Some impulse turbines built in Europe have end-tightened blades when a degree of reaction is used.

Some designers use a ratio t/r in the design of impulse blades, where t = width of blade passage, in., and r = radius of curvature of face of blade, in. Hodgkinson (Steam Turbines and Condensing Equipment, *Elec. Jour.*, Nov., 1924) says t/r should have decreasing values with increasing velocities. For a Curtis wheel, he suggests with 2000 ft. per sec. nozzle velocity, t/r for first row = 0.3, and for second row = 0.6.

The inlet angles of commercial blades usually are increased several degrees over that found on the velocity diagram. This allows the steam to enter without striking the rear of the blade if the initial pressure falls slightly and the nozzle velocity V_1, decreases. Less loss from shock occurs if steam strikes the face of the blade at a slight angle than if it

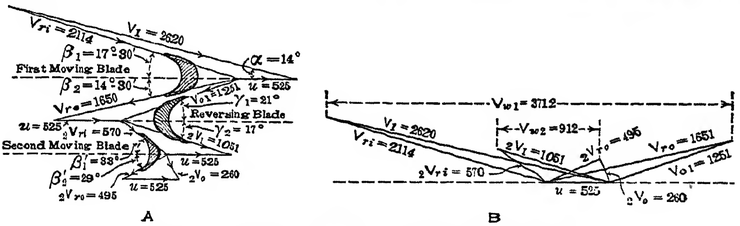

FIG. 20. Velocity Diagram for Velocity Type Turbine

strikes the rear of the blade. The former condition is *over-speeding*. The latter is *under-speeding*, and is undesirable.

BLADE WIDTH.—Several considerations influence blade width. Friction losses increase as the radius of curvature of the blade channels decreases. Hence, narrow impulse blades are undesirable. On the other hand, the surface friction of the sides of the channel may become prohibitive in very wide blades. Intermediate blade widths are therefore selected. Blade widths vary from 1/2 in. to 3/4 in. in small, single-stage impulse turbines, and from 3/4 in. to 2 in., or even larger, in multi-stage units. The wider blades are used in the larger machines. The maximum blade length should not exceed 8 to 12 times the width.

BLADE DESIGN.—When inlet and outlet angles and blade width have been chosen, the blades can be designed. The curve forming the face of the blade is drawn tangent to the lines forming inlet and exit angles. The pitch of the blades usually is chosen as 0.5 to 0.6 of the blade width, but never should exceed 1 in. Kearton gives the pitch $P = b/2 \sin 2\beta_1$, where b = blade width, in., and β_1 = entrance angle of blade. The rear flanks of the blade are made parallel to the inlet and exit angles. The curve of the back of the blade is fixed by experience and depends upon the degree of recompression to which the steam jet may be subjected. The outlet edges of the blades are made as thin as manufacturing considerations will permit. The inlet edges of high-pressure blading are made thin. On account of erosion in low-pressure blading, inlet edges are now thick and rounded.

Blading for velocity-type turbines can be computed from the velocity diagram. Figs. 20, *A* and *B* are for a Curtis turbine based on the following assumptions: Initial conditions, 140 lb. per sq. in., abs.; 450° F.; back-pressure, 20 lb. per sq. in., abs.; nozzle efficiency, 88%; blade angle, $\alpha = 14°$; wheel speed, 525 ft. per sec.; heat drop, $(h_1 - h_2) = 155.7$ B.t.u. per lb.; k_{b1}, k_{br}, and k_{b2} for first moving, reversing, and second moving rows respectively are 0.83, 0.84 and 0.87. Usually only the diagram Fig. 19*B* is drawn. The veloci-

ties of whirl from the diagram are 3712 ft. per sec. for the first row, and 912 ft. per sec. for the second row, a total of 4624 ft. per sec.

$$\text{Work done} = \frac{uV_w}{778.6\,g} = \frac{525 \times 4624}{778.6 \times 32.16} = 96.9 \text{ B.t.u.}$$

The combined nozzle and blade efficiency = 62.2%. Three rows of moving blades are used on some Curtis wheels, which will operate at low wheel speeds.

All exit angles are shown slightly less than the inlet angles, necessitating considerably increased outlet lengths for the blades.

The closure of exit blade angles in a Curtis stage, while increasing efficiency, may lead to too great a ratio, at the last row, of outlet length of blade to nozzle height, especially on long blades, since $l_3/l_n = V_1 \sin \alpha/2V_{ro} \sin \beta_2'$. In some designs, a ratio of l_3/l_n is assumed of from 2.5 to 3.5 on a two-row Curtis stage. Goudie (Steam Turbines, p. 305) shows a method of laying out the diagram and finding the blade angles and the work done to give the desired blade length ratio.

Velocity diagrams for re-entry turbines can be laid out in the same manner as for the Curtis stage. The blades often have equal inlet and outlet angles. k_b in the reversing chamber is about 3 to 5% greater than given by Zietemann. The discharge angle of the reversing chamber can be found graphically. It must be such that the relative velocity of steam to blades is at the angle fixed by the first part of the diagram for the blade outlet. See Goudie (Steam Turbines, pp. 288–9) for method of calculating helical flow blading.

SUCTION EFFECT.—When the steam jets pass through the clearance between nozzle mouth and blade entrance, the space corresponding to the thickness of the nozzle partition and in the direction of the nozzle angle, is not filled by the jets. The jets on either side of this space aspirate steam from clearance, and this suction effect is further increased by the pumping effect at blade entrance. The resulting losses may be reduced by chamfering the outlet edges of these partitions to a fine line to produce a continuous band of steam from the nozzles. This suction of steam from the inlet side of the disc may cause a pressure difference on the two sides of the disc unless enough holes are provided in the disc to balance pressures. Minimum clearance between disc and nozzle will reduce suction effects, but clearance must have minimum values for various sizes and speeds of discs, on account of disc fluttering and vibration, and of thermal expansions. End tightening of blades has been used to lessen suction effect in impulse blades. Suction effects also result from an inlet edge of the blade slightly wider than the nozzle mouth.

With partial admission, two losses occur. The steam jet must accelerate the dead steam in the blade passage when this comes in front of the nozzle opening. Eddies form during this action. The steam in the blade channel just passing from in front of the jet draws in clearance steam. If this clearance steam does not enter freely, some of the energy in the working steam delivered to this last channel is dissipated in the choking that follows.

SPEED RATIO.—An important factor in turbine performance is the speed ratio ρ, the ratio of the mean blade speed to the steam speed leaving the nozzle. Stodola states that turbine efficiency depends on this ratio alone, and not on the individual values of the velocities. For maximum theoretical efficiency of impulse wheels with no blade losses and no carry over, $\rho = \cos \alpha/2$ and for Curtis wheels, $\rho = \cos \alpha/2n$, where α = angle that the nozzle axis makes with the plane of the blades, and n = number of moving rows in the Curtis stage. Stodola indicates that highest efficiencies in a stage of a multistage impulse unit occurs when $\alpha = 12$ to $15°$.

Practice and consideration of blade losses and carry over show that values higher than the theoretical values of ρ give the best performance. Stodola (Steam Turbines, pp. 250–254) indicates that ρ may equal 0.60 for maximum efficiency under certain conditions. When highest economy is not desired, or where other losses, as in single-stage units, offset the higher blade efficiency at high wheel speed, much lower values of ρ are used. Variations of ρ above or below its most efficient value result in decreased efficiency. These variations may result from changes in steam pressure, temperature, vacuum, or load, acting either independently or together. Hence it is possible to analyze the effect of these changes if the effect on ρ is computed. Sets of curves have been printed on various papers showing the relations between ρ and stage efficiency. These indicate trends, but the absolute values given should not be used unless all assumptions on which the curves are based are known.

When carry over is large, larger values of ρ than $\cos \alpha/2$ may give higher stage efficiencies when this efficiency is based upon the isentropic heat drop only in the nozzle.

PARSONS BLADING consists essentially of a series of converging nozzles. The absolute exit velocity, or carry over, of the previous row is added to the velocity

produced by the pressure drop across the blade. Fig. 21 is a typical velocity diagram for a Parsons stage of one stationary and one moving row.

Provision is made for 50% reaction in usual designs, *i.e.*, half the heat drop is expended in the stationary guide blade and half in the moving blade. With this construction, $V_1 = V_{ro}$; $V_{ri} = V_o$; the discharge angle α is the same for both rows, varying from 18° to 23°. A usual value is 18 1/2°. Speed ratio $= \rho = u/V_1$. The diagram work per stage $= 2\,(V_1/223.8)^2 \times (2\rho \cos \alpha - \rho^2)$ B.t.u. The efficiency of this stage is proportional to $(2\rho \cos \alpha - \rho^2)$. It depends principally on ρ, as the outlet angle usually is a fixed quantity. This efficiency is a maximum at about 91% with $\alpha = 18.5°$, when $\rho = 0.94$, the efficiency decreasing if ρ decreases. In practice, ρ varies from 0.6 to 0.85 in land turbines, and seldom is less than 0.75 in large units. The higher values of ρ involve expensive, but economical turbines. Lower values of ρ give smaller, and less efficient machines. The work done $= (u V_w/(778\, g)$ B.t.u. per lb., where V_w is found as in Fig. 21*B*.

Losses in Parsons Blading.—One of the principal losses in Parsons blading is leakage over the blade tips, due to the difference in pressure across the blade row. The leakage passes directly across the clearance, while the working steam in the blades is turned through the angle α. The percentage loss from leakage through the clearance is

$$L = 100C \div (lM \sin \alpha + C),$$

where L = loss, percent; C = clearance, in.; l = length of the blade, in.; α = exit angle of blade; M = thickness coefficient = unity for most Parsons blading.

The steam passing through the blades $w_1 = w/C_1$ where w = total steam per hr. in lb. flowing through the turbine, and the clearance factor $C_1 = (1 + C\,/\,l \sin \alpha)$. The bucket efficiency $\eta_b = \eta_d/C_1$ where η_d = the diagram efficiency as calculated from a diagram similar to Fig. 21.

Leakage losses are greatest with short blades and proportionately large clearances,

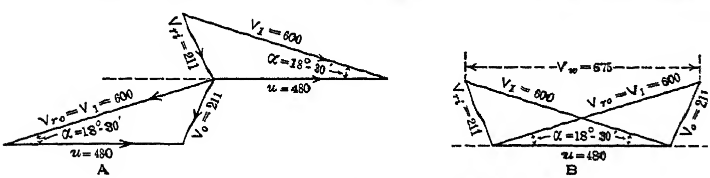

FIG. 21. Velocity Diagram for a Parsons Stage

and become comparatively small for the long blades of the last rows. A Curtis stage sometimes replaces the high-pressure section of Parsons turbines where the leakage losses are high, thus forming a Curtis-Parsons turbine. In Curtis-Parsons turbines the clearance on the shortest blades is never less than 0.025 in. With no clearance the efficiency of these blades is substantially that of nozzles, ranging from 92 to 95%. Clearance losses reduce this in standard turbines to 85–90%.

The face and rear flanks of Parsons blading are made up of a series of curves. One effective form is made from the intersection of two ellipses. On account of low entrance velocities, the entrance edge of Parsons blades can be quite blunt. To reduce erosion in low pressure blading, a blunt bull-nosed entrance edge has been successfully used.

Widths of Parsons Blades vary, with the different manufacturers, from 3/8 in. for blades 4 in. long, to 1 1/2 in. for blades 30 in. long. The pitch of blade rows is fixed somewhat by the type of shroud used to secure end packing, as it must be possible to shift the spindle toward the exhaust to clear these shrouds in lifting the rotor.

AREA THROUGH LAST ROW OF BLADES.—A factor of considerable importance in turbine design is the large volume of steam to be passed through the last row of blades, particularly when high vacuum will be used. If the area of the passage through the last row is too small, the steam will have a high exit velocity, involving a considerable energy loss. This area, therefore, should be as large as possible, while still retaining sufficiently small blade angles to insure good diagram efficiency with safe blade lengths.

Long low-pressure blades must be warped, *i.e.*, they must have varying entrance angles and cross-sections from base to tip. Kearton (Steam Turbines, p. 461) shows the details of such a blade for the last-stage wheel of a turbine operating at 1500 r.p.m. The ratio of blade length to mean diameter is 26.5%. The particulars of the blade are:

	Base	Mean	Tip
Mean diameter, in.	86	117	148
Peripheral velocity, ft. per sec.	563	766	970

The velocity diagrams at base, mean diameter, and tip are shown in Fig. 22. The inlet angles to the blades as required by the diagram varied from 38° at the base to 55° at the tip, with the outlet angle of 36° at tip and center and 44° at base. The blade can be formed by drop forging in a warped shape to give these angles, or by milling from solid bars with special convex- and concave-shaped cutters.

Kearton (Steam Turbines, p. 262) gives the centrifugal stress, lb. per sq. in., in steel blades of uniform cross-section as $f_c = 4.09\, l \left(\frac{d}{100}\right) \times \left(\frac{N}{100}\right)^2 = 0.215\, u^2 m$ for steel blades, where d = mean diameter, in.; N = r.p.m.; l = length of blades, in.; u = wheel speed, ft. per sec.; m = ratio of blade length to mean diameter. He also shows that $f_c = 1.88\, A\, (N/100)^2$, where A = area of annulus of last blade row, sq. ft. From this it is evident that the stress in the blades of the last row is directly proportional to the annular area of the blade ring for a given speed. These factors should be multiplied by 1.074 for brass or bronze blades.

CONSTRUCTION OF BLADING.—Blades may be rolled, drawn, or drop forged, or they may be machined all over from rectangular bars. They may be fixed in place by caulking pieces, or the base of each blade may form its own spacer. Blades of some impulse turbines straddle the disc, being held in place by rivets. DeLaval mills a bulb-shaped end on a straight shank at the blade base and drives these into similarly shaped grooves on the edge of the discs. The inverted T-base with one or more sets of shoulders is a common form for impulse turbines. These blades are entered into the groove on the disc at a slot which is closed by special devices when the last blade is entered. Modifications of the simple inverted T-base also are used. General Electric uses a straddle-base for its long blades which fits over a T-shaped rim on the disc. Sometimes the straddle ends of the blades are welded to the disc.

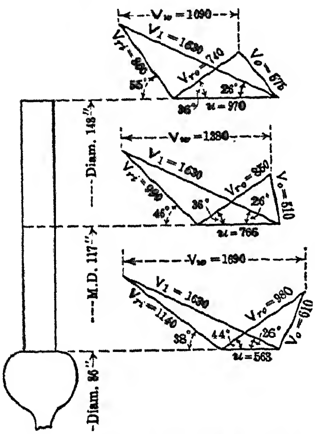

FIG. 22. Velocity Diagrams through Blading

Serrated grooves to receive blades and distance pieces are common with Parsons blading. Another form has a dovetailed groove into which the blades and distance pieces are inserted. These were formerly tightened by caulking. Westinghouse upsets a foot on the lower end of certain blades, which foot projects under the distance piece and is in turn locked in the dovetail groove by special driving wedges on one side. Allis-Chalmers sets the shorter blades cut from a rolled strip in a jig to insure uniform blade spacing and correct blade angle, and an alloy foundation ring is cast around their bases. A shroud ring then is silver-soldered to the outer end of the blades. The foundation rings are machined with one or more projections to fit under shoulders on one side of the groove and then balanced. A soft metal caulking strip on the other side of the groove holds the ring in place. No sharp corners or edges are permissible on any part of the blade, being a source of weakness from vibration fatigue. Westinghouse uses side entry blades on large low-pressure stages, with each row on a separate disc. These blades have serrated roots entering grooves milled nearly axially in the rim of the wheel, and as each blade is driven into place it firmly locks the preceding blade.

Parsons have developed a hollow low-pressure blade rolled from billets of stainless steel in which the hole tapers with the taper of the blade, and with the root integral with the blade. The walls gradually thicken towards the base. This construction substantially reduces the weight of the blades. With equal centrifugal stress these blades can operate at 15% greater blade speeds than solid blades, thus permitting a larger annulus at the last blade row and a greater output.

Blades of Parsons turbines are strengthened against vibration by lacing wires, silver-soldered to the blades at experimentally-determined points along their length. Copper-nickel, 5% nickel-steel, and pure nickel have been used for these wires. Shrouds on the ends of blades also lessen vibration.

Gaging of Reaction Blades is the ratio of the net area for steam flow on the mean diameter measured at the blade outlet at 90° to the direction of the jet, to the area of the

annular space occupied by the blade ring. Thus, a 25% gaging means a net area for flow of 25% of the blade ring annulus.

In some turbines, blades are adjusted by twisting, with special tools, after final assembly, to rectify irregularities due to workmanship. With Kingsbury bearings, it is no longer necessary to re-gage blades to correct end thrust.

Shrouds.—Some blades, particularly small ones, are formed with projections at their tips to form their own shroud rings. Shroud strips may be held by riveting over the tenons machined at the ends of the blades.

Shrouds may consist of flat strips in impulse turbines with a clearance of 0.03 in. between sections. Where radial clearance over the blade tips is of importance, as on Parsons blading, channel-shaped shrouds sometimes are used, with narrow channels projecting toward the casing to form small clearance.

Sometimes flat shrouds, which project on one side toward the base of an adjacent row, are used for end-tightening. The clearance between shroud and blade base can be adjusted to a much lesser amount than the permissible end clearance of similar blades. The reduced leakage with such shrouds results in better turbine economy.

For further information on blading materials, see: Materials and Design of Turbo-Alternator Plant, Lasche and Kieser, translated by Mellanby and Cooper; Brown Boveri *Review*, Jan., 1934, p. 30.

Strength of Blade Roots.—All blade roots must be sufficiently strong to withstand the stresses due to centrifugal force. Methods of calculating such stresses can be found in Stresses in Turbine Blading, by G. Stoney, *Engg.*, April 26, 1918, or in Goudie's Steam Turbines. The centrifugal force on a blade is

$$F = 0.00002842\,N^2\,Wr,$$

where N = rev. per min.; W = weight, lb., of blade and shroud ring (if any) beyond the section of the base carrying the load; r = radius, in. from the center of the shaft to the center of gravity of the blade and shroud figured beyond the section under stress. At normal speeds, blades should not be stressed greater than 0.5 their elastic limit. This allows the turbine a certain overspeed without risk of blade troubles.

Blade Failure may be due to the presence of some foreign substance in the casing, to defective material, to poor workmanship or to vibration. The first cause can be avoided by care in assembling the machine. All reliable manufacturers give particular attention to avoiding the second and third causes and are now devoting much study to vibration. See Vibration, Vol. 3 of this series.

Corrosion.—Certain blade materials corrode badly if the feedwater is not deaerated to free it of oxygen and carbon dioxide. Corrosion often is rapid in idle turbines into which a small amount of steam leaks through the throttle valve. If kept dry, corrosion should not occur. Kerosene injected at the throttle valve of the turbine before shutting down, gives the blades an oily coating and prevents corrosion. Aluminum-bronze blades have corroded badly in turbines receiving wet steam carrying magnesium and calcium chlorides.

Erosion of the inlet edges of low-pressure blades in turbines with high tip speeds has required the renewal of these blades in from 3 to 7 years. This is due to impact of water drops formed as a result of expansion. F. W. Gardner (The Erosion of Steam Turbine Blades, *The Engineer*, Feb. 5, 12, & 19, 1932) shows that the drops of water must be extremely fine; that they tend to concentrate on the outer ends of the blades; that the force of impact of the drops on blades moving 1000 ft. per sec. is about 90,000 lb. per sq. in.; that it is impossible to remove by any separating device all the water that condenses in these blades; and that hard blades and hard sheaths on blades are necessary to withstand this erosion. See Brown Boveri *Review*, Jan., 1934, p. 29, for curves showing braking losses caused by moisture in blading, given in percentage of the useful output at different pressures and temperatures. Curves are shown of improvements resulting from drainage grooves.

Christie and Colburn (*Turbines*, N.E.L.A., 1932) found that erosion was most serious in turbine blades with tip speeds over 1000 ft. per sec.; that it is more pronounced in reaction than in impulse blading; and that erosion is most severe in about 1 to $1^1/_2$ in. from the blade tip and around binding wires. They also show how steam conditions at the entrance to the last blade row may be estimated.

The use of hardened strips fastened or brazed to the inlet edges of the blades, of coatings of hard alloys as stellite, tungsten tool steel, tantalum, etc., fused onto the blade flank, of heavy chromium plating, of drainage systems to remove interstage moisture, of hard alloy steel blades, and of combinations of these, are all being tried to reduce erosion. Water drainage grooves are provided around the casing of some units to draw off water formed by condensation on blades and nozzles. These water drainage devices are said

to remove 25 to 30% of the moisture present. The low-pressure bleeder point also serves to draw off such water.

Blade Design must avoid any sudden change of form or corners where stress may be concentrated. Changes of section are made very gradually. The heat treatment and method of manufacture, such as drawing, forging, rolling, or pressing, must be such that the blade is not under any internal stress. The shaping of blade roots should be done by milling from the bar or forging. Pressing or stamping sets up internal stress in the blade root and is undesirable. In many cases, the distance-piece is made an integral part of the blade root, thereby increasing its strength.

Blade Material.—Brass has been used for blading of small turbines operating at low pressures and temperatures. Steel with 4.5 to 5.5% nickel has been used for highly stressed blading. When heat treated, such steel has an ultimate strength of 70,000 to 90,000 lb. per sq. in., and an elastic limit of 45,000 to 50,000 lb. per sq. in. Cupro-nickel (78–82% Cu, 22–18% Ni) with ultimate strength of 70,000 lb. per sq. in., elastic limit 50,000 lb. per sq. in., is widely used for Parsons blading where steam temperatures and blade stresses are comparatively low. Manganese-copper (4–5.5% Mn, 94.5–96% Cu), ultimate strength, 60,000 lb. per sq. in., elastic limit, 31,000 lb. per sq. in., has been utilized for low-pressure blading and temperatures under 450° F. Monel metal, ultimate strength, 85,000 lb. per sq. in., elastic limit, 50,000 lb. per sq. in., has been used with moderately high steam temperatures and stresses, as it does not readily corrode. Stainless steels (11.5 to 13% Cr, 0.10 to 0.15% C), ultimate strength, 90,000 to 100,000 lb. per sq. in., elastic limit, 60,000 to 70,000 lb. per sq. in., have been applied to blading subject to high temperature and in highly stressed low-pressure blades subject to corrosion. Some heat-treated blade material has an ultimate strength of over 100,000 lb. per sq. in. and an elastic limit of 70,000 lb. per sq. in. Other materials being tried for blading are chrome-nickel-, tool-, Hecla A.T.V., and chrome-vanadium steels and nickel-bronze. The choice of blade material depends on the steam temperature, length and stress of blade, and character of boiler feedwater. McVetty, Working Stresses for High Temperature Service, *Mech. Engg.*, Mar., 1934, presents data on allowable stresses where creep must be considered.

For further information on blading materials, see Materials and Design of Turbo-Alternator Plant, Lasche and Kieser, translated by Mellanby and Cooper.

Blade Clearance.—As the same pressure exists on both sides of impulse blades, the clearance over their ends may be large. The axial clearance between nozzle mouth and blade on some small impulse turbines varies from $^1/_{32}$ in. to $^1/_{16}$ in. Large machines have axial clearances up to $^1/_2$ in. Suction effects make it desirable to keep this clearance as small as mechanically possible.

The radial clearances over the ends of Parsons blades must be kept as small as possible, due to the pressure difference across each row. Consideration also must be given to the rigidity of the casing. Various formulas are used by builders of Parsons turbines for determining this clearance. Some formulas are based upon distance between bearings, others upon blade length and mean diameter of row, with consideration of the taper on the ends of the blades. An older formula for blades without taper at the top is

$$C = 0.015 + 0.003\,D + 0.005\,l_b,$$

where C = clearance, in., D = mean diameter of blade ring, ft., l_b = length of blades, in.

Stodola (The Efficiency of Reaction Blading, *Engg.*, Oct. 2, 1925) quotes one builder of Parsons turbines as allowing on large single-cylinder turbines a clearance of 0.001 × mean diameter, and on short two-cylinder units 0.0008 × mean diameter.

The clearance of end-tightened blading can be set at substantially that of the dummy pistons. This usually will be less than half the end clearance given by the above formula. The gain in efficiency by the use of end-tightened blades results from this reduction.

The axial pitch of blade rows on Parsons blades is given by the formula

$$P_a = 2B + 0.25 + (l_b/16),$$

where P_a = axial pitch of the blade rows, in., B = width of blades, in., l_b = length of blades, in. Greater pitch may be required by end-tightened blading.

Since leakage is one of the principal losses in Parsons turbines, great attention is given to maintaining clearances at as low a figure as is consistent with reliable operation. With end-tightened blading or blading in a conical cylinder, it is important that the clearance be made small enough to maintain high efficiency under load. This may be done by moving the thrust between limit stops, thus providing large clearance during the starting period and moving the thrust to secure minimum clearance and high efficiency when under load.

Blade Length.—Maximum blade lengths have been increased (1935) on the last low-pressure wheels to 35% of the mean diameter of the blade ring, while tip speeds have

increased to about 1250 ft. per sec. Further developments in blade materials may permit still longer blades. See Turbines (N.E.L.A., 1932) for data upon maximum blade lengths and tip speeds. The minimum blade length is from 1.5 to 2% of the mean diameter.

THE EFFICIENCY AT THE WHEEL PERIPHERY is found by combining the nozzle efficiency η_n with the diagram efficiency η_d. Stodola (Steam Turbines, p. 222) makes the following statements on the efficiency at the wheel periphery: 1. Efficiency depends only on ρ, the ratio of wheel speed to steam speed, and not on the individual values of the velocities. 2. Efficiency varies with the peripheral velocity according to a parabolic law with the maximum values over a narrow range. 3. With a small nozzle angle α the maximum value of efficiency at the wheel periphery is attained when the peripheral velocity is nearly half of the steam velocity. 4. The best efficiency for constant blade coefficient k_b is higher the smaller the nozzle angle α. 5. The effect of energy loss in the nozzle makes itself felt nearly four times as much as the effect of energy loss in the blades.

NOZZLE AND BLADE EFFICIENCIES IN TURBINE DESIGN.—Data upon nozzle and blade losses are not complete, and the factors given above can be used only with judgment. Experience has indicated that the use of such factors in turbine design may be misleading. Many designers start with internal efficiencies based upon tests of similar units from which stage efficiencies can be calculated, when the reheat factor is known. Then blade and nozzle efficiencies can be deduced with considerable reliability. Such deductive design based upon test performance is preferable to synthetic design using assumed efficiency factors. Detailed methods of proportioning nozzles and blading will be found in Stodola, Steam Turbines; Goudie, Steam Turbines; Zietemann, Dampfturbinen; Dampfturbinen; and Forner, Thermodynamische Berechnung der Dampfturbinen.

5. STEAM SUPPLY TO TURBINE

The steam supplied to turbines from boilers should be free from moisture, dust, acid, and corroding chemicals and as nearly pure as possible. Any corrosive element in the steam will destroy rapidly turbine blading, starting at the dew-point in the blading. Blade surfaces are continually swept clear by the high velocity steam, thereby accelerating this corrosive attack.

Although feedwater in modern plants consists of condensate and evaporated make-up water, impurities may be carried into boilers from condenser leakage. Chemicals must be added to maintain the desired sulphate-alkalinity ratio so that the average concentration in the boiler drums may range from 1500 to 6000 parts per million. Due to the evaporation of any moisture in the superheater, some impurities are carried over as dust or vapor and deposited on the governor valves, nozzles and blades of the turbine, closing off the passages and decreasing the turbine capacity. The decreased capacity may range from 15 to 50% in a few weeks in some cases. When this scale consists of soluble salts, it may be removed by washing with water during the overhaul period, by partly filling the turbine with water and slowly revolving the spindle or by dissolving the deposits with wet steam. The last operation is accomplished by slowly desuperheating the steam at the rate of 100° F. drop per hr. with the turbine in operation until wet steam enters the throttle. In some cases load is removed and speed reduced for this operation. This wet steam is allowed to pass through for one to two hours, thoroughly washing off all soluble scale, when superheat is slowly restored. Washing with kerosene also has been done on certain units. (See Turbines, N.E.L.A., 1931.)

On certain high-pressure turbines this blade deposit consists of a scale made up largely of silica and iron oxide, which has to be scraped off. This trouble has been overcome by reducing the boiler concentration and placing a separator on the line from the evaporator.

6. ROTORS

Rotors of small high-speed impulse turbines usually consist of a disc or wheel, carrying the blades or buckets, pressed on a shaft and held against a shoulder by a lock nut. Some turbines built upon the Curtis principle and with low wheel speeds, use two or more discs, each with a single row of blades, instead of one disc with several rows, which is a less expensive construction. Such turbines generally are designed with shafts sufficiently large so that they operate well below their critical speed.

Multi-stage impulse turbines have a series of discs mounted on the shaft, with intermediate diaphragms between to carry the stage nozzle, and usually, the labyrinth. The discs have holes for equalizing the steam pressure on the two sides. The edges of all such holes should be well rounded. The surfaces of the discs should be turned smooth and preferably polished.

Discs of Curtis Wheels carrying two rows of blading have a rapidly tapering section and a heavy hub. In single-stage machines, the blade speed at the mean diameter usually varies from 200 to 500 ft. per sec. Large machines have had Curtis wheels running at mean blade speeds of 600 to 650 ft. per sec. Many builders of compound turbines keep this mean blade speed low to reduce the windage loss of the idle blades, as well as to reduce the disc friction.

Discs for Multi-stage Impulse Turbines are made either of uniform thickness, of a conical section, or of a hyperbolic tapering section. With only a relatively light rim, the stresses are less than in the Curtis wheels. They operate at mean blade speeds varying from 400 to 900 ft. per sec., and with tip speeds up to 1200 ft. per sec.

DISC MATERIAL.—Discs on small turbines with low wheel speeds may be cut from rolled boiler plate of ultimate strength of 65,000–70,000 lb. per sq. in., and elastic limit of 30,000 to 40,000 lb. per sq. in. For larger discs, quenched and tempered carbon steel forgings of elastic limit of 50,000 lb. per sq. in., or quenched and tempered nickel-steel forgings of elastic limit of 65,000 lb. per sq. in. are used.

Gibb (Post War Land Turbine Developments, *Proc.* Inst. Mech. Engrs., 1931) gives full specifications for rotor forgings of C. A. Parsons and Co., England. These specify exhaust-end turbine discs of 100,000 to 110,000 lb. per sq. in. ultimate strength.

Carbon steel forgings are used with ultimate strength, 75,000 lb. per sq. in.; elastic limit, 28,000 lb. per sq. in.; elongation, 20 to 24%; reduction in area, 35 to 40%.

Where stresses are high, chrome-vanadium-steel discs, forged and heat treated, have been used that have a yield point not less than 70,000 lb. per sq. in., an ultimate strength of 100,000 lb. per sq. in., an elongation of at least 19%, and a reduction of area of not less than 45%. Extreme care is taken in the selection and testing of test pieces and in disc inspection. Guy and Jones (Metropolitan-Vickers Rateau Marine Turbine, *Engg.*, Feb. 15, 1923) give for forged discs: Ultimate strength, 107,500 lb. per sq. in.; yield point, 67,000 lb. per sq. in.; elongation, 17%; reduction of area, 40%; P and S each less than 0.05%. At 25% overspeed, the maximum working stress should not exceed the elastic limit. At normal speed this allows a working stress of 16,000 to 20,000 lb. per sq. in. Stresses at normal speed are figured with a factor of safety of about 2.

Certain manufacturers over-stress the discs by operating them at overspeeds. The discs then are allowed to age, resulting in an increase in the elastic limit of the material.

Care must be taken in forging the discs to thoroughly work all of the metal. No subsequent heat treatment can make up for lack of proper working. Discs are rejected for sponginess, dirty steel, blown steel, and slag inclusions that cannot be scraped out.

DISC DESIGN.—Discs usually are designed by assuming a thickness of disc under the rim, such that it will not buckle or bend during machining and erection. This thickness may be 3/8 in. on small wheels, increasing to 1 in. on some Curtis wheels and large-diameter impulse discs. The thickness at other points in a disc of hyperbolic profile is found from the equation $t = Cr^a$, where t = thickness, in.; r = radius at desired point, in.; C = a constant found for the conditions under the rim. The exponent a varies from (-0.4) to (-0.8) in multi-stage impulse wheels, and is taken as (-1) for Curtis wheels. Wide variations exist in the disc designs of various builders. Some discs have been made too thin, and have given trouble in service due to nodal vibration.

The first step in disc design is to assume the thickness under the rim. A value of exponent a then is chosen, depending on the type of disc desired. Since r is known, the value for the constant C can be found when the thickness is chosen. The thickness at any other radius readily can be calculated from the above equation. Present practice (1935) on large turbines is to make the discs rather heavy, as these are less liable to vibration.

The theoretical hyperbolic curve near the hub is modified to one or more arcs of a circle with much greater curvature than the hyperbola. This is done to provide a heavy hub in which a keyway may be cut without weakening the disc section. The proportions of the rim are determined by the size, number of rows of blades and the methods of fastening the blades to the rim. The rim is connected to the narrowest part of the disc by a section of easy curved profile, frequently consisting of arcs of circles of relatively short radius. The flanks of the discs between the curved sections at hub and rim are sometimes made straight taper, or wedge-shaped for easier machining. This form is slightly stronger than the hyperbolic profile, and is more easily made. The departures from true hyperbolic form make the solution of disc stresses complicated and tedious.

Rotors for small turbines for high pressures and temperatures and for very high speeds frequently are made complete from a solid forging, with the discs turned to form by removing the metal between them. This gives a strong, rigid construction.

DETERMINATION OF DISC STRESSES.—After preliminary designs are finished, calculations are made to determine whether the discs have sufficient strength. Three

stresses, radial, tangential, and axial, may act at any given point. The axial stress is of negligible value if there is no sudden change in axial thickness, as at a hub. Radial and tangential stresses can be calculated by neglecting the axial stress. Stodola in Steam and Gas Turbines developed formulas for the determining of these stresses, but which are complicated in the form presented.

S. H. Weaver (Disc-wheel Stress Determinations, *Trans.* A.S.M.E., xxxix, 173) describes a method of calculation which is simpler and more readily applied. For machining purposes radial sections of discs usually consist of straight lines and arcs of circles. The equations of these lines present mathematical difficulties in calculating stresses. Hence the section is assumed to consist of one or more hyperbolas of the equation, $t = cr^a$. In this equation the exponent a is the shape-constant of the profile and has a negative value when the thickness decreases with a larger radius; a zero value for a constant or uniform thickness; and a positive value when the thickness increases with a larger radius. For a given disc profile, Fig. 23, the value of a may be found from

$$a = (\log t_2/t_1) \div (\log r_2/r_1) \quad \text{or} \quad (-\log t_1/t_2) \div (\log r_2/r_1).$$

One or the other of these formulas is chosen which will give one or more values for the ratio of the thicknesses.

Stodola's equations for tangential and radial stress are as follows:

Notation.—m_1, m_2 and p are algebraic quantities as given in the equations of Group II, below; a = shape constant of profile of the particular portion of the disc section; V = Poisson's ratio of deformation = 0.3 for steel; E_1 = Young's modulus of elasticity; R = radial stress at radius r, lb. per sq. in.; T = tangential stress at radius r, lb. per sq. in.; r = any radius in disc section, in.; b_1 and b_{11} = boundary condition constants; ω = angular velocity of rotation in radians; u = mass of disc material per unit of volume = 0.2815 lb. per cu. in. for average steel; y = radial elongation, in.

$$R = \frac{E_1}{1 - V^2}\{(3 + V)\,pr^2 + (m_1 + V)b_1 r^{m_1 - 1} + (m_2 + V)b_{11} r^{m_2 - 1}\},$$

$$T = \quad E_1 \qquad\qquad {}^{-1} +$$

It will be necessary to know two stresses in order to determine the values of the condition constants, b_1 and b_{11} and to transform these equations. Known radial stresses R_1 at radius r_1 and R_2 at radius r_2 are assumed. The tangential stresses at r_1 and r_2 are

$$T_1 = Ar_2^2 - BR_1 + CR_2, \qquad \text{(I)}$$

where A, B, C, D, E and F have the values given in Equations (II).

The stresses due to the external centrifugal load and the weight of the disc itself vary as the square of the speed. If all stress values are calculated for 1000 r.p.m., the stresses at any other speed can be found by multiplying by the square of the speed ratio.

The following formulas (Group II) based on 1000 r.p.m., assist in solving for the various stresses:

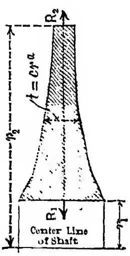

Fig. 23

$$\frac{\log}{\log(1/K)}, \qquad \frac{\log}{\log(1/K)}.$$

$$-\;0.3a + 1;$$

$$m_2 = -(a/2) + \qquad -\;0.3a + 1;$$

$$B$$

$$E \qquad \text{(II)}$$

$$B + a;$$

$$\frac{3.3(C -}{1 + 0.4125a}$$

$$\frac{3.3(F - K^2E) - 1.9}{1 + 0.4125a}.$$

The factors A, B, C, D, E and F are functions only of the shape constant a and the ratio of radii K.

These factors become relatively simple for the portions of the disc where the wheel section is of constant thickness, as at the hub and sometimes at the rim. At 1000 r.p.m. the functions reduce to the following (Group III) equations:

$$0. \qquad K = \frac{r_1}{}. \qquad C = \frac{}{1 - K^2}.$$
$$B: \quad F = C - 1. \qquad C - 2.$$
$$A: \quad 6.6 + 1.4K^2. \qquad 6.6K^2 + 1.4.$$

Since the determination of the values of the functions takes time in making a stress calculation, Weaver has prepared the following approximate equations (Group IV) for the more rapid determination of these functions by the use of common logarithms. The error in these equations is about 0.7% as a maximum.

$$B = \frac{\log (1/K)}{5.43}(a^2 - 1.2a) - (a/2) +$$
$$F = B + a;$$
$$E = \qquad \frac{}{10}(a^2 + 10a) - (a/2) + \frac{2}{1 - K^2} - 2\Big),$$

between the limits 0.8 and 0.1 for K, and (-5) and 0 for a;

between the limits 0.97 and 0.8 for K and 40 and 0 for a; . . . . . (IV)

between the limits 0.8 and 0.4 for K and (-5) and 0 for a;

between the limits 0.97 and 0.8 for K and 40 and 0 for a;

$$A = 3.1(1 - K)^{2.09} a + (6.6 + 1.4K^2);$$
$$D = 1.25(1 - K)^{1.75} a + (6.6K^2 + 1.4).$$

These functions can be plotted in simple alignment charts with negligible errors (see *Gen. Elec. Rev.*, Oct., 1917; Moyer's Steam Turbines).

The following example shows the method of applying these formulas. Fig. 24 is a half section of a disc designed to run at 3600 r.p.m. and carry two Curtis blade rows. The disc is divided into five sections, 1, 2, 3, 4 and 5. The curved profiles are assumed to be portions of hyperbolas whose a value can be found from Equation II for each section. All sections are assumed to have the same thickness where each joins the adjacent section. Rings 1 and 5 are of uniform thickness, hence $a = 0$. Ring 4 has a positive value of a, since thickness increases rapidly with the radius; a is negative in sections 2 and 3, since the thickness decreases as the radius increases.

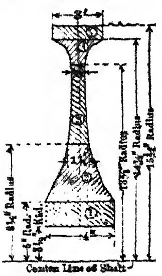

FIG. 24

Two of the radial stresses must be known. The radial stress at the bore may be taken as zero, as the shrink fit is supposed to be almost neutralized at normal speed by the centrifugal expansion of the bore, and at some over-speed the radial stress is zero. The outer radial stress of the blade load equals the centrifugal force of blades, shrouds, etc. The centrifugal force is

$$\text{C.F.} = 0.00001421\ N^2\ wd_1,$$

where N = rev. per min.; d_1 = diameter, in., to center of gravity of blades; w = total weight of blades, shrouds, etc., lb. The centrifugal force per inch of circumference at diameter d_2 at the edge of the disc = C.F. $\div\ \pi d_2$. This is assumed in the problem at 172 lb. per in., at radius $r = 15\,^3/_4$ in.

The unknown radial stresses at the lines dividing the imaginary rings are taken as e between rings 1 and 2, as f between rings 2 and 3, as g between rings 3 and 4, and as h between rings 4 and 5. The data may now be collected in Table 2. Constants A to F may be calculated from Equations (II) and (III); approximate results may be calculated from Equations (III) and (IV) or may be read from the alignment charts referred to above. The values given in Table 2 are calculated from Equations (III) and (IV).

There is only one thickness at any one radius owing to the construction of the disc. Hence, at the dividing line between any two imaginary rings, there can be only one radial stress and one tangential stress. Take the line between rings 1 and 2, at radius 5 in. The outer tangential stress of ring 1 must equal the inner tangential stress of ring 2. Hence,

$$T_2 \text{ (ring 1)} = T_1 \text{ (ring 2)}.$$

or $$(Dr_2^2 - ER_1 \cdot \qquad)_{\text{(ring 1)}} \qquad {}_1 + CR_2)_{\text{(ring 2)}}.$$

Similar equations can be written for each imaginary line at the given radius separating rings, substituting the values of radial stresses, e, f, g and h assumed above. These four equations next

can be solved for the unknown radial stresses e, f, g and h. The equations for the equal tangential stress at the various radii are as follows:

At radius 5 in.:

$$4.64 \times (5.0)^2 - 1.92 \times 0 + 2.92 \times e = 6.02 \times (8.5)^2 - 3.47 \times e + 1.57 \times f.$$

At radius 8.5 in.:

$$3.11 \times (8.5)^2 - 1.74 \times e + 1.28 \times f = 6.59 \times (13.375)^2 - 3.27 \times f + 2.3 \times g.$$

At radius 13.375 in.:

$$3.74 \times (13.375)^2 - 1.87 \times f + 1.74 \times g = 8.11 \times (14.875)^2 - 3.73 \times g + 20.86 \times h.$$

At radius 14.875 in.:

$$7.06 \times (14.875)^2 - 3.43 \times g + 18.51 \times h = 7.85 \times (15.75)^2 - 17.35 \times h + 18.35 \times 172.$$

These equations can be solved easily by a substitution method as follows:

From equation for 5 in. radius,

$$e = 0.246f + 49.9.$$

Substituting this value of e in the equation for 8.5 in. radius and solving,

$$f = 0.558g + 252.5.$$

Substituting this value of f in the equation for 13.375 in. radius and solving,

$$g = 4.71h + 360.8.$$

When this value of g is substituted in the last equation it is found that

$$h = 243.$$

Substituting in the three preceding equations, the following values are found:

$$g = 1503, \quad f = 1091, \quad e = 318.$$

The tangential stresses at the various radii can be found by substituting in either side of the foregoing equations the values of e, f, g and h as follows:

At radius 5 in.: $T_5 = 4.64 \times (5.0)^2 + 2.92 \times 318 = 1045.$

At radius 8.5 in.: $T_{8.5} = 3.11 \times (8.5)^2 - 1.74 \times 318 + 1.28 \times 1091 = 1068.$

At radius 13.375 in.: $T_{13.375} = 3.74 \times (13.375)^2 - 1.87 \times 1091 + 1.74 \times 1503 = 1244.$

At radius 14.875 in.: $T_{14.875} = 7.85 \times (14.875)^2 - 17.35 \times 243 + 18.35 \times 172 = 894.$

(Note.—Some decimals have been dropped to simplify the solutions.)

The tangential stress at the bore is found as follows:

$$T_{1_b} = Ar_2^2 - BR_1 + CR_2 = 7.29 \times (5)^2 - 2.92 \times 0 + 3.92 \times 318 = 1430.$$

At the rim:

$$T_{2_b} = Dr_2^2 - ER_1 + FR_2 = 7.28 \times (15.75)^2 - 16.35 \times 243 + 17.35 \times 172 = 817.$$

The stresses at 1000 r.p.m. are as follows:

At radius	3.5	5	8.5	13.375	14.875	15.75
$R =$	0	318	1091	1503	243	172
$T =$	1430	1045	1068	1244	894	817

The stresses at intermediate points in any ring can be computed from the known values of radii and thickness at these points by Equations (I).

At 3600 r.p.m. the stresses above should be multiplied by the square of the ratio of the speeds, *i.e.*, by $(3600/1000)^2 = 12.96$.

The resultant stresses are as follows:

At radius	3.5	5	8.5	13.375	14.875	15.75
$R =$	0	4,121	14,139	19,479	3,149	2,229
$T =$	18,533	13,543	13,840	16,122	11,586	10,588

Discs should be able to withstand an overspeed of 20% without exceeding the elastic limit. The stresses at this speed would be $(1.2)^2 = 1.44 \times$ stresses at normal load.

The maximum stress in the above table is 19,479 lb. per sq. in. at radius 13.375 at 3600 r.p.m. and at 4320 r.p.m. (20% overspeed) it would be 28,050 lb. per sq. in., which is within the usual elastic limit of steel used in discs. If this stress is considered excessive, the design may be modified by

Table 2.—Data on Stresses at Lines Dividing Imaginary Rings in Fig. 24

Ring No.	1	2	3	4	5
r_1	3.50	5.00	8.5	13.375	14.875
r_2	5.00	8.5	13.375	14.875	15.75
t_1	4.00	4.00	1.25	0.625	3.00
t_2	4.00	1.25	0.625	3.00	3.00
$K = r_1/r_2$	0.70	0.588	0.636	0.899	0.944
a	0	−2.19	−1.53	14.78	0
R_1	0	e	f	g	h
R_2	e	f	g	h	172
A	7.29	6.02	6.59	8.11	7.85
B	2.92	3.47	3.27	3.73	17.35
C	3.92	1.57	2.30	20.86	18.35
D	4.64	3.11	3.74	7.06	7.28
E	1.92	1.74	1.87	3.43	16.35
F	2.92	1.28	1.74	18.51	17.35

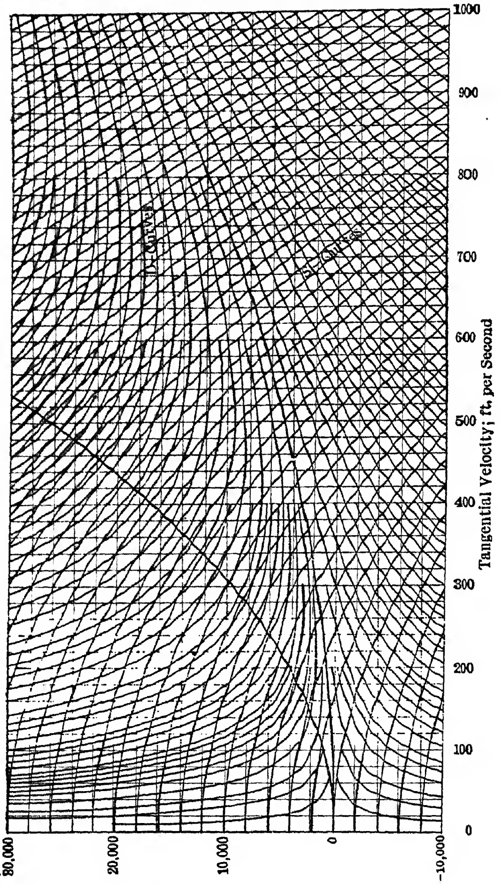
thickening the metal at this point and allowing a smaller taper on the disc. The radial elongation in inches at any radius r in inches is

$$y = (T - 0.3R)\ r + E_1,$$

where E_1 = modulus of elasticity for steel = 29,000,000 for usual disc material. The radial elongation is as follows at 3600 r.p.m.:

Radius..................	3.25	5	8.5	13.375	14.875	15.75
Elongation, y............	0.00212	0.00212	0.00281	0.00474	0.00546	0.00539

Weaver states that the approximate method generally gives stresses about 1% too high. The great advantage of this method is the reduction of the time required for computation.



Stress in lb. per Square Inch

FIG. 25. Disc Stress Diagram

H. Haerle (Strength of Rotating Discs, *Engg.*, Aug. 9, 1918) presents a simple method for the determination of disc stresses from a single diagram, shown in Fig. 25, which can be applied to any disc profile, and yield results sufficiently accurate for all practical purposes. The general formulas for disc stresses given by Stodola, and stated above in

discussing Weaver's methods, form the basis of Haerle's method. These formulas reduce to much simpler expressions when applied to a disc of constant thickness, in which case $a = 0$ in the expression $t = Cr^a$, where t = thickness of disc, in., at radius r, in., C = a constant, a an exponent governing the curvature and found by means of Equations (II) on page 8-27.

Let T = tangential stress, lb. per sq. in.; R = radial stress, lb. per sq. in.

Haerle's methods are based on the assumption that

$$S = T + R = \text{sum of principal stresses,}$$

and

$$D = T - R = \text{difference of principal stresses.}$$

The following equations derived from those of Stodola, apply to a disc of constant thick.

$$D = (1 - V)\frac{u}{g}\{$$

$$K_1 = \frac{}{(1 - V^2)u} \quad \text{and} \quad K_2 = \frac{}{(1 - V^2)u},$$

where V = Poisson's ratio (= 0.3 for steel); u = weight of disc material, lb. per cu. in.; $g = 32.2 \times 12$ (in.); ω = angular velocity, radians per sec.; U = tangential velocity of the disc, in. per sec.; E = Young's modulus (= 29,000,000 for steel); b_1 and b_2 are constants depending on stress conditions at bore and rim as in Stodola's formulas.

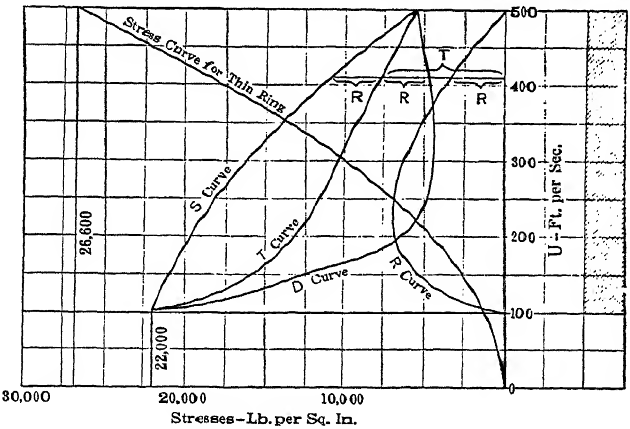


FIG. 26

The only variables at a given radius in the equations for S and D are K_1 and K_2. Series of curves as represented by the above equations are plotted in Fig. 25, each curve being based on a different value of K_1 and K_2, respectively. The problem is now simplified to that of selecting the proper curve or set of curves according to the specific details of the disc under consideration and finding S and D from the curves.

If S and D can be determined from the diagram, then

$$T = (S + D)/2 \quad \text{and} \quad R = (S - D)/2.$$

Fig. 25 is plotted with stresses as abscissae and tangential velocities as ordinates. The heavy line on the diagram curving toward the left is the stress curve for a thin ring.

The following examples show the application of this diagram: In the case of a disc of uniform thickness with a concentric bore and no load on the rim, the radial stress R at both bore and rim must be zero. Then

$$S = T + R = T \quad \text{and} \quad D = T - R = T \quad \text{or} \quad S = D = T$$

at both rim and at bore. That is, the S and D curves must intersect at both bore and rim, and these must be the same curves on the diagram at both places, for, since the boundary conditions are fixed, the values of K_1 or K_2 are the same throughout the disc. For example, let the rim speed be 500 ft. per sec., and the bore speed 100 ft. per sec. The same S and D curves must intersect at

the 500 ft. and 100 ft. ordinates, as shown in Fig. 26, at 5500 lb. and at 22,000 lb. respectively, which must be the tangential stress at these points, since the radial stress at both points is zero. Tangential stresses at other speeds may be plotted by bisecting the distance between the S and D curves at each speed. Radial stresses can be found by halving the difference between the S and D curves and plotting from the zero ordinate.

The ease and rapidity with which problems relating to discs of uniform thickness can be solved by this S and D chart suggests the application of this method to discs of other than parallel profile. If the hyperbolic or other profile is replaced by a stepped disc consisting of a number of concentric rings, each of constant thickness as in Fig. 27, this method can be applied.

The assumption is made that, provided the steps be comparatively small, the stresses in adjacent concentric layers on either side of the step are inversely proportional to the axial dimensions or thickness t' and t as in Fig. 27. Hence

$$\frac{t}{t'} = \frac{R'}{R} = \frac{T'}{T}.$$

Let ΔR denote the increment (positive or negative) of the radial stress at the step. Then

$$\Delta R = R - R' = R(1 - t/t').$$

The following expression is derived for ΔT:

$$\Delta T = V\Delta R = VR(1 - t/t'),$$

where V = Poisson's ratio = 0.3 for steel.

d

$$\Delta D = D - D' = -0.7\Delta R$$

r the change in the S and D curves at the step. It is now quite easy to determine the S and D

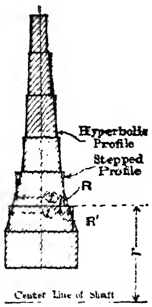

FIG. 27

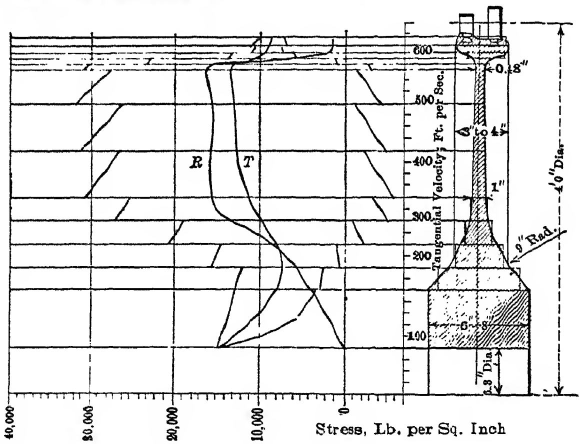

FIG. 28

values at all points on the irregular disc profile, as shown in the example, Fig. 28, when applied to a disc with tapered sides, for a Curtis stage with two rows of blades. The mean diameter is 48 in., and the normal speed, 3000 r.p.m. The stepped disc, in substitution for the actual profile, is shown by the fine lines. Assumed peripheral velocity of the disc proper, 615 ft. per sec. The net weight of blades, shrouds, etc., is assumed as 65 lb. at normal speed, exerting a centrifugal pull of 2860 lb. per inch of circumference. The net width of the disc at the periphery, after deducting for dovetail grooves for blades is t' = 2.2 in. Hence, radial stress due to blade load R (at periphery) = 2860/2.2 = 1300 lb. per sq. in. The tangential stress at the periphery may be assumed; let T = 9000 lb. per sq. in. Hence at the periphery,

$$S = 9000 + 1300 = 10{,}300 \text{ lb. per sq. in.}$$

$$D = 9000 - 1300 = 7{,}700 \text{ lb. per sq. in.}$$

These values constitute the point of origin of the S and D curves across the outermost step. It is assumed that R = 0 at the bore. Hence $S = D = T$ at the bore, *i.e.*, the curves intersect at the ordinate of the bore. If forced fit must be allowed for, R at the bore may be chosen with either a positive or negative value to suit the particular conditions.

Beginning at the tangential velocity of the periphery, follow the S and D curves across the radial extension of the first step, *i.e.*, from tangential velocity, 615 ft. per sec., to tangential velocity, 600 ft per sec. At step 600 read, $R = (S - D)/2$, find ratio t/t' from the substituted profile, and calculate ΔR, ΔS and ΔD. Plot the new S' and D' for the second step and continue the S and D

curves across it. The procedure is the same for all other steps. If tangential stress T at the periphery has been chosen correctly, the S and D curves for the innermost step must intersect at the bore of the disc. If they do not, another value of T at the periphery may be chosen and the process repeated until intersection occurs at the bore.

The axial thickness of the several concentric rings which form the substituted disc section correspond to the thickness of the true profile at points midway between the steps, and the stresses as determined by the S and D curves at these points coincide with the actual stresses in the original profile. Hence, if the horizontal distance between the S and D curves in the center of the stepped rings is bisected, points on the true tangential stress curve are obtained. A smooth curve through this series of points represents graphically the distribution and magnitude of the tangential stress T throughout the disc. The radial stress R at the middle of each step can be determined by measuring the distance of the tangential stress curve T from the S or D curves, and plotting this distance from the zero axis at the various radii. Another smooth curve through these points indicates the magnitude and distribution of the radial stress R. Both these curves are clearly shown in Fig. 28. Values of R and T have been scaled off from these curves at radii corresponding to the various peripheral speeds U in the first column of Table 3, and are tabulated in the last two columns for general information. They could be scaled at any other point if desired. The maximum stress in this disc is a radial stress of 16,600 lb. per sq. in. and it exists just below the rim.

M. G. Driessen (A Simplified Method of Determining Stresses in Rotating Discs, *Trans.* A.S.M.E., APM-50-10, 1928) discusses Haerle's method as above outlined and presents a larger chart for S and D curves than Fig. 25. The purpose of this paper is: 1. To shorten the steps necessary to pass from one element of the disc to the next. 2. To provide an alternative to this cut-and-try method. 3. To indicate a manner in which the results once obtained can be used for all other conditions under which this disc is used, *i.e.*, for different loads at the circumference and for different speeds. The suggestions simplify Haerle's method.

As in Haerle's solution, the change of stress at a change of section is assumed inversely proportional to the thickness. Driessen proposes to find the new S and D curves for the new section as follows: ΔR for the new section $= R - R' = R(1 - t/t')$. Haerle shows that $\Delta S = 1.3\,\Delta R$, and $\Delta T = -0.7\,\Delta R$. For the first section $S - D = 2R$ and for the second section $S' - D' = 2R'$. The change is $(S' - D') - (S - D) = 2\,(R' - R) = 2\Delta R$. Hence $\Delta S = (1.3/2)\Delta R$ and $-\Delta D = (0.7/2)\Delta R$. If $(S - D)$ and $(S' - D')$ are measured in inches on the chart, the distances ΔS and $-\Delta D$ in inches readily can be found, and the new points for starting the S and D curves for the changed sections easily are located on the chart and the quantities in lb. per sq. in. can be read from the diagram.

In Haerle's method the radial and tangential stress at one diameter, usually the hub were assumed, and the rim stresses determined. If the radial rim stress did not fit actual conditions, the disc was recomputed for other assumed tangential stresses at the hub until the desired radial rim stress results from the calculations. Driessen shows that if the tangential stress at the hub, T_h, is plotted against the radial stress at the rim, R_r, it follows a straight line. Hence when two points in this relationship are found, a straight line can be drawn through these points and any other T_h can be determined from this line for the actual R_r that prevails. This greatly shortens the computations.

Driessen points out that with large shrink fits, the stresses no longer are proportional to the squares of the speeds. He then outlines a method for computing and recording the limiting stresses of any disc, so that if an earlier design of disc is considered for a new turbine, reference to these limiting stress values will determine its suitability.

Other methods for calculating disc stresses will be found in: Stodola, Steam and Gas Turbines; Martin, Steam Turbines; Goudie; Steam Turbines; Kearton, Steam Turbines. For calculation

of discs with conical profile see Rotating Discs of Conical Profile (*Engg.*, Jan. 5, 26, 1923); B. Hodgkinson, Rotating Disc of Conical Profile (*Engg.*, Aug. 31, 1923); G. A. Arrowsmith, The Design of Rotating Discs (*Engg.*, Oct. 5, 1923).

SHRINK FITS FOR DISCS.—Experience has shown that discs tend to work loose on shafts if shrinkage allowance in the bore is insufficient. Tests covering the action of stress on disc bores are given in Lasche and Kieser's Materials and Design of Turbo-alternator Plant. Discs frequently are secured to the shaft by a conical bush. When a keyway is used on a disc, the key should serve only as a safety member, and exert neither radial nor lateral pressure. Sometimes two keyways are cut at opposite ends of a diameter to equalize stresses and to maintain balance.

Discs often are bored with an allowance for pressing on the shaft of 0.0015 in. per inch of bore diameter, requiring 1 $^1/_4$ to 2 tons pressure per inch of shaft diameter to force each disc in place. Such press fit compensates for the increase in bore of the hub of the disc when under stress, and prevents it from creeping along the shaft.

DISC AND BLADE VIBRATION.—(See Campbell, Protection of Steam Turbine Disc Wheels, *Trans.* A.S.M.E., xlvi, 1924.) Failures of some of the discs and blades of early turbines led to intensive studies of vibration. These developed the fact that stationary discs and blades vibrated harmonically in an even number of segments, between which were radial lines of quiet, called nodes. The nodes appeared at definite frequencies, as 4, 6, 8, 10, 12 or even higher numbers of nodes. Between these given frequencies the wheel was comparatively quiet. The higher the number of nodes, the higher the frequency of vibration and the less easily is vibration excited. Both disc wheel and the blades vibrate as a continuous disc and must be considered as a unit in this type of vibration. The frequency of a given type of vibration is determined by two factors: *a*, the stiffness, and *b*, the mass of the vibrating body. The stiffer the body, the faster it vibrates, and the more massive it is, the slower will it vibrate. Centrifugal force exerts a stiffening effect on a disc and increases the frequency at which the nodes appear.

The combined frequency of a particle, f_r due to the combined effects of stiffness and centrifugal force is $f_r = \sqrt{f_s^2 + B N_s^2}$, where f_s = natural frequency of a particle of mass m, with an elastic support of such stiffness that a force R_s is required to produce unit deformation; $f_s = (1/2\pi)\sqrt{R_s/m}$; N_s = rev. per sec.; B = a speed coefficient which varies with the design of the wheel and the type of vibration. B has a low value when vibrating sectors extend well into the wheel, and higher values as the number of nodes increases. B varies usually from 2 to 3.

The critical speed $N_s = f_s/\sqrt{(n/2)^2 - B}$, where n = number of nodes. Minor resonant speeds occur, the equation for the first of which is $N_{S1} = f_S/\sqrt{(1 + n/2)^2 - B}$. See Campbell's paper for other values.

When discs are revolved, their circumferences develop, at certain speeds, a form of wave motion which travels around the wheel circumference in the opposite direction to rotation. This wave motion has an even number of nodes which move around the wheel with the wave. Every part of the wheel rim thus vibrates over a period of time during each revolution. If the number of nodes is the same, the frequency of vibration of every particle along the edge of a disc wheel is the same either for standing vibration or for traveling waves. The speed of the traveling wave per second equals the number of complete vibrations of the corresponding standing wave per second multiplied by the length of a complete wave. For a traveling wave all particles vibrate through the same amplitude but their time phases vary successively along the wheel edge.

When these backward traveling waves have the same speed backward that the wheel has forward, a standing wave results. This condition has been most conducive to disc and blade failure. The speeds at which the standing wave forms, are called the **wheel critical speeds.** Wave trains in discs may be started by the application of a small extra force at a given point due to uneven nozzle dimensions, thick partitions, or other lack of symmetry. These waves persist after formation if the speed is suitable for the wave.

The effects of vibration are: 1. The wheel may burst; 2. The wheel may rub; 3. Blades may fail from fatigue. Mathematics have been developed to predict disc stresses, and discs are made heavier than formerly, but one can only be sure of a wheel after a direct test. For this purpose, machines have been developed in which to test discs for vibration under working temperatures and speeds. Safe limits between the operating speed and the critical speed are, for 4 nodes, 15% above or below the operating speed, and for 6 nodes, 10% above or below.

When disc wheel critical speeds fall within these limits, the wheel is *tuned*, that is, metal is removed either from the disc itself or from the blades until the critical speed has been shifted beyond the specified limits. Discs are smooth finished throughout so that

no tool marks may form starting points for fatigue cracks. All sharp edges are rounded off for the same reason.

Tangential vibration may be set up in the blades themselves at certain frequencies, depending upon blade design. Long slender blades must be so designed and tuned that the critical speed falls outside the limits above noted. Blades can be tuned by affecting their stiffness by: 1. Soldering or welding the ends to a shroud; 2. Adding an intermediate stiffening member between tip and base such as a lashing wire; 3. Decreasing the mass of the buckets. The position of the lashing wire has a very great effect on the resistance of blades to vibration.

The frequency of vibration of a reed is $f = tC/l^2$, where f = frequency, cycles per sec.; l = length, in.; t = thickness, in.; C = constant of proportionality. For turbine blades a factor S represents the scale of equivalent thickness. Comparing two blades $S_2/S_1 = f_2 l_2^2/f_1 l_1^2$. Thus a test blade is 14 in. long, with a frequency of 62. The scale of thickness for a similar blade 24 in. long with a frequency of 37 is $S_2/S_1 = 37 \times 24^2/52 \times 14^2 = 1.755$. That is, the required thickness of the new blade is 1.755 that of the one tested.

Blades that may be subject to resonant vibration which leads to fatigue failure, are heavier and somewhat wider than earlier forms and have both inlet and outlet edges rounded. Where possible, long blades are made sufficiently stiff without the use of lashing wires.

Further details and the mathematics of the subject will be found in Campbell's paper above mentioned; Tangential Vibration of Steam Turbine Buckets, W. Campbell and W. C. Heckman, *Trans.* A.S.M.E., xlvii, p. 654, 1925; The Experimental Investigation of Vibrations in Turbine Wheels and Blades, B. Pochobradsky, L. B. W. Jolley and J. S. Thompson, *Engg.*, Oct. 30, 1931; Vibration of Steam Turbine Discs, J. von Freudenrich, *Engg.*, Jan. 2, 1925; Axial Vibration of Rotating Steam Turbine Disc Wheels, R. H. Collingham, *The Engineer*, April 3, 10, 1931; Contribution to the Calculation of Blade Vibration in Steam Turbines, W. Peter, Brown Boveri *Review*, May–July, 1934; Influence of Lashing and Centrifugal Force on Turbine Blade Stresses, R. P. Kroon, *Trans.* A.S.M.E., APM–56–2, Mar. 1934; Design and Calculation of Steam Turbine Disc Wheels, I. Malkin, *Trans.* A.S.M.E., APM–56–8, Aug. 1934.

Compound Vibration.—While the critical speed can be calculated by the preceding formula, and the expected vibration will occur at that speed, it often is noted in practice that the turbine goes through several critical frequencies before reaching the calculated critical speed, due to the elastic scale of the foundations and the masses of the turbine parts. The foundation is subject to the periodic forces induced by the turbine speed, to the influence of the superimposed mass, and to the elasticity of the supports. If deflection in the supports is large, liability to vibration is increased. On the other hand, the steel columns supporting the unit may be too stiff. The completed unit, therefore, frequently is studied by a vibrometer, and adjustment made both in machine balance and in foundations to secure the desired quiet operation at normal speed.

DISC LOSSES.—Formulas for disc losses give conflicting values. Research has not definitely (1935) fixed these data. Several current formulas follow. Goudie (Steam Turbines, p. 529) gives the following formulas for disc and blade ventilation losses. Total disc friction in horsepower, $\text{Hp.}_d = 0.0607\, D_1^2\, (u_1/100)^3/v$. Total blade ventilation loss in horsepower for unenclosed idle blading, $\text{Hp.}_b = 0.458\, D_m\, (u_m/100)^3 \times (Bsl^{1.5}/v)$, where D_1 = diam. of disc, ft.; u_1 = peripheral speed of disc, ft. per sec.; v = specific volume of steam, cu. ft. per lb.; D_m = mean diameter of blade ring, ft.; u_m = peripheral speed of blades, ft. per sec.; l = blade length, in.; s = fraction of mean circumference not receiving steam from nozzles; B = a correction factor for the number of blade rows; $B = 1$ for single row, = 1.23 for 2-row, and 1.8 for 3-row wheels.

The detrimental effect of partial admission is diminished by placing a U-shaped ring in the casing which practically encloses the section of idle blades.

For enclosed blading, the loss, Hp._b is only 0.25 to 0.5 of the value as found above.

Stodola (Steam Turbines, p. 201) presents a later formula by Forner which gives lower losses than the above. This formula applies to an unenclosed wheel in an open casing with no steam admission, and for blade lengths from 0.4 to 4 in.

$$\text{Hp.}_r = 10^{-10} \beta D_m^4\, n^3\, l\, /v$$

where Hp._r = total friction loss in horsepower, other notation as in previous formula, except that $\beta = 0.83$ for discs with a single row, = 0.97 for 2-row, and = 1.32 for 3-row blades. With enclosed wheels between diaphragms of a multi-stage turbine, the loss is only $^1/_2$ to $^1/_4$ of the above amounts, being smaller the larger the disc diameter. Zietemann (Dampfturbinen, pp. 77–78) presents data from Brown Boveri and Co. that indicates still lower losses than either of the above formulas.

Stodola (The Efficiency of Reaction Blading, *Engg.*, Oct. 2, 1925) gives the following empirical formula for disc loss alone as $N_{kw} = 10^{-6} \times 0.256 \times d^{4.2}\, (n/1000)^{2.8}/v$, where N_{kw} = loss in kilowatts; d = diameter, in.; n = r.p.m.; v = specific volume of steam,

cu. ft. per lb. He states that this has been established by Brown Boveri and Co. and gives more accurate results than his earlier formulas.

F. Ribary, Brown Boveri *Review*, July, 1934, gives the following formula for the friction losses of an unenclosed disc:

where N_{kw} = friction loss, kw.; R_e = Reynolds number = Du/v; D = diameter, ft.; u = peripheral velocity, ft. per sec.; v = kinematic viscosity of the surrounding steam; γ = specific weight of surrounding steam, lb. per cu. ft.; g = gravity (32.2 at sea level).

Later designs embody elements for enclosure of idle blades and for reduction of clearances at side of discs to reduce pumping action in the surrounding steam. Even bolt heads are shielded.

Hodgkinson (Steam Turbines and Condensing Equipment, *Elec. Jour.*, Nov., 1924) calls attention to the displacement loss, which is the energy required in the case of idle blades in impulse turbines, to sweep out the inert steam from the blade passages when they come into the active arc of steam admission. This displacement loss for each nozzle group is $w_d = 8.5\, hbV_w/v$, where w_d = displacement loss, lb. of steam per hour; h = mean blade height, in.; b = blade width, in.; V_w = mean blade velocity, ft. per sec.; v = specific volume, cu. ft. per lb., corresponding to steam condition in impulse wheel chamber. Individual or group control of nozzles does not produce the gain in efficiency sometimes expected, on account of this displacement loss. The greater the arc occupied by the nozzles for a given steam flow, the smaller the blades will be, resulting in lower displacement and windage losses.

SHAFT DIAMETERS for impulse turbines are a compromise fixed by two considerations. To keep leakage low at the diaphragm labyrinths the diameter should be small. This results in a shaft lacking stiffness. Thermodynamic considerations thus require a small shaft, operating considerations a large shaft. Shaft sizes tend to larger diameters, favoring safe operation at some sacrifice of efficiency. With spherically-seated bearings, the maximum deflection of shafts carrying discs varies from 0.005 to 0.030 in. Shafts with solid bearings are stiffer, and have deflections only 50% of the above.

Kearton (Steam Turbines, p. 249) suggests the following formula for the first approximation of shaft diameter, $d = l\sqrt{ND/K}$, where d = mean diam. of middle portion of spindle, in.; l = span between bearing centers, in.; N = r.p.m.; D = average mean diam. of discs, in.; K = a constant; for land turbines K = 6,000,000 or above.

Rotors of Parsons turbines sometimes consist of solid shafts throughout, of solid shafts in the high-pressure section with rings or discs on the low-pressure end, of a hollow cylinder fastened rigidly to the spindle ends, or of other modified constructions. In Parsons turbines, with small radial clearances of blades a stiff shaft is required. With spherically-seated, self-adjusting bearings, the maximum deflection varies from 0.001 to 0.005 in. Hence, larger and stiffer shafts are used than with impulse turbines. When high mean blade speeds are necessary in the low-pressure section of a Parsons turbine, in order to handle economically the large volume of exhaust steam, discs of hyperbolic or conical cross-section, either integral with the spindle end or placed as rings on the shaft, are used. These discs carry from 1 to 7 rows of blading on their outer rims.

A bore hole concentric with the finished rotor, with a maximum eccentricity of about 0.02 in., is drilled through each large shaft for complete periscopic inspection of its interior structure. In heat treating, this hole assists attaining uniform heating and in relieving

In one design, solid discs are welded together at their peripheries, annealed to eliminate welding stresses, no through shaft being provided. The advantages claimed are: The stiff rotor runs far below its critical speed; the distribution of material is excellent; the spindle heats quickly and uniformly; the wheels cannot work loose; no keys or keyway are needed; the stresses are small; and the weight is low.

STRESSES IN DRUM ROTORS.—J. M. Newton in High Speed Steam Turbine Rotor Design and Construction, Junior Inst. of Engrs., 1910, gives methods of calculating stresses in drum rotors.

Goudie (Steam Turbines, p. 379) suggests the following method of calculating the stresses in drum rotors: Let f_t = total tangential stress at a given section in the drum, lb. per sq. in.; f_{t_1} = stress in the drum when there are no blades, lb. per sq. in.; f_{t_b} = additional stress due to blade load, lb. per sq. in.

Then $$f_t = f_{t_1} + f_{t_b} = \frac{\omega^2}{g}$$

where ω = angular velocity, radians per sec.; r = mean radius of the drum, in.; g = 32.2;

w = weight, lb. per cu. in., of the drum steel; w_b = weight of blading per ring, lb. per in. of circumference at radius r; P_a = axial pitch of blade rows, in.; d = equivalent thickness of rim, in., allowing for the blade groove; and

$$\left(\frac{f_t}{\omega^2 r^2} - \frac{w}{g}\right.$$

Let d_1 = actual thickness of drum, in.; d_2 = depth of groove, in.; b = width of groove,

Then $$P_a d = P_a d_1 - bd_2 \quad \text{and} \quad d_1 = d + bd_2/P_a.$$

The weight of the blading for Parsons turbines can be found by the following equation suggested by J. M. Newton:

where b = axial width of Parsons blade row, in.; l = length of blades from base of groove to tip, in.; α = a coefficient varying from 0.15 to 0.3; β = a coefficient varying from 0.06 to 0.11. This approximate formula, when the constants are known for the particular form of blading, saves the calculation of the weights of the blades themselves and also of the packing pieces.

Considerable judgment must be used in applying these formulas for drums, as several arbitrarily variable factors are involved. There also is considerable leeway in the choice of permissible stress f_t, which varies from low values up to about 18,000 lb. per sq. in. for mild steel, and 25,000 lb. per sq. in. for nickel-steel forgings as a maximum. Furthermore, the drum must be made of such thickness that no distortion is possible when caulking the blades. The minimum thickness at the high-pressure end of hollow drum spindles should not be less than 1 1/2 in. Rotors with blade ring construction have the additional stiffening effect of the radial pull in the web just as in a disc.

STEEL FOR DRUM ROTORS.—Certain parts of rotors may be subject to low wheel speeds and low temperatures. Low-carbon steel forgings, having the following properties, may be used for such purposes: Elastic limit, 22,000 to 25,000 lb. per sq. in.; ultimate strength, 65,000–70,000 lb. per sq. in.; elongation, 15 to 18%; reduction of area, 20 to 25%. This steel must be of the best quality with 0.50 to 0.60% Mn, 0.25% C, 0.25% Si, and not over 0.025% of S or P. The limiting stress at 20% overspeed should not exceed 20,000 lb. per sq. in., which gives 13,900 lb. per sq. in. stress at normal speed.

On account of the sensitivity of alloy steel to the effects of bad judgment in heat treatment, some builders prefer to use carbon steels for all rotor parts where the stresses will permit. One such steel contains 0.48% C, and has 85,000 lb. per sq. in. ultimate strength, and 45,000 lb. per sq. in. elastic limit.

Various alloy steels are used for rotor parts subject to high temperatures and to high stresses. These parts are often of 3 to 5% nickel-steel, and have the following properties: Elastic limit, 40,000 to 60,000 lb. per sq. in.; ultimate strength, 80,000 to 95,000 lb. per sq. in.; elongation, 20%; reduction of area, 35 to 40%. Such forgings are given an elaborate heat treatment to ensure relief from internal stress and to provide the desired properties. Nickel-molybdenum steel with 2.5% Ni and 0.2% Mo, 90,000 lb. per sq. in. ultimate strength, and 50,000 lb. per sq. in. elastic limit, and chrome-molybdenum steel with 0.6% Cr, 0.25% Mo, 100,000 lb. per sq. in. ultimate strength, and 60,000 lb. per sq. in. elastic limit, also are used for highly stressed drum rotor parts.

BLADE SPEEDS ON PARSONS ROTORS.—In order to pass the large volumes of steam in low-pressure stages, tip speeds of 1257 ft. per sec. and blade lengths of 40 in. have been used, resulting in a mean blade speed of about 920 ft. per sec. Early Parsons rotors consisted of a series of barrel-shaped cylinders of increasing diameters. Losses are reduced by making these rotors of conical shape with no abrupt changes in diameter. This conserves carry-over and reduces eddy losses. Small diameters are necessary at the high-pressure end, with blade speeds of 200 to 300 ft. per sec. in order to have as long blades as possible with the small volumes of high-pressure steam, and thus reduce blade tip leakage.

In the earlier drum arrangement a definite proportion of the total work was assigned to each drum. In modern (1935) designs with conical casings, each row of blades develops the work for which it is designed and which depends upon the ratio ρ of wheel to steam speed. In certain turbines, the small-diameter portion of the turbine with its many rows of blades has been replaced by a Curtis wheel, which gives a shorter and more compact turbine with lower steam pressures in the casing.

DYNAMIC BALANCE.—All rotors must be in dynamic balance to avoid excessive vibration at high speed. Lack of balance may be due to non-homogeneous disc or drum material, to slight eccentricity of the rotating masses, or to errors in workmanship. Static

balance first is obtained by mounting the shaft on carefully leveled knife edges and applying counterweights until it remains at rest in any position. Disc wheels are balanced similarly by mounting them on true arbors. For theory and description of unit, see A Statical Balancing Machine, E. H. Lamb, *Engg.*, May 27, 1932.

Static balance of the assembled shaft and its disc or drum is no assurance that it will be in good dynamic balance, as two heavy masses in the completed rotor may be so placed as to form a static couple. This will cause severe vibration at high speed, due to the dynamically unbalanced centrifugal forces resulting from these masses. They may be balanced by providing additional masses to set up an equal and opposite couple.

All manufacturing plants now have dynamic balancing machines in their plants where rotors, partly or completely assembled, can be quickly and accurately balanced. When it is necessary to balance a rotor in the field, it is run up to the operating speed, the high spot is marked and counterweights added by a cut-and-try method until balance is obtained. This operation is tedious and difficult, and final balance depends upon the skill and experience of the one who adjusts the balance weights. See section on Vibration.

CRITICAL SPEED.—As every horizontal rotor deflects somewhat under its own weight, it is never possible to have the center of mass and the true center line of the shaft coincide. As the rotor speeds up this eccentricity of mass results in an increasing centrifugal force tending to bend the shaft. Any slight unbalancing in the mass aggravates this condition. At a certain speed this unbalanced centrifugal force neutralizes the elasticity of the shaft which resists deflection. The shaft deflection progressively increases, and if unrestrained, failure would result. In an actual turbine the shaft will rub on the glands and blading before this happens, causing considerable damage. The speed causing indefinitely large deflection of the rotor for a small initial eccentricity is the *critical speed* of the shaft. If the speed is increased above the critical speed, the shaft begins to straighten and tends to revolve about its true center of mass. Operation may be very smooth under these conditions, although other critical speeds may be encountered at still higher speeds.

The calculation of critical speed is difficult, except in the simplest forms of shafts and wheels. Methods of finding critical speeds will be found in Stodola's Die Dampfturbinen; Morley's Strength of Materials; Goudie's Steam Turbines; Kearton's Steam Turbines; and in Calculation of Vibration and Whirling Speeds, by Professor A. Morley (*Engg.*, June 30, 1909). Some engineers use the following formula for a rough approximation:

$$\text{Critical speed, r.p.m.} = 188/\sqrt{y},$$

where y = maximum shaft deflection, in. The deflection y depends on bearing and coupling conditions being less with solid bearings and couplings than with flexible ones.

Some small turbines run at speeds above their critical speed. Hence, in starting they pass through this speed. To avoid serious deflections they are brought to speed quickly, thus passing through the critical speed so fast that no extreme vibration can occur. Running speeds in all machines are chosen about 30% above or below critical speed. If the critical speed figures out only slightly above running speed, the shaft is made larger and stiffer and the critical speed thereby raised.

Rotor shafts often are bent if a rub occurs from any cause. This is due to local overheating on the side that rubs. The resulting expansion merely makes the rub worse, and finally the overheating causes a permanent set in the shaft. Danger from rubs of such character is being removed by the use of thin metal labyrinth packings in diaphragm glands and the use of thin-tipped blades in Parsons blading.

7. TURBINE DETAILS

Thrust Bearings

There is little end thrust in impulse turbines. In small units, thrust bearings frequently consist of collars placed on the shaft on each side of one of the bearings.

Large turbines often are fitted with a marine type of thrust bearing comprising a series of collars turned on a sleeve keyed to the main shaft. These fit between stationary rings in a sleeve fastened to the pedestal. Each half of the thrust sleeve on Parsons turbines can be adjusted in opposite direction, so that the spindle can be set relatively to the stationary blades in both directions. Allowable pressures on these collar bearings should not exceed 50 to 60 lb. per sq. in. of bearing face. In certain impulse turbines, where the thrust is small, the thrust bearing rests in a spherical seat to provide flexibility in alignment.

Large impulse turbines are built with a moderately large single-thrust collar firmly fastened on the shaft. This revolves between two babbitt-faced bearing rings fitted with

liners in the bored casing and made in halves. The rings have large radial oil grooves with well-rounded edges to insure ample lubricating oil, which is furnished at the bore of the rings. Slight end play of 0.005 to 0.010 in. is permitted for the shaft. Emergency or squealer rings sometimes are fitted to warn the engineer when the thrust surfaces have worn a certain amount, usually 50% of the clearance of the first-stage wheel. Ball bearings are used as thrust bearings on some small turbines.

Thrust collars and bearings are provided on some generator rotors which are connected to the turbine by a flexible coupling. These thrust bearings always should be provided if the generator is to operate uncoupled as a synchronous condenser.

KINGSBURY THRUST BEARINGS.—Reynolds' theory of lubrication has been applied to thrust bearings by Albert Kingsbury in America, and A. G. M. Michell in England, and their names designate forms of bearings widely used by turbine builders.

See Vol. 3 for detailed data upon Kingsbury thrust bearings. The Kingsbury bearing for steam turbines usually is designed to carry a load of 250 to 425 lb. per sq. in. to allow for dirty or worn oil and to provide a wide margin of safety. Under ideal conditions it could carry 3000 lb. per sq. in. In the fixed type of thrust bearing, liners are placed between the thrust bearing cage and the pedestal to fix the spindle position in the turbine. The bearing sometimes is mounted in a cage which can be adjusted axially to properly locate the moving blades relative to the casing.

The mean speed on Kingsbury thrust blocks may be as high as 215 ft. per sec. However, to keep the diameter small, lower speeds generally are used. Ample quantities of oil at low velocities must be supplied.

Couplings

Solid couplings are used on some turbines. These stiffen the shafts of both turbine and generator but require careful alignment. Spacer rings are provided in solid couplings to permit the spindle to be lifted out for inspection and to allow the generator to operate as a synchronous condenser. The claw type, which has a certain amount of flexibility, consists of two halves, each in two parts. The inner sleeve, keyed to the shaft, has jaws on the outer flange. The outer sleeve has a plain flange to bolt to the other outer sleeve on the other shaft. A set of claws, cut on the other end of the outer sleeve, fits into the jaws of the fixed sleeve. The two halves of the coupling are held together by fitted bolts. Lubrication of the bearing surfaces of the jaws is usually insured by an oil catcher and holes through the jaws to the bearing faces. Hardened steel plates are used on the jaw wearing surfaces.

The Westinghouse coupling has the two inner and outer sleeves, but instead of claws, the machine end of the outer sleeve has a flange carrying hardened steel pins projecting axially into bronze-lined holes in the flange of the inner sleeve. This forms a pin drive coupling instead of the claw form.

Both claw and pin couplings are subject to wear that results from slight mis-alignment or unbalance in the coupling and which cannot be entirely overcome by lubrication.

A second type of pin-type coupling used on several turbines consists of two standard flange couplings, each fastened to its respective shaft. Steel pins, firmly fastened to one half-coupling, project into holes in the other half-coupling where it carries a rubber bushing, brass-lined, bearing against the inner face of the bored-out hole.

The Fast flexible coupling comprises two hubs, each keyed to its respective shaft. Each hub has external spur teeth cut on it, at the maximum distance possible from the shaft end of the hub. A sleeve surrounding these hubs is flanged and split vertically at its center for disconnecting the two shafts. The two halves are bolted together through the flanges. Each half of the sleeve has internal spur teeth cut on its bore at its outside end, which engage the external teeth of the hub. The sleeve is carried at each end by an oil-tight supporting ring. The error in alignment of the two shafts can be about 10 times the clearance between the external and internal teeth, which are in an oil bath when in operation. The Fast coupling has proved very satisfactory where expansion from heat, as on turbo-drives for auxiliary equipment, makes it difficult to maintain correct alignment. It is now used with certain modifications on many small and large turbines.

Various plans for securing true alignment include leveling pads on the bed-plates, squaring and leveling coupling faces, stretching piano wire over the centers and checking up, and the use of surface gages. Allowance must be made in non-condensing units for expansion above the bed-plate on heating up. On some turbines the outer end of the machine is raised slightly to make the coupling faces come square after allowing for the natural deflection of the heavy rotating field.

Turbines may be thrown out of alignment by pipe strains. Piping must have bends so arranged that no strains are transmitted to the turbine casing. All base plates have a certain amount of deformation when stress is applied. Hence reliance cannot be placed on these to take all pipe strains without affecting the turbine. Spindle jacking gear,

operated by oil, is incorporated in the coupling design of large units for turning the spindle during erection or overhaul.

Dummy Pistons

TYPES OF DUMMY PISTONS.—Balance, or dummy, pistons are used on Parsons turbines to equalize the end thrust towards the exhaust due to difference of pressure between the inlet and outlet of each row of moving blades and also to the unbalanced pressure on the annular surfaces when the drum is stepped-up in size. In some turbines, there is a balance piston for each diameter of blade drum on the spindle; three is the usual number. Pipes fitted outside of the casing connect with the corresponding blade section, and provide the equalizing pressure. Using three balance pistons increases the overall spindle length, and requires an irregular cylinder construction to care for the large low-pressure balance piston on large machines. Such cylinders may distort under sudden temperature changes, due to variation in load. In some turbines, the low-pressure balance piston is in the exhaust. The webs carrying the blade rings of the last drum have steam equalizing holes. Dummies on this piston have radial clearance only. On some designs, a single balanced piston of small diameter is used with high-pressure steam on one side and low-pressure steam or vacuum on the other. Any unbalanced thrust is taken by the Kingsbury bearing.

Balance pistons with axial clearance consist of a steel ring, pressed or keyed to the spindle, with a number of rectangular grooves or teeth cut in its outer face. The stationary dummy section is either integral with the casing, or consists of a cast-iron ring fastened to the casing. Dummy strips of brass, bronze, manganese-copper, nickel, cupro-nickel or Monel metal are caulked in grooves in this ring, and project into grooves on the balance piston, forming a labyrinth packing. Dummy strips are cut and fitted in sections approximately 1 in. long. Small clearances between the side of the groove and a projecting sharp edge of the dummy are adjusted by the thrust blocks. More recent forms (1935) of dummy packing have several axial knife-edge projections instead of one, thereby increasing the number of throttlings in the dummy piston. Experimental data are used as a basis for calculating losses from such dummies. Dummies must provide space between throttling points to act as expansion chambers, must dissipate heat readily should contact occur, and one material must wear away rapidly with little heat generation. With radial clearances, dummies frequently consist of plain radial strips alternately deep and shallow, sealing against alternately low and high lands on the spindle dummy piston. Radial dummies depend on throttling through the small radial clearance at the tips of the projecting teeth for reducing the leakage. Ljungstrom turbines have a dummy using a thin nickel-steel ribbon, which provides fine radial clearance. Sealing strips of nickel ribbon, chromium stainless steel and other alloys are used.

AREA OF DUMMY PISTONS.—Goudie (Steam Turbines) says that the dynamic thrust on the blades in an axial direction is usually less than 1% and never exceeds 2% of the total thrust in Parsons turbines, and may be neglected. For the annular area A_d of the balance piston for each cylinder of Parsons blading, he gives on p. 424, the formula

$$A_d = \frac{P_2 A_1}{P_1 - P_c} + \frac{\Sigma(P_i - P_o)a}{2(P_1 - P_c)}$$

where P_1 = pressure on front of dummy; P_2 = difference of pressure on any annular drum area A_1; A_1 = annular area of any step-up in drum at entrance; P_c = condenser or back pressure; $(P_i - P_o)$ = drop in pressure in a group of blades of constant mean diameter; a = annular area between drum and casing at a group of blades; pressures are lb. per sq. in., absolute; areas are in sq. in.

LEAKAGE OF STEAM THROUGH DUMMY PISTONS.—H. M. Martin (*Engg.*, Jan. 10, 1908, and Jan. 3, 1919) discusses the leakage of steam through dummy pistons and submits a formula which is claimed to check within 1% of the actual loss. From this the following equation is derived:

$$W = 0.4722A\sqrt{\quad} \times \frac{1}{N + \log_e r}$$

where W = steam leakage, lb. per second, through whole dummy; A = area available for flow of steam at any dummy constriction, sq. in.; P_1 = initial pressure, lb. per sq. in.; v_s = specific volume of steam at pressure P_1, cu. ft. per lb.; N = number of rings or constrictions in the dummy; r = ratio of initial to absolute final pressure over the dummy $= P_1/P_2$, where P_2 is the pressure on the rear side of the piston, lb. per sq. in., absolute.

Goudie (Steam Turbines, p. 512) reduces the results of several formulas for balance pistons and dummies to a series of curves and an alignment chart which makes the solution of the problem comparatively simple.

To determine the number of rings required at each piston, Morrow, in Steam Turbines, suggests the empirical equation,

$$N = (40P_1 - 2600W/A) \div \{540\,(W/A) - P_1\},$$

where N = number of dummies in piston; P_1 = steam pressure before piston, lb. per sq. in., absolute; W = permissible leakage of steam, lb. per sec.; A = annular area of clearance through dummy, sq. in.

Naylor (Steam Turbines, p. 99) gives for leakage through Ljungstrom disc packing

$$w = 0.4722 \cdot \qquad \frac{p_1}{v} \times$$

where A_1 = first ring leakage area, sq. in.; A_n = last ring leakage area, sq. in.; $\beta = A_1/A_n$. (It is assumed that the diameters of the labyrinth rings increase in arithmetical progression); w = steam leakage, lb. per sec.; p_1 = pressure before packing, lb. per sq. in., abs.; v_1 = specific volume at condition p_1, cu. ft. per lb.; N = number of dummy strips or throttlings; p_o = exhaust pressure, lb. per sq. in. abs., and $r = p_1/p_o$.

CLEARANCE OF DUMMIES.—Radial dummies must be used where the balance piston is distant from the thrust, and considerable expansion can occur. Side-contact dummies are ground to fit by revolving the spindle slowly and drawing up on the thrust until contact occurs. They are afterwards set, when thoroughly heated, by drawing up on the thrust, the spindle revolving very slowly, until first contact is heard by listening on the casing. The thrust then is moved over to obtain the desired running clearance, which varies from 0.004 in. on small Parsons turbines, up to 0.012 to 0.015 on large turbines. Balance pistons near the middle of the spindle require somewhat larger clearance. When finally set, all thrust blocks are locked after allowing sufficient end play for lubrication. This adjustment should be checked periodically to detect wear in the thrust collars due to clogged oil supply or dirty oil. Radial dummies are given a clearance of 0.010 to 0.025 in.

Labyrinth Glands

Glands must be provided in all turbines where the shaft leaves the casing. Impulse turbines also require glands where the diaphragms between stages encircle the shaft. The following glands are used: Carbon rings, dummy pistons, labyrinth teeth, water glands, water glands combined with some form of labyrinth.

Carbon Ring Glands comprise several carbon rings, each in its own compartment of a cast-iron or steel case. The several segments of the ring are pressed together by a garter spring or an arched flat spring. The rings usually are divided into three or four segments. Clearances on the shaft diameter are from line-to-line, to approximately 0.006 in., depending on the size of shaft.

Dummy Piston Glands are used in certain Parsons turbines.

LABYRINTH GLANDS for diaphragms consist of cut teeth projecting from the shaft toward a smooth stationary casing, from the casing toward the shaft, or from both with the teeth alternating similar to radial clearance dummy pistons. The ends of these teeth are knife-edged, and usually no clearance is allowed in design. The turbine is turned over slowly when first assembled, and a clearance of about 0.005 in. is worn on the sharp ends of the teeth. The gland loss varies approximately in the inverse ratio to the square root of the number of constrictions. The object of these constrictions is to throttle the steam into a larger space where it forms eddies and thus restricts flow. Gland strips with "pine-tree," comb, and other forms of fingers are used. Where impulse blading is placed upon drums, labyrinth packing has been put upon the blade ends. Metal ribbon teeth also have been used in such glands.

The high-pressure labyrinth gland, where the spindle leaves the casing, can be made in two sections. The longer inner part seals against the internal pressure, the outer part against atmosphere. Steam is withdrawn from or supplied to the gland at this middle point. Steam above atmospheric pressure must be supplied at the intermediate point in the exhaust-end gland to seal it against air leakage, which would tend to destroy the vacuum. The high-pressure gland leakage either is used in this low-pressure gland, or led to an intermediate stage, continuing its expansion in the turbine. Provision usually is made to admit live steam to both low-pressure and high-pressure glands to seal them on starting. The clearance between the teeth of these glands and the shaft or casing is usually from 0.005 to 0.008 in. Materials used for labyrinth glands are babbitt, aluminum, brass, and bronze, and for high temperatures, stainless or other alloy steels.

Later designs of labyrinth glands are planned so that any rubbing causes the parts automatically to separate. Glands made of packing rings of anti-friction metal are used on some small turbines which hardly warrant the expense of a more elaborate type.

WATER GLANDS where the spindle leaves the casing, consist of a small impeller or paddle wheel, fastened to a long sleeve or hub on the shaft, which revolves in a gland casing. This gland is supplied with water under a pressure of 10 to 15 lb. per sq. in. The water is unable to leak along the shaft, as the action of the impeller holds it in a solid ring against the outer casing. On the other hand, air cannot leak into the turbine because of this solid ring of water under pressure much greater than atmosphere. Several forms of combined water and labyrinth glands can be steam sealed when the turbines are run at speeds too low to maintain the water-gland seal. The governor may regulate the supply of water or steam to the glands. Proper leak-off passages are provided for steam and water.

Water glands generally are used outside of the labyrinth glands on high-pressure ends of impulse turbines, to prevent steam leakage into the turbine room, which leads to sweating troubles in winter. On account of the high temperature at this gland, condensate must be circulated through it, discharging into the feed system.

Any water free from acids or scale-forming impurities may be used in the glands. Condensate from the hotwell pump generally is used for this purpose.

Power Required by Water Gland.—Guy and Jones (Metropolitan-Vickers Rateau Marine Turbine, *Engg.*, Feb. 9, 1923) state that experiments indicate that the power required by a water gland with the paddle completely immersed in water is $P = 6\ u^3D^2/10^6$, where P = horsepower required; u = peripheral velocity of paddle wheel, ft. per sec.; D = diameter of paddle wheel, ft. Under actual operating conditions the paddle is not fully immersed on both sides and tests indicate that the power required is about 50% of that given by the formula.

The water required by water-glands varies from 0.5% to 2% of the condensate, but little of this is lost, since at the low-pressure end the vapor from the gland enters the exhaust and is recovered in the condenser. At high-pressure glands, the water must circulate, and the heat it absorbs can be fully recovered. Water glands usually seal above $^1/_3$ to $^1/_2$ of normal speed.

Steam Required by Casing Glands can be estimated by considering the small clearances at the ends of the teeth as equivalent nozzle area, and applying the following nozzle formulas. Since the pressure drop in both high- and low-pressure shaft glands is less than critical pressure, Goudie (Steam Turbines, p. 497) gives

$$W = 0.3155A\sqrt{P_1/v_s}\ \text{lb. per sec. for superheated steam;}$$

$$W = 0.0173AP_1^{0.96875}\ \text{lb. per sec., for dry or slightly wet steam,}$$

where A = average annular clearance area, sq. in., over the teeth of the gland; P_1 = initial pressure, lb. per sq. in., absolute (at turbine side on high-pressure end, and from steam supply line at low-pressure end); v_s = specific volume of superheated steam in cu. ft. per lb. at pressure P_1.

Leakage of diaphragm glands depends on the number of stages. If few are used, the pressure difference across the gland will exceed the critical ratio and the above equations can be used. Leakage decreases toward the exhaust end. The pressure drop across the diaphragm is frequently less than the critical ratio. Goudie (Steam Turbines, pp. 523–4) suggests that this be calculated by first finding the allowable heat drop $(h_1 - h_2)$ from adiabatic expansion between these two pressures, assuming a nozzle efficiency of 85%, and calculating the resultant velocity, in ft. per sec., from the formula,

$$V = 223.7\sqrt{0.85(h_1 - h_2)}.$$

The leakage, in lb. per sec., is $w = AV/v$, where A = average clearance area through the gland, sq. ft.; v = specific volume of steam after expansion, cu. ft. A chart to solve problems in labyrinth packing is presented in *Engg.*, vol. 128, p. 65, 1929.

Bearings

Turbine bearings may be divided into two classes: Self-oiling, and forced lubrication. Self-oiling bearings are used only on small turbines and generally consist of babbitt-lined cast-iron shells, with oil supplied by oil rings revolved by the shaft. Bearings for large units and for reduction gears always have forced lubrication from the main oiling system.

Large turbines may have spherically-seated, self-aligning bearings. In Parsons turbines, the spherical seats take the form of four pads under which are placed steel adjusting shims of varying thickness. Clearances at the ends of the blades can be equalized by changing the shims and thus shifting the position of the shaft relative to the casing.

As impulse turbines do not require close clearances over the ends of the blades, their bearings have plain spherical seats. When light shafts are used in some forms of impulse turbines, it is desirable to decrease the deflection and increase the critical speed, by using solid parallel bearings. Such bearings also are used for reduction gearing where accurate alignment is essential.

Large bearings consist of cast-iron shells split in half horizontally and lined with white metal. They are relieved for 30° at the sides above and below the joint, except for $^3/_4$ in. at each end, by re-boring slightly oversize with a separating plate between the halves. The lower halves are scraped to fit the journal for an arc of 120° at the bottom. Bearings usually are bored 0.002 to 0.003 in. large per inch diameter of journal. With forced lubrication, oil usually is supplied both at the top and sides of the bearings. Oil throwers either are turned on the shaft, or attached to it at the outer end of the bearing, to prevent escape of oil. Oil guards are provided on the bearing cover for the same purpose. Provision is made for the escape of entrained air from the bearing pedestals.

The design of the spindle usually fixes the size of the bearing. The rubbing velocity of the journal should not exceed 150 ft. per sec. The bearing pressure is found by dividing the total load on the bearing by the product of its length and diameter. A safe limit of this pressure is 135 lb. per sq. in. The maximum limits reached have been 195 ft. per sec. velocity and 175 lb. per sq. in. pressure. The ratio of bearing length to diameter varies from 1 to 2.5. Bearings are made shorter than formerly, as this reduces the total length of the turbine. The design should be such as to reduce spattering and splashing of oil, which leads to oxidation troubles and acid formation.

Bearings on some small turbines are so located that they are heated by conduction through the casings and through the shaft. Such bearings may heat to 250° F. and a heavy oil is required. Usual bearing temperatures range from 125° F. to 150° F. with occasional cases where the oil leaves at 175°. See Hodgkinson, Journal Bearing Practice, *Proc.* Inst. Mech., Engrs., 1929.

Bearings depend for their proper functioning upon the supply of a thick wedge-shaped oil film on the side of the bearing where the shaft turns downward. This film spreads out fan-like and maintains a separation of the two metal surfaces. There is no true coefficient of friction, but the shearing action of the oil offers a resistance to motion which is the so-called coefficient of friction. Kraft (The Modern Steam Turbine) states that this factor is 0.008 for a bearing of good workmanship. The heat, B.t.u. per min., generated in a bearing, $H = (\pi dN\mu W)/(12 \times 778)$, where d = bearing diam., in.; N = r.p.m.; μ = so-called mean coefficient of friction between journal and bearing; W = total load on the bearing, lb.

After analyzing the data of Lasche, Kearton (Steam Turbines, p. 191) presents the following formula for the heat generated in the bearing, in B.t.u. per min.

$$H = (1.72\, ld^2N)/\{100\ (t - 32)\},$$

where l = length of bearing, in.; d = diameter of bearing, in.; N = r.p.m.; t = temperature of bearing, deg. F. This formula indicates that the friction loss decreases as operating temperature of the bearing increases, which is in accord with practical experience.

The Oil Required Per Bearing can be estimated by the following formula, also from Kearton (p. 192): $G = 0.00206ld^2N/\{s\delta(t - t_s)(t - 32)\}$, where G = U. S. gal. per min.; l = length of bearing, in.; d = diam., in.; s = specific heat of the lubricating oil (about 0.45); δ = specific gravity of the lubricating oil at the working temperature (about 0.86); t = maximum oil temperature deg. F.; t_s = oil supply temperature to the bearing. $(t - t_s)$ usually may be assumed to be 20° F., although a greater temperature rise is allowed on some turbines.

Hot Turbine Bearings may be caused by insufficient oil, due to plugged-up oil pipes or oil grooves, or by failure of the supply. Sometimes bearing clearances are insufficient to admit the proper amount of oil, particularly at the sides of the bearings. Heating also may be due to too heavy an oil, to emulsified oil, or to old used-up oil. The true cause of the heating should be found and corrected at once, as no chances should be taken with bearings.

8. REDUCTION GEARING

See Section on Machine Design for design of reduction gearing. Also Section on Marine Engineering for marine applications.

The Efficiency of Reduction Gears is difficult to determine by mechanical methods. A common method of calculating gearing efficiency is to measure the friction heat carried away by the lubricating oil and to allow for radiation from the gear casing. Carefully made laboratory tests by both input and output measurements, and by heat measurement on single-reduction gears, show practically the same losses. Large single-reduction gears have shown efficiencies of 98 to 99%. The efficiency of small single-reduction gear sets ranges from 96 to 98%. Double-reduction gearing has given efficiencies varying from 88 to 97% on test.

9. TURBINE LUBRICATION

Oiling Systems

Small turbines provided with ring-oiled bearings require merely the maintenance of a suitable supply of pure mineral oil, changed at frequent intervals, in the reservoir below the bearings. The outer surfaces of the pedestals dissipate the heat generated by friction.

Large turbines have a complete self-contained oiling system, which consists of fine wire screens (35 to 60 mesh) to remove coarse particles, an oil pump, an oil cooler, and suitable piping systems.

The Oil Pump is driven by gearing from the main turbine shaft, or if reduction gearing is used, sometimes from the slower speed shaft. The pump, usually of the rotary gear type, supplies oil on occasion at 100 lb. per sq. in. pressure when used in an oil relay. The volumetric efficiency of gear-type pumps ranges from 70 to 80% with hot oil. Oil pressures to the bearings range from 2 lb. to 5 lb. per sq. in., depending on the type of turbine.

An Auxiliary Turbine-driven Centrifugal Oil Pump is placed on medium size and large turbines to circulate oil through the bearings before starting the unit.

On large units, a second pump may furnish oil under the bearings at 600 to 1000 lb. per sq. in. pressure, to lift the bearings and form an oil film on starting the unit after a shut-down. On some units, this is a multi-plunger reciprocating pump with a plunger and piping for each bearing.

Oil Coolers are built in many forms with brass or copper cooling coils. These coolers should be readily accessible for cleaning if raw water is used. Frequently, condensate forms the cooling medium, in which case less cleaning is necessary. The cooler surface is proportioned for the desired oil temperatures and the available cooling water. Usually the oil is circulated through the tubes. According to Stodola, the heat transfer coefficient in oil coolers is low, varying from 10 to 20 B.t.u. per sq. ft. per hr. per deg. F. temperature difference. Coolers lower the oil temperature about 20 to 30° F. Oil should pass to the bearings at temperatures between 105° F. and 140° F. Temperatures leaving the bearings range from 130° to 160° F. It is frequently specified that sufficient oil cooler capacity shall be installed to keep the maximum temperature of the oil below 150° F. when using cooling water at the maximum temperature specified by the purchaser for summer conditions.

Oil Pump Capacity is fixed by the total amount of oil required by the bearings and thrust and the amount needed by governing and overspeed gear, together with a liberal additional amount to provide for pump slip, air vents, etc. Each manufacturer has developed his own standards for oil pump capacity.

The oil pump capacities furnished by one builder for 3600 r.p.m. units varies from 33 gal. per min. on 1000-kw. units to 75 gal. per min. on 6000-kw. turbines. On 1800-r.p.m. units the capacities range from 115 gal. per min. on 10,000-kw. units to 400 gal. per min. on 60,000-kw. turbines.

Oil Reservoirs vary in size with the different turbines and with the several manufacturers. A frequent requirement for units of 5000 kw. and over is that the capacity of the oil reservoir at the turbine shall be such that it will take not less than 10 min. to circulate a quantity of oil equal to the tank capacity. With smaller turbines the period for complete circulation shall not be less than 5 min. Special precautions must be taken to minimize the danger of fires in oil reservoirs. Emergency drain lines to reservoirs, CO_2 and other non-inflammable flooding equipment, and location of the reservoir in a fireproof room below the turbine, now are used.

OIL PIPING.—Seamless copper, with brazed flanges and cast iron or brass fittings, has been used for oil piping. As this is expensive, brass pipe, with screwed fittings, is used. Steel piping and steel tubing also have been used with welded nipples for branches and joints. This material should be well pickled before assembly to remove mill scale and rust. The threads are made tight against oil pressure by shellac or similar material. Only gate valves should be used on oil lines.

Following are recommendations (Station Piping, Edison Elect. Inst., Aug. 1933) for the

enclose sufficiently so that it is not used as a ladder or for hanging things upon. Design with good supports and as nearly free from stress as possible.

Main oil lines should be of standard weight pipe, or seamless tubing of equal wall thickness, with extra heavy steel flanges and steel fittings; use welds as extensively as possible. Erect barriers around all oil joints when these must be used. Weld all threaded joints. Provide lock washers on all flange bolts. Male and female flange joints are preferred. Use metal-to-metal unions.

No connections should be made with less than 1/2-in. pipe size, with shut-off valves as close as

possible to the main pipe. Screen reservoir vents, and locate them at a distance from the steam lines. Reservoir covers should be self-closing.

Avoid gage glasses and use a mechanical indicator for oil level. Nipples for pressure gages must have restricted openings.

Keep oil system, particularly oil storage or reservoir, as remote as possible from high temperature steam connections.

Lubricating Oils

LUBRICATING OIL FOR TURBINES must be a properly refined, highly filtered, pure mineral oil, free from alkali or acid. While organic acids form from oxidation of unsaturated compounds or those containing sulphur, oxygen, or nitrogen, in the presence of water during use, that oil should be chosen which has the lowest organic acidity, not only when fresh but also after continued use. Organic acidity expressed as the amount of potassium hydroxide required to neutralize 1 gram of oil, should not exceed 0.07 mg.

Oil should be able to separate rapidly from water and not form emulsions; if these are formed they should be quickly separated on heating. Oil must be free from components of low boiling point, in order to maintain constant viscosity. It should have little tendency to break down and form sludge, when agitated at the actual operating temperature and mixed with air and water. The ideal lubricating oil should have maximum adhesion and minimum cohesion. Some operators of large turbines use an oil of as low as 100 sec. Saybolt at 100° F., claiming thereby to materially reduce friction losses. Color is of slight, if any, value in judging a lubricating oil, as the manufacturer can adjust color at will.

Foaming Oil may be caused by water in the system or may be due to air entering through leaks in the oil pump suction piping or strainer. Air also may be forced into bearing pedestals by the ventilating system of the generator. Foaming can be corrected by removing the water and preventing the entrance of the air.

Oils Which Tend to Decompose and age rapidly in service will deposit a hydrocarbon sludge in bearings, piping and oil cooler. Besides plugging passages in bearings, thrusts and couplings, it forms an insulation on the cooling coils. Higher oil temperatures result, causing still more rapid aging. Such oils should be removed and filtered, the system thoroughly cleaned and new, higher-grade oil purchased. Cotton waste must not be used to clean the oil system, as lint is left behind to cause trouble later by stopping up the oil passages. Good practice requires the oil to be drawn from turbines in operation every six weeks or two months and replaced with fresh filtered oil.

Reduction Gears have higher tooth pressures per sq. in. than the usual bearing pressures, and require a heavier oil than bearings. In some cases, these gears have their own oiling systems, using a heavy oil. When both gears and turbine bearings are on the same system, either a medium or a heavy oil may be used. Hot oil may be supplied to the turbine bearings and only the gear supply circulated through the oil cooler.

FILTRATION AND PURIFICATION OF OILS are necessary with moderate and large-size turbines. This usually is done in one of the following ways: 1. Continuous by-pass system. 2. Batch system. 3. Continuous by-pass batch system.

The continuous by-pass system continuously takes out a certain amount of oil for treatment. The batch system takes out a large amount at periods. The continuous by-pass batch is a combination of the other two methods. Separation of water and sludge may be secured by: *a*, Passing through a centrifugal separator or filter such as the DeLaval, Sharples, and others, which separate the substances on the basis of their specific gravities. This removes water and dirt, but not alkalies and acids nor soluble sludge. *b*, Bag filters, which remove insoluble sludge, but will not remove acids nor soluble sludge. *c*, Separating tanks, in which the oil is cooled and where water and sludge can settle out and be withdrawn. Much soluble sludge separates out when cooled. Usually oil reservoirs in the turbines are provided with piping which allows any water that gets into the oil to overflow automatically when it settles in the reservoir. See Lubrication (N.E.L.A., 1922–23–24).

Commercial turbine oils are available from a large number of refiners. Manufacturers in some cases offer to the purchaser a list of turbine oils that have proved satisfactory in the past, and from these a suitable oil generally can be selected. Non-inflammable fluids for lubricating systems are being tried (1935) to lessen danger from oil fires.

CHARACTERISTICS OF OIL.—Oil must be free from tarry, slimy or saponifiable matter, and also from soaps or other materials added to give body to the oil. It should contain no dirt, grit or other suspended matter. The specific gravity should be between 0.86 and 0.88 at 60° F.; flash point, not below 334° F.; fire test, 375° F. Acids can be detected by blue litmus, which turns red in the presence of acids. Animal and vegetable oils, used as adulterants, can be detected by a milk-white emulsion which forms when the oil is shaken with a strong solution of borax. After standing in a cool place the

clear mineral oil will be at the top, the borax solution at the bottom, and the emulsion in between.

Sludge in oil is highly undesirable. It plugs piping, coats oil cooler tubes and causes hot bearings by reducing the lubricating value of the oil. Sludge forms as a result of agitation of impure oil in the presence of water and air. To test the sludging properties of oils, a sludge accelerator has been developed which produces sludge in 1% of the time in actual service. For a description of this equipment and information on its use, see Lubrication (N.E.L.A., 1924). This report also contains detailed instructions for making flash, fire, viscosity, pour, total acidity, alkalinity, corrosion, carbonization, and demulsibility tests on lubricating oils.

VISCOSITY.—The viscosity is fixed by the oiling system of the turbine and the temperature conditions. Oils of the following Saybolt viscosities, all at 100° F., have given satisfaction:

Ring-oiled bearings with or without water jackets	150–200 sec.
Ring-oiled bearings, subjected to extreme radiated heat	300–500 sec.
Circulating systems, ordinary conditions	140–200 sec.
Circulating systems, with reduction gears	250–350 sec.

For specifications for steam turbine oils see Lubrication (N.E.L.A., 1922).

10. GOVERNORS

Turbines may be governed by throttling or by nozzle control. In *throttling governing*, the steam is throttled to some pressure lower than steam line pressure, at which lower pressure the heat available for work is sufficient to maintain the load. In *nozzle governing*, a series of valves are provided which admit steam under control of the governor to each valve in series as the load increases. The only valve under throttling action is the last one being opened; the others operate at full steam line pressure.

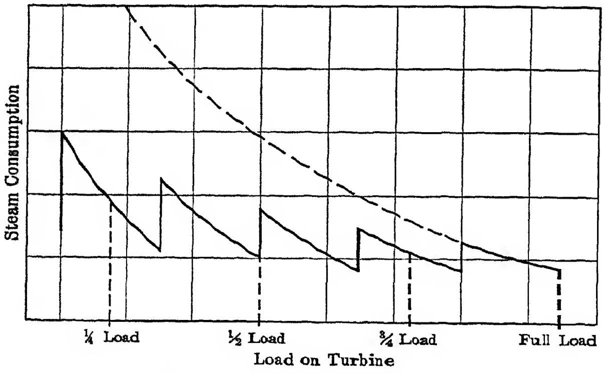

Fig. 29. Effect of Nozzle Governing on Steam Consumption

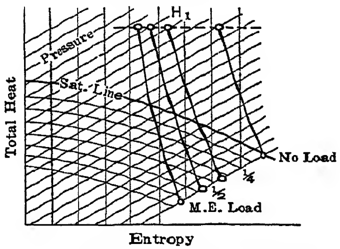
Theoretically, nozzle governing should be the more efficient, and in practice this is evident on small single-stage turbines. The water rate curve on such a nozzle-governed turbine is shown in Fig. 29. The solid line shows steam consumption with nozzles cut out consecutively, while the dotted line shows probable steam consumption with throttle governing. On large units, these theoretical gains are offset somewhat by idle blade losses, and in multi-stage units by the fact that the pressure drop in the first stage becomes excessive at light loads, leading to serious under-expansion and high nozzle and blade losses. Some builders have overcome this by providing two sets of nozzles, one for light load only, and the second for heavy loads, at which time the light load nozzles are cut out by suitable change-over devices in the governing system.

Throttle Governing is used on turbines having full peripheral admission, as on Parsons and some multi-stage impulse turbines. The water-rate curve with throttle governing can be made to simulate that of nozzle governing by selecting a *Most Efficient Load* at a relatively low percent of rating and by providing for the additional capacity by secondary,

tertiary, and even quaternary valves admitting steam to lower stages of the turbine.

Christie and Colburn (Turbines, Prime-movers Comm. Report, N.E.L.A., 1932) point out that the type of governing has a serious effect upon end-point conditions, and upon quality in the last stages under light load conditions. Figs. 30 and 31 show condition curves with the two types of governing.



30. Effect of Throttle Governing on Condition Curve

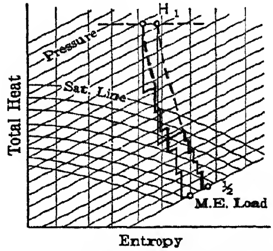


Fig. 31. Effect of Nozzle Governing on Condition Curve (1/2-load curve is displaced to right and should be superimposed on M.E. curve)

According to Podnossoff, on reduction of load with throttle governing, more operate in regions of increased superheat or quality, whereas with nozzle control, at the same reduced steam flow, more stages are transferred to lower temperatures and quality in the wet steam regions. This is evident from a study of Figs. 30 and 31. Such considerations are of commercial significance in the operation of high- and low-pressure turbines in series with a reheater between, and also in connection with blade erosion in single-cylinder turbines which operate for long periods at light loads.

Governors for Small Turbines.—The speed of most small turbines is controlled by a powerful centrifugal governor mounted directly on the end of the rotor shaft. Movements of the governor spindle are transmitted through a single lever to the regulating throttle valve which is usually a poppet valve. The governor weights are carried on levers by tool-steel knife edges in tool steel bearings requiring no lubrication. In some types, ball bearings are used instead of knife edges. One type has weights which roll on flat tempered steel springs with no pins, bushings, bearings or knife edges. Sometimes the lever connecting the governor spindle to the regulating valve also is provided with knife edges. These governors must be examined frequently to see that no parts are loose or worn. Some designs use a ball-and-socket, or similar connection, to the regulating valve lever. This connection must be well lubricated, and lost motion taken up when wear occurs. Fig. 32 is such a governor for a small Sturtevant turbine. Other companies use similar direct-connected governors. Speed regulation of these governors is about 2% above and below normal.

In several designs of small geared turbines the governor either is mounted on the slow-speed gear shaft or, in other designs, is geared from it. These governors, revolving at comparatively low speeds, are heavier and more powerful than when directly mounted on the high-speed shaft.

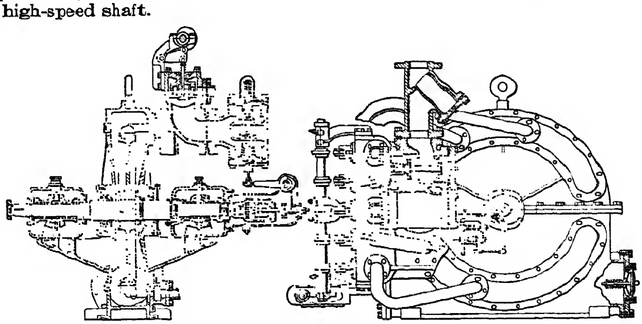

Fig. 32. Section of Small Sturtevant Turbine

Care must be taken that all levers always are free, and that stuffing-boxes on the regulating valves are not screwed too tight. Wear in collars of some types of governor must be taken up periodically if good regulation is to be maintained.

Governors for Large Condensing Turbines.—Condensing turbines may use governors of the centrifugal, fly-ball, or inertia types, geared from the turbine spindle. The oil pump often is placed at the lower end of the governor spindle and driven through the same gears. Regulation is obtained by some form of oil relay. Oil at from 25 to 100 lb. pressure is led from the oil supply system to a small relay valve, controlled by the governor. This compensated relay valve admits oil above or below a piston directly connected to the regulating valve, or controlling the admission valves through a proper mechanism. It often is provided with a device to open the secondary overload valve when the primary valve has lifted a certain distance. The relay on some machines oscillates, so that the valves are always in action.

On some turbines, the motion of the oil piston is transmitted by levers or by rack and pinion to a cam shaft which opens in succession a series of spring-loaded valves. Each valve admits steam to one or to a group of nozzles. This method of governing gives a comparatively flat water-rate curve over a considerable range of load. When reheat is used, intercepting valves and dump valves are usually oil operated, and may be actuated by the governor or the overspeed trip.

Pressure Regulating Governors are placed on many turbines driving pumps, etc. These are usually differential control valve gears, which admit sufficient steam to the turbine to maintain a given pressure or pressure differential at the pump discharge or at a specified point in the piping system. Pressure regulating systems must be arranged to work with the regular speed and overspeed control governors.

An Oil-operated Governor has been developed by Westinghouse which depends for its functioning on the variation in oil pressure delivered by an impeller pump mounted on the main shaft. The oil pressure varies as the square of the turbine speed. The discharge oil from the impeller is led to the governor housing, where it acts upon the operating piston of the main governor valve. Suitable relay valves are provided to insure only such movement as will tend to maintain the speed substantially constant. Remote control is provided in these relays for synchronizing and for varying the speed in operation, to give the desired frequency at a given load. Arrangements also permit tripping-out the turbine and of applying an overspeed test if desired.

To lessen the danger of fire due to breakage or leakage of oil control piping, this is now welded as much as possible. As a further precaution, a non-inflammable fluid such as chlorinated diphenyl is being introduced for high pressure turbine control systems.

Governors on Turbo-alternators have their regulation fitted to the service for which the unit is designed. In general, 2% variation between no load and full load is allowed for electric lighting service. Greater variation may be desirable where the load changes are large. Too close regulation is not necessary or desirable, as this may cause the load to surge between machines that are in parallel. Surging often can be reduced by increasing the speed variation of the governors. Turbines operating in parallel with hydro units usually do not require close regulation.

Since the introduction of electric clocks, constant frequency must be maintained on the power system of public utilities, regardless of load. This is obtained by hand or automatic regulation of frequency on the governor auxiliary spring, which also is used to synchronize the unit with other turbines.

Regulating Valves.—Balanced valves are used in nearly every case for regulating valves of the throttling type. These were formerly of the double-seated poppet type. The difficulty of keeping the two seats tight when using superheat, led some builders to adopt the balanced single-seated valve. Valves and seats for low temperatures are generally of close-grained cast iron, well annealed and seasoned before final turning, to remove the growth in the iron. Such valves must be kept absolutely steam-tight when closed. Monel metal and Everbrite seats are used with superheat. Alloy steel bodies and valves must be used with high temperatures.

Secondary Valves are generally of the balanced type, and can be adjusted to open at any desired amount of load. In large units, a multiplicity of control valves is provided to give better efficiency over a wide range of load. Single-seated valves, stream-lined to reduce eddy losses, are used on nozzle-controlled turbines.

Steam Strainers in front of the throttle valve prevent grit, pipe scale or other foreign substances from reaching the turbine. These are made of perforated brass, with holes $^1/_{16}$ to $^1/_8$ in. diameter, and generally in basket form, although flat strainer cages are used on some units. The steam chest of many large units is bolted rigidly to the turbine foundation and connected to the cylinder by several flexible steel pipes. This removes any pipe stress from the turbine casing.

For methods of testing governors see A.S.M.E. Code for Speed Responsive Governors.

OVERSPEED GOVERNOR.—All turbines have some form of automatic overspeed governor. A small centrifugal governor sometimes is provided in the end of the spindle shaft. This trips a latch at about 10% above normal speed, allowing a heavy weight to drop and unlatch a spring-loaded throttle valve which instantly closes. The usual form of overspeed governor consists of a bolt-headed pin in the spindle end at right angles to its axis. The centrifugal force on the unbalanced bolt-head is opposed, up to 10% overspeed, by a spring. At that speed, the bolt flies out, striking a trigger, which releases the spring-loaded throttle valve and permits it to close. On some large machines, the trigger operates a steam relay valve which causes a second small piston to unlatch the main throttle valve and allows it to close. A modification of this form of governor is an eccentric ring on the governor spindle, the centrifugal force of the eccentric part being balanced by a spring. At a given overspeed this spring is compressed, the eccentric ring strikes a trigger and the throttle valve is closed either by a spring or by an oil relay.

LOAD RELEASE, particularly when the turbine is provided with several stages of bleeding, may cause serious overspeeding. *Turbines* (N.E.L.A., 1927) presents data on a 30,000-kw. turbine where the speed rose 13% before slowing on release of full load.

Westinghouse has developed an anticipator device which closes the main throttle upon complete loss of load of the generator and before the rotor has speeded up sufficiently to operate the overspeed governor.

Mixed pressure and extraction turbines may have quite complicated governing gear to regulate the steam from two sources, to maintain constant pressure on the bleeder supply outlet, or to meet the electrical demands on the generator end. Also, where steam accumulators are used alone or as auxiliaries to the normal steam supply, the governing gear must control several variable conditions. For discussions of such governor gear see: Kraft, Steam Turbines; Zietemann, Dampfturbinen; Stein, Regelung und Ausgleich in Dampfanlagen.

BLEEDER PRESSURE CONTROL may be achieved by a pressure regulating valve outside of the casing, which returns steam to the low-pressure section of the turbine when the bleeder pressure reaches a desired amount. In other designs, it consists of a pressure-controlled piston outside of the casing which, through a link, controls an oscillating port ring or valve in the casing. This port ring or valve can oscillate to give any degree of opening to the ports leading to the nozzles of the low-pressure portion of the turbine or to shut them off entirely.

THROTTLE VALVES often are opened against a heavy spring. The handle for opening the valve is fastened to the valve stem by a latch which may be released, usually by an oil relay, when the overspeed governor acts, thus forming a combined throttle and trip valve. It serves as a throttling valve only when coming up to speed. The unit always should be shut down by tripping this throttle valve.

Other overspeed governors on small turbines release a flap valve, which closes of its own weight. Still others control a butterfly valve in the steam supply.

When any of these overspeed governors operate, the speed of the turbine must decrease considerably below normal before the valve can be hooked up and the governor gear reset.

11. STEAM TURBINE CASINGS

CASING MATERIALS.—Casings of simple impulse turbines for low steam pressures and temperatures are made of cast iron, often split horizontally, with all steam and exhaust connections usually in the lower half. Several designs split the casing vertically, where one head may be removed and the wheel and shaft removed. The steam chest sometimes is carried around one end in the form of a cored passage, with hand-controlled valves to the nozzles. When high-temperature steam is used, casings must be made of steel. Casings for pressures of 1200 lb. per sq. in. and higher have been made of forgings.

Casings for large turbines usually are split horizontally, so that the upper half can be removed to permit examination and repairs. High-pressure sections of turbines carrying temperatures over 425° F. should be of cast steel.

CASING CONSTRUCTION.—While strength is an important consideration in casing design, rigidity under varying temperature conditions is more desirable. Hence, they usually are cast without ribs on the outside and with only sufficient flanges for bolts. They approach the smooth barrel form, and all large abrupt changes in diameter should be avoided. If flanges or ribs are provided, these must not be too deep, or distortion will occur due to slow adjustment to changes in temperature. Cored passages are to be avoided.

Stationary dummy rings often are cast separately and fastened to the inside of the casings.

Gibb (Post-war Land Turbine Development, *Proc.* Inst. Mech. Engrs., 1931) gives

specifications for cast steel casings as: Ultimate strength, 60,000 to 72,000 lb. per sq. in.; yield point, 30,000 to 35,000 lb. per sq. in.; elongation, 25%; reduction in area, 45%.

Curves of temperature measurements on the flanges and bolts of a 35,000-kw. Metropolitan-Vickers turbine, 350 lb. per sq. in., 750° F. are given in *Engg.*, Mar. 11, 1932 These indicate that flange and bolt temperatures lag several hours behind steam temperatures on starting up, but follow closely any subsequent changes. The bolts are substantially at flange temperature; the maximum difference noted was 75° F.

Narrow flange faces are used on high-pressure turbines to increase the unit compressive stress on the joint up to 10,000 lb. per sq. in. A groove sometimes is cut inside the bolt holes and connected to the exhaust to reduce the pressure difference across the outer portion of the joint. In some cylinders, subject to high pressures and temperatures, vertical saw-cuts are made from the outside of the flange to the bolt holes so that expansion and contraction of the casing wall will be influenced as little as possible by the temperature of the outer part of the horizontal flanges.

The high-pressure end of casings often is supported on sliding feet, located near the horizontal center line, to allow free expansion. Transverse alignment is obtained by vertical keys. In some designs, a flexible support, in the form of a steel I-beam or channel under the high-pressure end, holds the unit in sidewise and vertical alignment but permits longitudinal expansion through flexure of its web. With such construction, the cylinder is bolted solidly to the pedestal which rests on the I-section.

Some single-disc, overhung turbines have two safety blades, placed 120° apart, which rupture at a predetermined overspeed, thereby unbalancing the turbine. The shaft end then rubs on a heavy steel restraining ring in the casing, which braking action prevents further overspeed.

Casings must be designed to withstand bursting pressures 50% above normal working load. For low-pressure cylinders, this may be taken as 30 to 50 lb. per sq. in. The deflection between supports should be a minimum. The pull of the vacuum on the exhaust outlet, when an expansion joint is used, must be considered in figuring this deflection. The lifting force of a spring-supported condenser also must be considered.

Cylinders should be blanked off and subjected to about 25 lb. steam pressure for about 24 hours before final boring, to season the metal and relieve casting stresses. Cylinder supports should be as near to the center line of the machine as possible, to avoid changes in shaft alignment from heat changes. Usually the generator end of the casing is fastened rigidly to the bedplate with provision for expansion at the opposite end.

The thickness of the metal casing is usually calculated by the thin cylinder formula, $t = pd/2f$, where t = thickness, in.; p = internal pressure, lb. per sq. in.; d = internal diam., in.; f = allowable stress in the material, lb. per sq. in. See Stodola (Steam Turbines) for further details.

Drainage grooves to remove moisture are provided in many of the last stages of large turbines. These appear capable of removing 25% of the moisture present.

BOLTS as large as 4 in. diam. are in use. When used at high temperatures and pressures they are tightened to a definite stretch. Each bolt is heated to a certain temperature by an electric heater placed in a central hole in the bolt. The nut is set up snug and the bolt allowed to cool. The resultant stretch then is checked. Similar heating is used when bolts are to be removed. Bolts or studs for high temperatures sometimes are made extra long with a collar under the nut to spread the stress on heating up over such length as to avoid over-stressing.

Chrome-nickel-steel of 140,000 lb. per sq. in. ultimate strength, and yield point of 90,000 lb. per sq. in., has been used for bolts. Creep at the working temperature must be taken into consideration when deciding upon the loading of the bolts. Thompson and Van Duzer (*Trans.* A.S.M.E., FSP–56–9, July, 1934), state that a heat-treated chisel steel gave the best performance with 1000° F. steam. Its composition was: Carbon, 0.45 to 0.50%; chromium, 1.25%; tungsten, 2.0%; vanadium, 0.25%.

DIAPHRAGMS, when cast in halves, must be made sufficiently strong and rigid to avoid undue deformations due to temperature and pressure differences. They usually are dished towards the high-pressure side to increase strength. Diaphragms in large machines are of cast steel, fitting on centralizing supports in turned circumferential slots in the casing. These diaphragms sometimes carry a shoulder projecting almost to the adjoining diaphragms and just outside the blade ring. If the disc fails, the flying pieces must rupture this heavy steel shoulder before piercing the casing.

Diaphragms generally are built with the orifices around the outside made of sheet steel partitions, varying in thickness from $^1/_{16}$ to $^3/_{16}$ in., cast into the diaphragm. In another form of construction, properly-formed brass or bronze guide vanes are spaced and held by pins on the outer edge of the cast-iron diaphragm, a steel ring being shrunk on their outer edge to hold all the guide vanes in place. Still another form consists of

bronze crescent-shaped blades, placed in nozzle segments and bolted to the periphery of the diaphragm. On small diaphragms the partitions are carefully located and hydrogen-welded in place. Another design has a steel central section with accurately formed nozzles mounted straddling the outer edge of this central part, like blades, and riveted or welded in place. The outer ends form a solid rim for the diaphragm. This produces robust, rigid nozzles of high efficiency.

Design constants for diaphragms are largely based upon experience, since split diaphragms are not easily analyzed mathematically.

EXHAUST OUTLETS of large turbines are stiffened and reinforced against the crushing effect of the vacuum. This is done by cast-in or bolted partitions, or by means of heavy staybolts with extra heavy pipe spacers. These partitions or struts must not be placed close to the last blade row since they may cause undue blade vibration.

Kraft (The Modern Steam Turbine) states that the design of the exhaust should fulfil the following conditions: *a*. The transformation into pressure of the kinetic energy of the steam leaving the blades must begin as soon as possible after the last wheel; it must take place as quickly as possible yet it must be gradual; *b*. The curvature must be gentle; the area of the steam passage in a direction perpendicular to the flow must increase continuously, causing the steam velocity to decrease gradually; *c*. The jets of steam escaping from the last wheel must not interfere with each other and cause eddies; *d*. As few guiding surfaces as possible should be provided in the exhaust casing, to keep down the friction losses against the walls. Diffusing guides are employed in all large exhausts. See Robinson, Leaving Velocity and Exhaust Loss in Steam Turbines, *Trans.*, A.S.M.E., FSP-56-10, July, 1934, for data on exhaust hood losses.

ATMOSPHERIC EXHAUST.—Provision usually is made for an atmospheric exhaust on all condensing turbines, to discharge exhaust steam to atmosphere through a relief valve. These valves are difficult to keep tight. The valve and piping are expensive and take up room in a plant. In modern operation, where machines are started and shut down under vacuum, it is considered improper to operate non-condensing, particularly when high superheat is used. Hence the relief valves are seldom, if ever, used. Turbines have been installed with no relief valve, but with a lead blow-out or explosion diaphragm set at 2 lb. per sq. in. gage and placed over the atmospheric port. These turbines have a special vacuum control device which trips the throttle valve if the vacuum drops below a certain value.

12. ERECTION AND OPERATION

Turbine Foundations

The foundation should have sufficient weight and mass to hold the turbine rigid against vibration. The sub-foundations are determined by the character of underlying material, but must be so designed that the concentrated weights of the turbo-generator are spread over an ample area to prevent springing or settling. For bearing power of soils see Vol. 3.

A type of foundation extensively used is reinforced concrete, with heavy side walls and columns under the base of the unit, tied together by deep arching bridges. Necessary openings for condenser connections, air ducts, drain and steam piping, etc., should be provided together with additional reinforcing around these holes. The maximum unit pressure of the turbine and generator on the concrete should not exceed 250 lb. per sq. in. *Reinforced concrete foundations* are heavy and impose added loads upon the sub-foundation. They generally are used where the footings rest directly on rock. The concrete superstructure occupies space that might be used for auxiliary equipment. To overcome this objection *steel foundations enclosed in concrete* have been used to reduce the mass. Concrete should consist of a 1–2–4 mixture, well placed and seasoned.

STRUCTURAL STEEL FOUNDATIONS are widely used, as these permit the placing of much auxiliary equipment under the turbine itself. This type imposes least weight upon the sub-foundations, and hence is favored where the footings are supported upon piling, caissons, or a reinforced concrete mat. The steel piers are connected by a deep I-beam superstructure to carry the unit. The supports must be strongly buttressed and braced to prevent deflections and vibrations. The beams must be designed for a maximum deflection under load of 0.020 to 0.030 in. Columns should not deflect axially more than 0.030 in. The allowable deflections usually are stated upon the turbine builder's foundation plans.

THE DESIGN AND CONSTRUCTION OF TURBINE FOUNDATIONS usually is carried out by the purchaser. While the turbine builder will assume no responsibility for such plans, it is desirable to submit them to the builder for his approval in order to avoid mistakes, omissions of openings for drains, ducts, etc., and for suggestions as to resonance, rigidity, etc.

Foundations generally are designed with rigidity, mass, etc., solely in view, without

regard to resonance. Resonance must be considered, particularly with structural steel foundations, for periodic vibrations may occur corresponding to the r.p.m. of the turbine and to certain multiples of this speed. This vibration may be horizontal or vertical and may affect different parts of the foundation in opposite ways. The foundation may even be too stiff for the particular turbine load and speed, and may vibrate severely as a result. Resonance in foundations may lead to objectional vibration in turbines themselves.

In case of vibration trouble, a study of the structure by means of a vibrometer may indicate means for removing the difficulty. These instruments may be used to analyze vibrations in the turbines. See T. C. Rathbone, Vibration of Turbine-generator Foundations (*Power*, April 3, 10, 1928) and Dohme, Modern Steam Turbine Foundations (*Power*, Aug. 2, 1927).

Provision must be made in foundations for the necessary air ducts for air coolers, when used, for pipe openings, and for cable and drain outlets. Provision also must be made for the down-pull of the vacuum if an expansion joint is placed between turbine and condenser. This down-pull equals the product of the area of the exhaust opening in sq. in., multiplied by the vacuum, as shown by a mercury column reduced to absolute pressure in lb. per sq. in. In some turbine designs this pull is carried entirely by the exhaust end supports. In others it is divided between front and rear supports. When the condenser rests on springs and is bolted directly to the turbine exhaust, there is no down-pull due to vacuum, but there may be an upward lift from the springs when the condenser is empty. Foundations should be designed to support machine load plus 25% for impact, condenser load, floor load, and dead loads. Cross bracing must be provided to care for a force equal to 25% of the machine load.

Some turbines are leveled by steel shims on the steel work, and bolted in place. In other cases, the steel is so designed that a concrete top is provided and 1 to 1 grout is poured around the bed plates in the usual way after leveling with wedges.

Floors between adjacent turbines in a power-house are frequently built across between turbine foundations. Vibrations thus are communicated to all parts of the power-plant. To prevent this transmission of vibration, the floor beams may be carried on separate columns leaving a space 1 in. wide between floor and foundation. This afterwards is filled with a board of soft wood or a rubber strip is fitted loosely in the opening. These do not transmit vibration.

In many large stations only an operating platform about 6 ft. wide is built around the turbine bed plate, leaving the remainder of the engine-room open to the basement floor. This provides better light around the condenser auxiliaries, and the condenser equipment is more accessible to the crane. Dismantling and repairs can be carried out on the basement floor. If these were done on a floor at the turbine elevation, heavy steel or concrete flooring and floor supports would be required.

Erection of Steam Turbines

Before proceeding with the erection of a steam turbine one should be sure that the foundation is sufficiently strong and rigid to carry the unit. This is particularly necessary if the turbine is to be placed on the engine-room floor, as is sometimes done with small units. In erection, if turbine and generator are on one shaft, it is only necessary to level the unit carefully. If the set consists of a turbine with a separately-driven unit, as a generator or pump, or if gears are used, care must be taken to insure not only correct levels but also accurate alignment, particularly at the couplings. Leveling pads are furnished on many bed-plates. Levels should be checked with the turbine heated to operating temperature, as the alignment of some designs is affected by expansion due to the heating of the exhaust end. Leveling is done by steel wedges at frequent intervals under the edge of the bed-plate, allowing a space of 1 in. under the bed-plate for grouting.

There should be sufficient wedges to insure that no deformation occurs between them. After the grout has set for a day, they can be withdrawn. Some engineers slightly raise the outboard bearings of both turbine and generator to obtain more accurate alignment at the coupling by allowing for the deflection due to weight of the spindle and revolving field. This, however, is unnecessary with most couplings. Leveling always should be done with all weights in place. Detailed information on erection will be found in the instruction books of manufacturers. Kearton's Steam Turbine Operation also contains many data and suggestions for alignment methods, erection, etc.

When leveling is completed, the bed-plate is grouted in place, using one part of high-grade Portland cement and one part of sharp sand, mixed in a thin grout and well rammed to prevent air bubbles under the base. This should cover the foot of the bed-plate at least 3 in. Provision usually is made to grout in bed-plates supported on steel. Occasionally lead, 1/2 to 1 in. thick, is used in place of grout on structural steel foundations.

Sometimes the inside of the bed-plate is completely filled with cement to add more mass to the foundation and lessen vibration.

Some bed-plates are provided with foundation bolts. These are desirable, but not necessary. They are drawn up tight after the grout has set.

Great care must be exercised when erecting the unit to prevent any dirt lodging in the bearings or oil chambers, or foreign matter in the blading. All oil chambers should be carefully cleaned, but waste must not be used on account of the lint left behind.

Oil piping generally is blown out with steam and allowed to dry thoroughly before assembly, to remove dirt that may have gotten in during shipment. Steam lines should be blown out with full steam pressure before permanently connecting up, to remove any pipe scale or dirt from the inside.

In assembling turbo-generators, great care must be taken to avoid injuring the stator coils or bruising the laminations when entering the rotating field into the stator frame. This may be prevented by placing wooden strips or bearing plates on the laminations.

Steam Piping

PIPING to turbines must provide for expansion and contraction, both of the turbine and of the pipe line, so that the least possible stress will be imposed on the turbine. Pipe vibrations also must be avoided.

The steam chest containing the governor regulating valves is either, *a*, bolted directly to the turbine casing, or, *b*, fastened firmly to the foundation with flexible pipe connections from it to the turbine casing. The throttle valve, usually of the automatic spring-closing type operated by the overspeed governor, bolts directly to the steam chest and may be supported by springs, or in case *b*, be supported by the foundation. In the latter case stresses from the piping cannot be transferred to the casing.

In both cases, it is desirable, in order to keep the flange joints tight, that there be minimum stress on the throttle valve from piping. Allowance should be made in case *a*, for the maximum turbine expansion from cold to working temperature, and the same for the piping. This expansion may be halved and piping made up cold by springing into position for half the total expansion. Torsional stresses also should be avoided. See Sect. 5 for various data on pipe, flanges, etc.

Practice is tending towards welded pipe joints for high pressure piping. In some cases this includes welds between piping, throttle valve and steam chest. See Field Welds in Pressure Pipe Lines of Steam Systems, H. N. Boetcher, *Trans.* A.S.M.E., FSP–56–1, Jan., 1934.

Drains must be provided for all low points in piping, steam chests, bends, etc. The manufacturer's drawings should show the location of these drains.

Exhaust Piping must be absolutely air tight. When an expansion joint is used, consideration must be given to the collapsing effect of the vacuum, and provision made by suitable brackets, anchor bolts or other devices to prevent distortion.

Plant Design

Turbo-generator plants are arranged in either of two ways: *a*. The turbo-generators are set with their axes at right angles to the boiler-room wall. Condensers are placed directly under the turbines. The units are spaced to give ample room between them for operating and for dismantling. This distance often is fixed by the space required by auxiliaries, which usually are in the basement. Space must be provided at the ends of the units to permit the field to be withdrawn from the generator. With large units, this results in a wide turbine room and long crane span. *b*. Large turbines often are placed with their axes parallel to the boiler-room wall. The distance between turbines is fixed by the space necessary to withdraw the generator field. The condenser usually is set at right angles to the turbine axis. Space must be allowed for withdrawing condenser tubes, and also at the side of the turbine for dismantling. Vertical condensers at the side of the turbine or in condenser pits frequently are used.

THE CONDENSER in every case should be placed as close to the turbine exhaust as possible. In small sizes, a bellows type copper expansion joint must be placed between turbine exhaust and the condenser inlet. Large units often are built with no expansion joint, the condenser being bolted directly to the exhaust nozzle. The supporting pads on the condenser shell rest on springs. These are adjusted to carry all, or a major portion of, the weight of the condenser when full of water. They provide a certain amount of flexibility to care for expansion from temperature changes. All water, air pump, condensate pump and atmospheric exhaust connections should have expansion joints when the condenser is bolted firmly to the turbine in this manner. Rubber expansion joints are used for this purpose.

HEADROOM UNDER THE CRANE above engine-room floor must be sufficient to permit lifting off the turbine cover and removing the spindle for repairs or inspection.

PIPING.—The purchaser furnishes piping for cooling water to and from the oil cooler, to and from the regenerator air cooler, for water glands, for steam to and from auxiliary oil pump and for drip connections. Manufacturers' drawings will show where these connections can be made. The manufacturer usually supplies all oil piping, piping to steam-sealed glands and water cooling piping about bearings when such is used.

COOLING AIR for small generators may be taken from below the unit, and after passing through the generator, may be discharged into the engine-room. In some of the older units, air from outside is passed through washers before entering the generator and the discharged air is delivered to the boiler-room. This involves much duct work. In both the above methods, much dirt enters the generator and adheres to the windings. In case of a short-circuit, a fire in the windings usually results from the continued supply of fresh air. Units now are furnished with a closed system of air circulation and with air coolers supplied with condensate or with cooling water from other sources. These eliminate the necessity of cleaning generators, and in case of a short-circuit, the fire is smothered by the exhaustion of the limited oxygen supply in the closed system. Small breathers with viscous air filters provide for changes in volume in this closed circuit.

One manufacturer uses the following formulas to give the approximate amounts of cooling air that are circulated through generators rated at 80% power factor. For 3600-r.p.m. generators from 3000 to 15,000 kw. rating inclusive, cu. ft. per min. of air $= 3.7 \times$ kw. rating/1000. For 1800-r.p.m. generators from 20,000 to 60,000 kw. rating inclusive, cu. ft. per min. of air $= 2.4 \times$ kw. rating/6000.

FLOOR SPACE.—Table 4 gives the approximate overall floor space required by General Electric alternating-current turbo-generators for 80% power factor and with direct-connected exciters. Table 5 gives similar data on Allis-Chalmers Parsons turbines.

Table 4.—Space Required by General Electric Turbo-alternators for 80% Power Factor and Direct-connected Exciters

Care and Operation of Steam Turbines

Manufacturers issue complete instructions for the care and operation of their respective units. The Operating Code Manual for Prime Mover Plant, N.E.L.A., 1929, should be available to every operator. The following notes direct attention to a few operating considerations:

The logical steps in starting a turbine are: First, the condenser circulating pump and the other condenser auxiliaries should be started; next, the auxiliary oil pump on the turbine, and a full oil

supply furnished to all bearings. Cooling water should be turned on the oil cooler. Any new oil added to the system should be poured through several thicknesses of cheese-cloth to remove any chips, cuttings, etc.

The most difficult part of starting is the proper warming-up of spindle and casing. With steam-sealed glands, the vacuum pumps are started and steam turned into the glands. A small amount of steam allowed to pass the throttle valve will, on account of its density, rise to the top of the casing, causing it to heat and expand. The lower half remains filled with cold air and does not change in temperature or form. The result is a distorted cylinder. The same thing occurs on a spindle of Parsons construction. Discs also distort if one-half only is heated. It is evident that warming with a small amount of steam may cause undesirable distortions, which may result in blade rubs. A better method is to suddenly admit enough steam through the throttle valve to revolve the spindle, and to then close the throttle until only sufficient steam enters to keep the spindle turning over slowly. The rotating blades carry the steam around the casing, causing it to heat more evenly and rapidly than in any other way. This should continue until the turbine is evenly heated, before allowing the machine to speed up. All drains must be kept open during the warming process. A blade rub developed in starting probably is due to local distortion, and often may be relieved by allowing the turbine to stand for a short time while the heat in the casing diffuses through the whole body. Another careful start then may indicate that the blades are clear. It is unwise to bring a turbine up to speed without warming, as severe stresses undoubtedly are produced in certain parts.

STARTING UP AND LOADING are important considerations on large turbines. The time required to bring turbines of 20,000 kw. and larger from cold up to speed varies from $1/2$ to 3 hr., and load may be added at the rate of 1000 to 3000 kw. per min. If possible large turbines ought not to be operated at less than 20% of rating.

Large spindles must be warmed and cooled with great care to avoid bowing of the spindle by uneven heating or cooling. Indicators are provided on the shafts of many turbines to show whether the spindle is straight. If a spindle is bowed, it must be brought to rest and allowed to stand until all parts are normal and the bend has disappeared.

Large units are provided with motor-driven turning gear which can continuously revolve the spindle at about 25 r.p.m. during the shut-down period to keep the spindle straight. This gear automatically disengages when starting up. Sometimes oil at high pressure must be supplied to the bearings when starting to establish the oil film.

E. Brown (*Engg.*, Aug. 22, 1930) proposes placing a heat-insulated cover outside the casing, and heating the intervening space electrically to normal operating temperature during the shut-down period to permit instantaneous starting. He states that 0.1 kw.-hr. per sq. ft. of outside cover will maintain the turbine in a hot state. This is equivalent to 0.1% of full-load steam per hour.

When turbines connected to generators, and in parallel with water-power plants, operate for considerable periods at no load or at times are motored, sufficient steam must be admitted past the governing valves to cool and ventilate the blades.

As the turbine speeds up the glands begin to seal and the vacuum builds up. It is well to ascertain if the governor-regulating valve is sufficiently tight to prevent overspeeding with no load and full vacuum on the turbine. The turbine next can be synchronized and the load added.

In operation, the oil supply to the bearings requires constant watching.

SHUTTING DOWN.—The turbine is shut down by reversing the above processes in the regular order. The machine usually is stopped by tripping the emergency valve, to see that it is free and acting properly, or by speeding up the turbine by holding the governor lever until the emergency governor itself acts, at 10% above normal speed.

It is inadvisable to throw large loads suddenly on turbines, as this may cause the boilers to prime and throw water into the superheater. Large, efficient separators before the throttle valve are absolutely essential where wet steam is used.

If the exhaust pipe turns up after leaving the turbine, and rises to a higher level, the pocket formed must be drained. Otherwise it will fill with water and lower the vacuum on the last rows of blades. A tank pump is best for drainage of such a pipe.

INSPECTION.—Every turbine should be opened up and inspected periodically, usually once a year, to note any wear of parts or other troubles. If wet steam is used from boilers that prime or foam, the blades in the first rows may become clogged with material carried over in the steam. Corrosion of blades in rows at the dew point generally is due to impure feed water or to no deaeration. Wet steam may cause erosion of the last rows of blades. Oil reservoirs require cleaning. Water glands scale up, unless condensate only is used. Clearances in the cylinder require checking. Wear on thrust blocks should be noted and corrected. Leakage in throttle and regulating valve seats should be stopped. Care must be taken in reassembling to avoid damage to the blading.

The highest vacuum should be maintained at all times in the condenser exhaust. Frequent use of heavy asphaltum paint on all exhaust joints is a good preventive against air leaks.

Care must be taken in tightening packing on governor valve or automatic valve stems to make sure that these are not made so tight as to cause the valve to stick in service.

Accidents to steam turbines generally are due to one of the following causes: Failure of the oil supply; overspeeding, due to failure of the automatic overspeed governor to act; failure of blades due to fatigue of material from vibration; fouling of blades with foreign parts in the casing; failure of the discs or drum from internal defects; or starting quickly an unevenly-heated and distorted turbine. Some of these conditions can be foreseen and prevented by proper vigilance on the part of the operating engineer.

TURBINE OPERATING DATA for a period of years will be found in *Turbines*, N.E.L.A. and E.E.I. The following terms have been adopted as standards in stating turbine performance:

Period Hours.—Total hours per year; 8760 in 1933.

Service Demand Factor.—The ratio of demand hours to period hours.

Service Demand Availability Factor.—The ratio of service hours to demand hours.

Unit Capacity Factor.—The ratio of kilowatt-hours generated to the product of the unit rating and period hours.

Unit Output Factor.—The ratio of kilowatt-hours generated to the product of the unit rating and service hours.

Unit Operation Factor.—The ratio of service hours to period hours.

Maximum Possible Unit Operation Factor.—The ratio of the sum of the service hours and the reserve hours to the period hours.

Table 6 from *Turbines*, E.E.I., 1934, gives such performance data over a period of years. This shows a steady improvement in those factors associated with availability and reliability and also indicates the outage factors of the complete unit. The effects of the depression after 1930 also can be noted.

OPERATION INDICATORS.—The erection of turbo-generator sets in the open has necessitated a more complete enclosure of all parts and the development of new instruments to show the conditions of operation. Instruments are under development to show the expansion of spindle relative to casing, to detect the degree of vibration or changes in vibration, to indicate the touching or rubbing of parts inside the casing, shaft eccentricity and axial clearance, and to control valves from remote stations. These instruments probably will be placed in all new stations, open or enclosed. See Apparatus for Steam Turbine Control, R. B. Smith, *Elec. Jour.*, Sept., 1932.

Availability and Reliability are important factors in turbine construction and opera-

tion, since outages not only cost money but may lead to shut-downs of the entire electrical system. Possible gains in economy sometimes have been sacrificed to obtain more rugged and reliable operating units.

SYNCHRONOUS CONDENSER OPERATION of steam turbo-generator sets often is practiced. Generally the manufacturer refuses to accept responsibility for such an operating condition, although few failures have been assigned to this cause. If the turbine is still coupled to the generator during such operation, particular care must be taken with disc-type turbines to properly ventilate the unit with steam to remove the heat generated by windage in the various stages. This is done by admitting steam through an orifice into the first stage of the casing. This steam, while supplying some of the energy to overcome the mechanical losses of the set, is less than the normal no-load steam. The amount of heat generated, and the location of the hottest stage depends upon the size, type and number of stages and on the density in the turbine casing. The condenser usually is kept in service to maintain a high vacuum. Thermometers are placed on the turbine casing to indicate the rise in temperature when operated as a synchronous condenser. The limiting temperatures are about 500° F. for a steel casing and 400° F. for a cast-iron casing for small units. In large turbines, manufacturers have placed even lower limits.

When the turbine is uncoupled and the generator operated alone as a synchronous condenser, it is started as a motor by being tied-in electrically with another operating unit and brought up to speed.

13. CORRECTION FACTORS FOR TURBINE DATA

AN INCREASE IN STEAM PRESSURES increases the heat drop, which tends to reduce steam consumption at a given load and leads to lower leaving losses. Increased density leads to higher friction losses in the high-pressure section of the turbine. If initial temperature is constant, moisture increases in the low-pressure stages, tending to decrease efficiency. ρ, the ratio of wheel to steam speeds, decreases for each stage but R, the reheat factor, increases. Hence cumulative heat increases. The net result is a slight decrease in efficiency, together with lower steam consumption.

AN INCREASE IN VACUUM increases the heat drop and decreases steam consumption. ρ decreases, tending to lower efficiency. The leaving loss increases. The net result is lowered efficiency, but also decreased steam consumption.

AN INCREASE IN INITIAL STEAM TEMPERATURE decreases density of the high-pressure steam and tends to increase efficiency. It increases the heat drop, and decreases ρ, which tends to decrease efficiency. This often is offset by the decreased moisture in the low-pressure section, although leaving losses tend to increase. The net effect is a slight increase in efficiency, accompanied by a decrease in steam consumption.

CORRECTION FACTORS.—As it may be impossible to reproduce on a plant test exactly the standard conditions specified in the contract, every steam turbine guarantee should contain in the contract, the corrections agreed upon for such variations from standard conditions as may occur on test. The corrections will vary with the various types and sizes of turbines, and with certain assumptions in their designs, and should cover variations in initial pressure, superheat or quality, vacuum and load.

Only the manufacturer can state, with any degree of assurance, reasonable correction factors for his particular design. The purchaser, however, can check these by noting whether there is any appreciable change in the engine efficiency when the corrections are applied.

In the interests of fairness and accuracy, the purchaser should ask for guarantees only under actual every-day operating conditions, such as usual throttle pressure, superheat or quality and vacuum, which he reasonably can obtain on test, and which will, therefore, not need corrections. True values for corrections can be determined only by a series of tests where the conditions are varied one by one, all other conditions being maintained standard, and the results compared.

Correction factors for all possible conditions cannot be stated for lack of space. The following data (Tendencies in Steam Turbine Development, H. L. Guy, *Proc.* Inst. Mech. Engrs., 1929) will indicate the relative magnitude of the various corrections:

The steam or heat consumption at standard conditions is found by multiplying the measured quantity from the test by the correction factor. Standard conditions are 350 lb. per sq. in. gage; 750° F.; 29 in. vac.; four-stage bleeding to heat feed to 300° F. Although not stated in article, these figures probably apply to 40,000-kw., 1500 r.p.m. units.

The correction for initial steam pressure, temperature, and vacuum is much smaller

if performance is expressed as heat consumption than as steam consumption. The correction factors apply to one specific load, the *Most Efficient Load*. Other factors must be provided for partial or full loads, particularly vacuum correction factors which vary appreciably with load. See Goudie, Steam Turbines, p. 621.

Pressure Correction Factors

Pressure, lb. per sq. in. gage	300	325	350	375	400
For steam consumption	0.979	0.99	1.00	1.011	1.022
For heat consumption	0.982	0.991	1.00	1.009	1.018

A straight line variation may be assumed for lesser increases or decreases.

Superheat Correction Factors

Steam temperature, °F	720	735	750	765	780
For steam consumption	0.980	0.989	1.00	1.012	1.025
For heat consumption	0.989	0.995	1.00	1.007	1.014

Vacuum Correction Factors

For steam consumption	0.968	0.979	0.989	1.00	1.01	1.021
For heat consumption	0.977	0.985	0.993	1.00	1.005	1.009

Feed Temperature Correction Factors

Feed temperature, °F	240	260	280	300	320	340	360
For steam consumption	1.041	1.028	1.015	1.00	0.984	0.966	0.945
For heat consumption	0.985	0.992	0.997	1.00	1.001	1.002	1.002

LOAD CORRECTION where necessary is determined by an interpolation or extrapolation of the Willans Line drawn from the results of actual tests and after all other corrections have been applied. The total steam (or heat) consumption for the output for which the correction is desired, may be determined from the formula:

$$M_c = \frac{(M_t - M_a) \times (W_c - W_a)}{(W_t - W_a)} + M_a$$

where W_c = output for which correction is desired; W_t = output of the test requiring correction; W_a = output for an adjacent test employed for determining the load correction; M_c = total steam (or heat) for the corrected output W_c, lb. (or B.t.u.) per hr.; M_t = total steam (or heat) for the output W_t of the test requiring load correction, otherwise corrected to the specified operating conditions, in lb. (or B.t.u.) per hr.; M_a = total steam (or heat) for the output W_a of the adjacent test, corrected to the specified operating conditions employed in determining the correction, lb. (or B.t.u.) per hr.

RULES FOR STEAM TURBINE TESTS are given in the A.S.M.E. Power Test Code. See p. 16–22.

14. TURBINE PERFORMANCE

Steam turbine performance usually is stated in tables giving size, speed, initial steam and exhaust conditions, and pounds of steam per kw.-hr. These tables, while of interest to engineers for reference, have three limitations: 1. It is impossible in a small space to quote tests for every possible steam condition under which turbines of many sizes may operate; 2. Builders seldom allow any tests to be published except the best records made by their equipment, and such tests obviously do not represent average conditions; 3. Turbine builders are prepared to furnish different types of the same size of unit, and frequently of different efficiencies, built to meet quite different conditions. For instance, a simple, cheap unit, with a low ratio of blade speed to steam speed and high leaving losses may be best suited for certain commercial conditions. For other conditions, a more expensive turbine, of more refined construction, with a high ratio of blade speed to steam speed, and with low leaving losses, may be most desirable. The latter will have a much lower steam consumption and higher cost than the first unit.

The following data will serve as a guide in estimating turbine performance or in checking tests:

ENGINE EFFICIENCY.—Operating conditions, particularly on small turbines, vary over such a wide range that tables covering every condition are beyond space limitations. The engine efficiency is used in the following paragraphs as a measure of performance of the smaller units.

The steam consumption of these units readily can be determined by dividing 3412 (the heat equivalent of 1 kw.) by the product of the engine efficiency, η_e at the generator terminals and the adiabatic heat drop from initial steam conditions to exhaust pressure. Thus lb. per kw-hr. = $3412/[\eta_e(h_1 - h_2)]$

The isentropic heat drop $(h_1 - h_2)$ can be found from a Mollier diagram or can be

calculated from the Steam Tables (see p. 5–03). The steam consumption in terms of brake-horsepower can be calculated by substituting 2543 for the horsepower and η_e for the engine efficiency at the coupling. Thus lb. per B. Hp.-hr. = $2543/[\eta_e(h_1 - h_2)]$

Leaving loss also may be considered at the same time as engine efficiency, as it is a measure of the unutilized velocity from the last row of blades.

Since turbines operate best under the conditions for which they are designed, the efficiency ratio under any other set of operating conditions will vary from the ratio at the specified conditions. On account of the high leaving loss from the last rows of blades of high-vacuum turbines, it often happens that a higher efficiency ratio may be obtained at a somewhat lower vacuum than specified, even though the steam consumption per kw-hr. may be higher.

HEAT CONSUMPTION of a turbine is expressed in B.t.u. per hr. See p. 3–72.

British practice expresses turbine performance in terms of thermal efficiency. This is the ratio of 3412 (the heat equivalent of 1 kw.) to the heat consumption of the unit, expressed in B.t.u. per kw-hr.

Another British practice is to state the k value for a unit where

$$k = \Sigma\left(\frac{d}{10}\right)^2 \times$$

where Σd^2 is the sum of the squares of the mean diameters, in., of all rows. The higher the value of k, the greater is the engine efficiency as a rule. Another similar factor called by Kraft (The Modern Steam Turbine, p. 31) the *Parsons coefficient* or *quality factor* $q = \Sigma u^2/h_0$, where Σu^2 = the sum of the squares of the various wheel speeds, ft. per sec.; and h_0 = isentropic heat drop, B.t.u., from initial conditions to final pressure. Σu^2 gives an idea of the bulk of a turbine and consequently of the price of the unit. Kraft gives the following values of engine efficiency at the coupling for various values of q:

q = 5000	7500	10,000	12,500	15,000	17,500
η_c = 69.8%	77.2%	81.5%	84.2%	85.5%	86%

He points out that an increase in q means an increased number of stages, and that a large increase in q gives only a comparatively small increase in efficiency in the higher ranges. Also, the quality factor q may be higher for reaction turbines for the same efficiency than for impulse units.

Table 7 represents the performance of single-stage velocity-type non-condensing turbines for direct connection to the driven apparatus. Blade speeds vary from 300 to 500 ft. per sec. The higher values of engine efficiency refer to the performance under the most favorable steam conditions for that particular design; the lower values refer to performance under less favorable conditions.

Table 7.—Performance of Single-stage, Non-condensing Steam Turbines

Brake Hp.	Engine Efficiency Referred to B.Hp.	Brake Hp.	Engine Efficiency Referred to B.Hp.	Brake Hp.	Engine Efficiency Referred to B.Hp.
25	34 to 44%	125	41 to 48.5%	300	47 to 53%
50	37 to 46	150	42 to 49	400	48 to 54
75	38 to 47	200	44 to 51		
100	40 to 48	250	45 to 52		

The figures in Table 8 represent best efficiencies for single-stage, direct-connected velocity-type steam turbines operating under the conditions stated, as furnished by one American manufacturer. All figures are for dry saturated or slightly superheated steam. Exhaust pressure, 14.7 lb. per sq. in., abs. Lower efficiencies often will be quoted to obtain a cheaper turbine.

Table 8.—Engine Efficiencies Based on B. Hp. of Single-stage, Velocity-type, Non-condensing Turbines

Rated B.Hp.	Inlet Pressure= 300 lb. per sq. in., gage			Inlet Pressure= 150 lb. per sq. in., gage		
	3600 r.p.m.	2700 r.p.m.	1800 r.p.m.	3600 r.p.m.	2700 r.p.m.	1800 r.p.m.
25	34.5	34.0	30.5	36.2	36.0	32.9
50	39.0	38.0	32.6	40.7	40.0	35.0
100	44.5	42.5	33.6	46.2	44.5	36.0
200	49.0	44.5	34.1	50.5	46.5	36.5
400	51.5	45.5	34.4	53.0	47.5	37.0

Blade speed has an important influence on turbine efficiency. Higher blade speeds can be secured either by a relatively large wheel at moderate speed, or a relatively small

wheel at very high speed. In practice, the latter condition has been found most desirable, as the disc friction and blade losses usually are less for the smaller wheel. The very high speed must be reduced through mechanical gearing to the required slow speed of the driven unit.

The figures of Table 9, applying to single-stage, geared, velocity-type turbines, running at blade speeds of 500 to 650 ft. per sec. show by comparison with Table 7 the improvement to be obtained with high blade speeds obtained through small discs and reduction gearing. While these values do not refer to one specific type of turbine in both cases, it would seem that the increase in blade speeds has resulted in an apparent increase in the efficiency ratio of approximately 5%.

Table 9.—Performance of Non-condensing Single-stage, Geared Turbines of High Blade-speed

Brake Hp.	Engine Efficiency Referred to B.Hp.	Brake Hp.	Engine Efficiency Referred to B.Hp.	Brake Hp.	Engine Efficiency Referred to B.Hp.
25	42 to 51%	125	47 to 55%	300	51 to 58%
50	44 to 53	150	48 to 56	400	53 to 59
75	45 to 54	200	49 to 57		
100	46 to 55	250	50 to 58		

For certain purposes, as driving boiler-feed pumps, fans and other station auxiliaries, steam economy of the driving turbine is usually not a matter of great importance, since the exhaust is used to heat feedwater. Rugged construction and reliability of operation, combined with low first cost are usually the controlling factors in the choice of such a unit.

EFFICIENCY RATIO OF RE-ENTRY TURBINES.—Curves are given by Francis Hodgkinson (Historical Review of Steam Turbine Progress, *Elec. Jour.*, 1918) which indicate that the engine efficiency, based on electrical output of non-condensing, direct-connected, single-wheel units of the re-entry type, such as are used for small lighting outfits by contractors is as follows, with 175-lb. gage pressure dry steam: 12% on a 1-kw. unit, 20% on a 5-kw. unit, and 23% on a 10-kw. unit. Geared turbines of the re-entry type give the following probable engine efficiencies, based on electrical horsepower, with 175-lb. gage pressure dry saturated steam, non-condensing: 50-kw., 44%; 100-kw., 47%; 150-kw., 48.5%; 200-kw., 50%.

SMALL IMPULSE TURBINES.—J. Y. Dahlstrand (Characteristic Curves of Steam Turbines, *Power Plant Engg.*, Aug. 1, 1924) discusses certain main characteristics of turbines of the impulse type below 500 kw., where the steam is throttled into the first-stage nozzles. He points out that:

1. The relation between power output and ring pressure before first-stage nozzles approximates a straight line function. 2. The no-load pressure will increase with increased operating speed, and also will rise with increased back pressure. 3. An increase in steam line pressure on a given turbine with a given output, speed and back pressure, will not materially benefit the steam rate of such a turbine. The only benefit results from a slight superheating of the steam through throttling. To realize full benefit from increased steam pressure, the nozzle areas should be reduced to raise ring pressure to the maximum permissible, the nozzle expansion ratios being made correct for the higher pressure. 4. The relation between ring pressure and steam flow through nozzles will closely follow a straight line function, especially at its upper points, unless back pressure is very high; it then will bend along its entire length, following a hyperbolic equation. 5. The steam flow is practically independent of operating speeds with impulse turbines. 6. It is impossible to give definite rules for relations between steam rate or lb. of steam per kw-hr., at full load and at partial loads, but, in general, the following factors will vary but little for any size or type of impulse turbine up to 500 kw.

	1/4 load	1/2 load	3/4 load	Full load
Non-condensing	40%	20%	8%	0
Condensing	20%	10%	4%	0

With throttle governing these factors state the percent by which the steam rate at partial loads exceeds the steam rate at full or most efficient load on such throttle-governed turbines. 7. The power output for a given ring pressure will be influenced to a very small extent by superheating the steam. For a turbine operating condensing there will be practically no change, but for a non-condensing turbine, superheat will increase the power output at the rate of 0.3% for 10° F. superheat for the first 150° F. of superheat. The total steam flow at a given ring pressure of a non-condensing or condensing turbine will decrease at an approximate rate of 1% for 14° F. of superheat for the first 150° F. of superheat. As a result of these two considerations, the steam rate of a non-condensing turbine will decrease about 1% for an average of 10° F. superheat, and that of a condensing turbine will decrease 1% for an average of 14° F. superheat for the first 150° F. of superheat. 8. Moisture will increase the total steam flow through a turbine for a given ring pressure by as many percent as the percentage of moisture present for qualities above 97%. It will decrease the power for a given ring pressure to about the same extent for the same qualities. That is, the steam rate will be increased at the rate of 2% for each percent of moisture for qualities

above 97%. For qualities below 97% the effect will not be quite so great. 9. For steam line pressures of 150 lb. per sq. in. gage and over, small changes in back pressure or vacuum will not affect the steam flow of impulse turbines appreciably.

For non-condensing turbines, power will decrease and steam rates will increase, on an average, by the percentages given for each pound of added back pressure up to 15 lb. gage.

Steam pressure, lb. per sq. in. gage	200	150	125	100	75
Percent decrease in power or percent increase in steam rate	2	1.5	3	4	5

Condensing turbines, designed for 28-in. vacuum, with steam pressures of about 150 to 200 lb. per sq. in. gage, will increase in steam rate at about the following percentages:

Vacuum, in. of mercury	27	26	24
Increase in steam rate	6%	11.5%	18.5%

At partial loads, the increases will be greater. 10. As stated under (3) the steam line pressure will not greatly improve the steam rate, unless ring pressure also is raised to give proper pressure drop over the governor valve. If this change is made, the effect of steam line pressure on steam rate is as follows, 150 lb. per sq. in. gage, being taken as normal.

Non-condensing.

Steam line pressure, lb. per sq. in., gage	200	175	150	125	100	75
Percent change in steam rate	−5	−3	0	+5	+10	+22

Condensing.

Steam line pressure, lb. per sq. in., gage	200	175	150	125	100	75
Percent change in steam rate	−2.5	−1.5	0	+2.5	+5	+10

It will be found that many of these general rules apply also to throttle-governed turbines of greater size than 500 kw.

PERFORMANCE OF NON-CONDENSING TURBINES at 3600 r.p.m. under 1934 plant conditions is given in Table 10 in terms of engine efficiency at the generator terminals in percent. Most efficient load is generally full rating.

Table 10.—Engine Efficiencies of Non-condensing Turbines, 3600 r.p.m.

Size, Kw.	A*	B †	C ‡	Size, Kw.	A*	B †	C ‡
500	53%	58.5%	58 –61%	5,000	....	73%	72 –73%

Engg.*, July, 1930, to apply to average non-condensing turbines of various speeds for steam conditions up to 250 lb. per sq. in. gage, 550° F., and atmospheric pressure at exhaust.

† B. From discussion by R. T. Luce, *Mech. Engg.*, April, 1931, p. 275; gives performance of well-designed non-condensing turbines of 3600 r.p.m. for practice in 1931, in operating conditions where advantage is taken of the fact that expansion is confined almost wholly to the superheat region, and of the large quantities of steam required which permits the use of long blades. High values of the speed ratio can be used and leaving losses can be reduced to a minimum.

‡ C. Figures supplied by a leading builder of small turbines, and apply to 1934 plant conditions.

PERFORMANCE OF SMALLER CONDENSING TURBINES at 3600 r.p.m. under 1934 conditions, based upon engine efficiency at the generator terminals at most efficient load, usually at 80% of rating, is given in Table 11.

Table 11.—Engine Efficiencies of Small Condensing Turbines, 3600 r.p.m.

* A. From Economic Considerations in the Application of Modern Steam Turbines to Power Generation, A. G. Christie, *Mech. Engg.*, July, 1930; applies to average single-cylinder, 3600 r.p.m. turbines for steam conditions up to 300 lb. per sq. in. gage, 600° F., 28.5 in. vacuum.

† B. Figures supplied by a leading builder of small turbines, and apply to 1932 plant conditions.

‡ C. Similar figures to B, from a second builder of small units for industrial plants under 1932 steam conditions.

The figures of Table 12, supplied by an American manufacturer, represent best efficiencies for multi-stage, geared, condensing turbines of the impulse type, operating with conditions that roughly approximate: 200 lb. per sq. in. gage, 150° F. superheat, 28 1/2 in. vacuum. These units are suitable for pump drive, blower drive, marine service and other

applications. Turbine speed will be selected to suit the conditions by selecting proper gear ratio. Figures include the gear loss.

Table 12.—Efficiency of Multi-stage, Geared Condensing Turbines

Rated B.Hp.	Engine Efficiency Based on B.Hp.	Rated B.Hp.	Engine Efficiency Based on B.Hp.	Rated B.Hp.	Engine Efficiency Based on B.Hp.
200	52.5	750	64.5	3,000	71.8
300	57.0	1000	66.0	5,000	73.3
400	60.5	1500	68.2	7,500	73.8
500	62.0	2000	69.8	10,000	74.0

VACUUM in all the above and subsequent data is assumed to be measured in inches of mercury, and referred to a 30-in. barometer. Thus a 29-in. vacuum is equivalent to (30 − 29) = 1 in. absolute pressure = 0.491 lb. per sq. in., absolute = 96.67% vacuum.

TESTS OF SMALL TURBO-GENERATORS.—Tables 13 and 14 are from tests of small turbo-generators such as are used in industrial plants and small central stations.

Efficiencies in Table 16 may be exceeded in modern efficient turbines operating with higher steam temperatures.

Performance of 1800 r.p.m. Condensing Turbines under steam conditions up to 450 lb. per sq. in. gage, 750° F. and 29 in. vacuum is shown in Table 17. (From data in Economic Considera-

tions in Application of Modern Steam Turbines to Power Generation, A. G. Christie, *Mech. Engg.*, July, 1930.) This table presents values of the engine efficiency η_e at the generator terminals at the most efficient load for given name plate ratings of the turbines. In general most efficient load is at about 80% of rating. Thus for a turbine rated at 30,000 kw. the engine efficiency η_e = 77.2% applies to a generator output at most efficient load of 30,000 × 0.8 = 24,000 kw.

Table 17.—Performance of 1800 r.p.m. Condensing Turbines

Rating, kw.	Engine Efficiency, η_e	Rating, kw.	Engine Efficiency, η_e	Rating, kw.	Engine Efficiency, η_e
10,000	74.8	50,000	78.3	90,000	79.4

40,000	78.0	80,000	79.2		

DISTRIBUTION OF LOSSES.—K. Baumann (Some Recent Developments in Large Steam Turbine Practice, *Jour.* Inst. Elec. Engrs., lix, p. 590, 1921), presents the following figures for the parasitic losses of an impulse steam turbine of 28,900 kw. output at the generator coupling at 1500 r.p.m.

a. Mechanical losses—constant kw. losses in per cent of turbine output at coupling.

	Loss Measured in kw. at Coupling	Loss in Percent of Output
Disc friction	315	1.09
Diaphragm leakage losses	174	0.6
High-pressure gland losses	185	0.64
Water and steam seal losses	36	0.12
Bearing losses	109	0.38
Governor and oil pump drive	16	0.05
Total mechanical losses	835	2.89

b. Velocity losses in percent of isentropic heat drop $(h_1 - h_2)$.

Steam chest losses	0.53%
Leaving losses, last blades	2.85
Exhaust losses	0.75
Total steam chest and leaving losses	3.38
Total in percent of turbine output at coupling	3.64
Total losses of turbine in percent of turbine output at coupling	6.53

These losses do not include nozzle or blade losses usually expressed as diagram or blade efficiency.

DATA ON ENGINE EFFICIENCIES will be found in Post War Turbine Development, C. D. Gibb (*Proc.* Inst. Mech. Engrs., 1931). He states the following values of the *internal engine efficiency* of turbines built by C. A. Parsons & Co.; 1000 kw., 67%; 2500 kw., 80%; 5000 kw., 82%; 10,000 kw., 84%; 25,000 kw., 85.5%. He calls particular attention to the gains made in years 1920–1930 in the efficiency of the smaller turbines. This gain is attributed to improved designs of nozzles and blading, to the use of higher values of ρ, the ratio of wheel to steam velocities, to the elimination of eddies in the steam flow by the use of coned blading, to careful design of steam chests and nozzle boxes, and to thin leaving edges on nozzles and blades. A comprehensive table of turbine performances is included in the paper.

The Brown Boveri *Review*, Jan. 1931, states that the largest single-cylinder turbine at 3000 r.p.m. built by that company develops an engine efficiency at the coupling of 81%, with 300 lb. per sq. in. gage steam pressure. Data are presented on a peak load turbine which operates over a range of load from 50% to 150% of nominal rating at an average engine efficiency at the coupling of 81%. The heat consumption varies only 6% from 50% to 150% of nominal rating.

Sweden,
before the [illegible]
at the generator terminals was 85.6%. These are among the best recorded figures and indicate a high efficiency of the turbine blading.

Alden and Balcke (Steam Turbine Practice in the U. S., *Trans.*, A.S.M.E., FSP–55–3a, 1933)

[illegible] the range of 72.5% to [illegible]

Tests of a 40,000-kw. General Electric Turbo-generator Unit.—No steam extracted from turbine. (See Turbines, N.E.L.A., 1930, Test No. 11.) 17-stage turbine, 1800 r.p.m.; generator, 13,800 volts, 3-phase, 60 cycles; exciter, 250 volts at full load, 160 kw., 1800 r.p.m., direct-connected; generator furnished with U-tube fin air cooler. The test results are given in Table 18.

Test of an 80,000-kw. Westinghouse Steam Extraction Turbo-generator Unit with steam extracted at four stages of turbine (See Turbines N.E.L.A., 1931, Test No. 2). Cross-compound unit; combination impulse and reaction type; high-pressure cylinder, single flow design, with a 2-row impulse wheel and 13 rows of Parsons blading; low-pressure turbine, double flow with 9

Parsons rows on each side. The turbine has three governor control valves arranged to carry 45,000 kw. with the primary valve, 60,000 kw. with the primary and secondary valves, and 80,000 kw. with the primary, secondary, and tertiary valves, when operated bleeding under design steam conditions. Each turbine runs at 1800 r.p.m. All bleeder heaters are of the closed type. Each turbine drives a 40,000-kw. generator, 90% power factor, 13,800 volts, 3-phase, 60 cycles. The 300-kw. exciter is direct-connected to the high-pressure turbine. Each generator has a 15,000-sq. ft. U-fin air cooler, to use condensate, together with a 6255-sq. ft. U-fin air cooler to use raw river water. The results of the tests together with bleeder heater data are given in Table 19. A surge tank is placed between No. 4 and No. 3 heaters, and this accounts for differences in the feed-water passing through No. 4 heater and through the other heaters in series.

Abbreviations in the table: Under "Type" is given an abbreviation for the manufacturer and the type of turbine. Thus the first unit "BB; HP" designates a Brown Boveri & Co. turbine operating high pressure. The symbols are as follows:

BB = Brown Boveri & Co. (Switzerland). AC = Allis-Chalmers Mfg. Co. STAL = Svenska Turbinenfabriks Aktiebolaget Ljungstrom, (Sweden). O = Maschinenfabrik Oerlikon, (Switzerland). EB = Erste Brunner Maschinenfabrikgesellschaft, (Czecho-Slovakia). AEG = Allgemeine Elektricitats-Gesellschaft, (Germany). GE = General Electric Co., (America). How = Jas. Howden & Co., (Scotland). LMAN = Ljungstrom turbine built by Maschinenfabrik Augsburg Nürnberg, (Germany). GMA = Gorlitzer Maschinenfabrik Actiengesellschaft, (Germany). RW = Richardson, Westgarth & Co., (England). EW = Escher Wyss & Co., (Switzerland). BTH = British Thomson-Houston Co., (England). Stork = Machinefabriek Gebr. Stork & Co., (Holland). CAP = C. A. Parsons & Co., (England). West. = Westinghouse Elec. & Mfg. Co., (America). MV = Metropolitan-Vickers Co., (England). SSW = Siemens-Schuckert-Werke, (Germany). SACM = Société Alsacienne de Construction Mécaniques. HP = High-pressure unit. NB = Condensing unit, no extraction heaters. 2S = Condensing unit with two stages for extraction heating of feedwater. 3S = Unit with three stages for extraction heating. 4S = Unit with four stages for extraction heating. R = Reheat Temperature. VDI = *Zeitschrift des Vereins Deutscher Ingenieure*. *Engg.* = *Engineering*, London. NELA = Publications of National Electric Light Association. In 1933, this association was consolidated with the Association of Edison Illuminating Companies to form the Edison Electrical Institute. *The Engr.* = *The Engineer*, London.

EFFECT OF AGE ON EFFICIENCY OF TURBINES.—Data in *Turbines*, N.E.L.A., 1932, indicate that replacements of blading and turbine overhauls tend to restore turbines to their original efficiency. It is difficult to draw any general conclusion as to effect of age over an extended period since variations in individual cases are considerable. The loss does not appear to be more than 1% per year, which may be offset by current renewals and maintenance. The last rows of blades on many units may be badly eroded by moisture, yet the efficiency is affected little. This suggests the use of rugged, well rounded blade shapes to resist erosion.

TURBINE TEST DATA from the sources noted have been gathered in Table 20. The figures quoted represent the steam rate or heat rate of the turbine at most efficient load.

15. STEAM TURBINE CALCULATIONS

Steam turbine calculations may be made for the purposes of: *a*, design; *b*, to estimate turbine performance with extraction heaters or bleeder connections; *c*, to check test results. The methods of making these calculations are varied, since the procedure is not standardized. Many assumptions are made to simplify the work. The following methods yield results satisfactory for estimating and checking purposes.

CHARACTERISTIC CURVES.—Three characteristic curves are needed to analyze turbine performance. The first of these, the *Willans Line*, curve *A*, Fig. 33, indicates the relation between total steam per hour and load. This line may be assumed for throttle governing to be straight between no load and *most efficient load*. Above most efficient load, the form of the line depends upon the overload valve arrangement, and the points at which overload steam is admitted to the turbine. In any case, the slope of the line differs from that below most efficient load. With nozzle governing, the Willans Line should consist of a series of straight lines at slightly different slopes, with steps at each valve opening. For estimating purposes a straight line up to most efficient load may be substituted for this series, or the series of stepped lines may be used if data are available for their estimation.

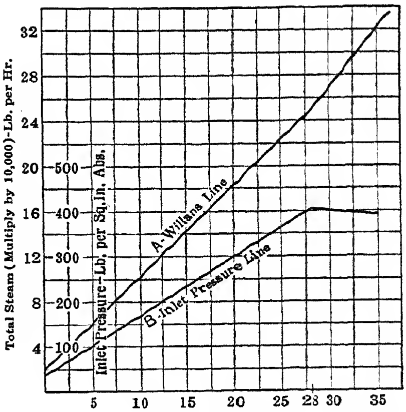

FIG. 33. Willans and Inlet Pressure Lines for 35,000-kw. Turbine

When guarantees of steam consumption, or when performances of the given turbine or of a similar unit are not available, the Willans Line may be plotted as follows: The heat drop from initial conditions to final pressure can be found. From Tables 7 to 12, or from Table 17, the engine efficiency at most efficient load, based on generator output (or B.Hp.), can be selected. At most efficient load of a turbo-generator,

$$\text{Total steam} = \frac{3412}{\text{Engine efficiency} \times \text{Total heat drop}} \times \text{Most efficient load in kw.}$$

The no-load total steam with generator at full voltage may be approximated from Table 21, which expresses no-load steam in percent of total steam at most efficient load for various name plate nominal ratings. These figures apply to single-cylinder turbines with most efficient load at 80% of the name plate ratings for units 500 kw. and above. Most efficient load in small non-condensing turbines is frequently full load.

Non-condensing No-load Steam depends largely on steam conditions. For units of 500 kw. and less, assume no-load steam, y = 20 to 25% of total steam at most efficient load.

No-load steam depends upon turbine design and may vary considerably from the values given in Table 21. For multi-cylinder turbines, the no-load factor may be greater than stated, on account of the additional bearings.

The preceding values of the no-load factor y, apply only to straight condensing turbines. Few data are available on values for regenerative and reheating turbines. Morse

(Power Plant Engineering and Design) suggests another factor ψ to find no-load steam. ψ is the product of no-load steam and isentropic heat drop from initial throttle conditions to exhaust pressure. Morse (p. 362) finds that ψ depends on the size of unit, and the values in Table 22 are taken from his data, based on recent tests.

Table 21.- No-load Steam Consumption of Turbines, Percent of Total Steam

Name Plate Rating, kw. condensing..	1000	2000	3000	4000	5000	10,000	15,000	20,000	25,000	30,000	40,000	50,000 and over
% of Total Steam at Most Efficient Load..........	13.8	12.5	11.8	11.3	10.9	9.9	9.2	8.8	8.6	8.4	8.2	8.0

Table 22.—Values of ψ

Rated capacity of unit, thousands of kw...	20	30	50	60	70	80	90	100
ψ, millions of B.t.u. per hour.............	6.5	10.4	17	18.8	19.9	20.8	21.8	22.8

When the heat drop $(h_1 - h_2)$ is known, the no-load steam becomes $w_n = \psi/(h_1 - h_2)$ lb. per hr.

The Willans Line now can be drawn between no-load and most efficient load. At full load the steam rate depends on the design of turbine and exceeds that at most efficient load. It may for estimating purposes be assumed 5% in excess of that at most efficient load. The total steam at full load then can be computed and the remainder of the total steam line can be drawn.

Example:—A 35,000-kw. turbine, 1800 r.p.m., single-cylinder, complete expansion, operates with 400 lb. per sq. in. gage, 750° F., and 29 in. vacuum. Assume most efficient load = 0.8 × 35,000 = 28,000 kw. Heat drop from 415 lb. per sq. in., abs., 750° F. to 29 in. vac., entropy, s, = 1.6586 = 1389.5 − 891.3 = 498.2 B.t.u. per lb. Engine efficiency at generator terminals at most efficient load of 28,000 kw. for turbine of 35,000 kw. rating, η_e = 77.6%. ∴ Steam rate at most efficient load = 3412/(498.2 × 0.776) = 8.82 lb. per kw-hr. output. Total steam at most efficient load = 28,000 × 8.82 = 246,960 lb. per hr. No load factor = 8.3%; no load steam = 0.083 × 246,960 = 20,497 lb. per hr. Full load steam rate = 1.05 × 8.82 = 9.26 lb. per kw-hr. ∴ Full load total steam = 9.26 × 35,000 = 324,100 lb. per hr. The Willans Line is shown in Fig. 33 as curve *A*.

The Inlet Pressure Curve is the second characteristic curve. In throttle-governed turbines it shows the relation between the pressure before the first stage and the load. It has been confirmed by test that the inlet pressure is nearly proportional to the flow of steam through the turbine. The steam supply as shown by the Willans Line is related to load. Hence inlet pressure can be plotted against load. Inlet pressure at most efficient load is less than throttle pressure by the amount of the pressure losses through throttle valve, strainer, and governor valve. This loss ranges from 3 to 5% of the absolute initial pressure. Below most efficient load, inlet pressure at any load is proportional to total steam flow. Above most efficient load, added steam passes through the throttle valve with added losses. These throttling losses above most efficient load can be assumed to vary as the square of total steam, since velocity through these areas is proportional to the total steam.

Example:—In the 35,000-kw. unit of the preceding example, let the throttle and governor drop at most efficient load = 3% of abs. initial pressure = 0.03 × 415 = 12.5 lb. per sq. in. Inlet pressure at most efficient load = 415 − 12.5 = 402.5 lb. per sq. in., abs. Inlet pressure at no-load = (20,497/246,960) × 402.5 = 33.4 lb. per sq. in., abs. Throttling and governor loss at full load = $(324{,}100/246{,}960)^2$ × 12.5 = 21.5 lb. per sq. in. ∴ Full load inlet pressure = 415 − 21.5 = 393.5 lb. per sq. in., abs. Inlet pressure line plotted on Fig. 33 as curve *B*.

With nozzle-governed turbines, the pressure before the nozzle is presumed to remain constant. However, the pressure before the second stage will vary with steam flow up to most efficient load, and can be plotted and estimated in the same way as inlet pressure, provided one knows or can assume the first-stage pressure at any given flow.

The Condition Curve is the third characteristic curve. It represents the loci of points on a Mollier diagram which approximately represent the steam condition at the entrance to each stage and the final true end point. The exact condition curve which may be needed for design purposes only can be plotted from a step-by-step calculation of the nozzle, blade, disc and leakage losses of each stage, consideration being given to carry-over velocities. For estimating purposes, and for checking performance, such an accurately drawn curve is not necessary. Experience has shown that approximated curves serve for ordinary needs, such as for estimates of station performance with regenerative heating.

In the case of a complete expansion turbine with throttling governor, it is assumed that the steam is throttled at constant total heat from the steam pressure and temperature (or quality) before the throttle valve to the inlet pressure. The inlet pressure points

therefore can be readily located upon the Mollier diagram. Fig. 35 shows these points plotted from the data on Fig. 33, assuming throttle conditions at all loads of 415 lb. per sq. in., abs., 750° F. Should temperature at the throttle decrease with load due to superheater characteristics, the new throttle condition could be used as the starting point for the throttling to inlet pressure. However, it would be necessary to plot Willans Lines and new inlet pressure lines for the changed steam conditions in order to determine the inlet pressure under the new throttle conditions.

Manufacturers usually will furnish either condition curves for given loads or data on the conditions of the steam at various bleeder and reheating points, and at exhaust from the last row of blades, as well as data on the leaving losses. This information is considered as part of the performance data on the unit. These condition points can be readily plotted on a Mollier diagram, and the condition curves drawn through them. Similarly, if test data are at hand indicating steam conditions at various points, and from which tests the true end point can be found, condition curves can be drawn through these points.

An Estimate of Performance of any turbine, needed for preliminary studies, can be made by plotting condition curves on the basis of certain assumptions. In the case of a turbine with throttling governor, the probable engine efficiency of a unit at most efficient load, if operated straight condensing, can be assumed from data in Tables 7 to 12 or Table 17. The steam rate based upon generator output can be computed from the assumed engine efficiency. The method of finding the probable true end point is outlined in Conditions at Turbine Exhaust, by Christie and Colburn (*Turbines*, N.E.L.A., 1932), from which the following paragraphs are abstracted.

The steam in expanding must furnish energy to supply the net output at generator terminals plus all generator and mechanical losses plus the energy equivalent to the leaving losses.

The manufacturer usually furnishes data upon generator efficiency. If such data are not at hand, the following approximate formulas may be used which express present-day (1933) generator efficiency at nominal or name plate rating. Generator efficiency in percent at nominal rating of unit, which rating is expressed in kw., is

For 1800 r.p.m. turbines $\eta_g = 98.85 - \{9/(\sqrt{\text{rating}/1000})\}$

For 3600 r.p.m. turbines $\eta_g = 96.0 - \{2.5/(\sqrt{\text{rating}/1000})\}$

Corrections for partial loads in percent of full load efficiencies are approximately:

Generator load, Percent of rating	100	80	75	50	25
1800 r.p.m.	100%	99.6%	99.5%	98.3%	95%
3600 r.p.m.	100%	99.3%	99.0%	96.5%	92.5%

The *coupling kw.* can be found by dividing the output by the generator efficiency.

Example:—Referring to the 35,000-kw. unit noted above, the generator efficiency at full load $\eta_g = 98.85 - (9/\sqrt{35{,}000/1000}) = 97.33\%$. At most efficient load, generator efficiency $\eta_g = 97.33 \times 0.996 = 96.94\%$. Coupling kw. = (28,000/0.9694) = 28,885 kw. at most efficient load. Coupling kw. at other loads can be found in a similar manner.

THE MECHANICAL LOSSES of a turbine consist of friction in bearing and thrust devices, power to drive governor, oil pumps, and water glands, if used, and any other mechanical losses. Radiation is of a small order, except in small auxiliary turbines, and being in the nature of heat abstracted from the steam, can, for purposes of computation, be included in the mechanical losses.

Mechanical losses depend almost entirely upon the speed of the unit, and may be considered constant at all loads, since the speed is maintained substantially constant. They are expressed as a percentage of the nominal rating of the generator, and also can be supplied by the manufacturer. When not so supplied they may be estimated by the following approximate formulas for single-cylinder units up to 100,000 kw.

1800 r.p.m. turbines,

$$\text{Loss in percent of nominal rating} = 1.5 - 1.15 \log_{10} (\text{rating}/10{,}000)$$

3600 r.p.m. turbines,

$$\text{Loss in percent of nominal rating} = 4/(\sqrt{\text{rating}/1000})$$

Mechanical losses added to coupling kw. give *internal kw.* that is, the net power that must be developed upon the shaft just inside the gland casing.

Example: The mechanical losses in the 35,000-kw., 1800 r.p.m. unit would be

$$1.5 - 1.15 \log_{10} (35{,}000/10{,}000) \times (35{,}000/100) = 306 \text{ kw.}$$

These losses are constant at all loads. ∴ Internal kw. at most efficient load = 28,885 + 306 = 29,191 kw. Internal kw. at other loads can be found by adding 306 kw. to the coupling kilowatts at that load.

The heat to internal work h_e in B.t.u. per pound of steam at a given load now can be found.

$$h_e = 3412 \times I\ \text{kw.}/w$$

where I kw = total internal kw. and w = total lb. of steam per hr. passing through the turbine.

Of the total heat h_1 that enters the throttle, h_e is all that passes out of the casing as work; the remainder goes to the condenser with the exhaust steam. The heat to exhaust per lb. of steam is $h_o = h_1 - h_e$ as shown on Fig. 34. h_o is known as the *exhaust point*.

EXAMPLE: Heat to internal work at most efficient load on 35,000 kw. turbine = $(3412 \times 29{,}191)/246{,}960 = 403.4$ B.t.u. per lb. Heat to exhaust $h_o = 1389.5 - 403.4 = 986.1$ B.t.u. per lb.

WETNESS AT EXHAUST is an important factor in leaving losses, erosion, resuperheating, and condenser design. It readily can be found from the Mollier diagram when the total heat h_o is determined.

Guy (Tendencies in Steam Turbine Development) presents curves from which the following data are taken. These enable a quick estimate to be made of exhaust conditions. Table 23 indicates the steam temperature in degrees F. at the throttle required to provide the given percent moisture at exhaust for stated internal efficiencies η_i.

Table 23.—Relation between Throttle Temperature and Pressure and Moisture in Exhaust Steam

1400	.....	.....	980	940	910	875	840	.....	.....	.....	.....	.....	980	940

THE LEAVING VELOCITY AND EXHAUST LOSS occurs in the exhaust hood between the last wheel exit and the exhaust flange to the condenser. See Leaving Velocity and Exhaust Loss in Steam Turbines, E. L. Robinson, *Trans.* A.S.M.E., FSP–56–10, July, 1934. The loss consists of both kinetic energy loss and pressure loss through the hood, since, according to the Power Test Code, vacuum is measured at the exhaust flange. This loss increases rapidly with load, and also varies with location around the wheel annulus. The heat equivalent to the loss produces no useful work and passes to the condenser as part of h_o. The energy equivalent to this loss comes from the expansion of the steam from initial conditions to exhaust pressure. The steam condition at the end of the condition curve is represented by point h_{Bo}, Fig. 34, where $h_o - h_{Bo}$ = leaving velocity and exhaust losses.

The leaving velocity and exhaust loss sometimes called simply the *leaving losses* may be expressed in B.t.u. per lb. flow to the condenser, as a percent of adiabatic heat drop, or as a percent of the total energy theoretically available for conversion to switchboard power. In practice, it varies from 4 to 36 B.t.u. per lb. flow to the condenser or from 1 to 7.5% of the adiabatic heat drop. See Turbines, N.E.L.A., 1932.

The manufacturer should furnish an estimate of leaving velocity and exhaust loss, as this can be determined from the turbine design. Robinson states that with a particular exhaust operating at fixed steam conditions, the leaving velocity and exhaust loss increases roughly as the square of the quantity of steam flowing to the condenser. With a particular exhaust passing a fixed flow, increasing the total available energy in the higher stages of the turbine by improved steam conditions, correspondingly reduces the percentage loss in the exhaust. With a fixed percentage loss in a particular exhaust, the power may be increased, by improved steam conditions, as the $^3/_2$ power of the total available energy by increasing the flow to the condenser.

When data are not available, the average annulus velocity, equivalent to the leaving velocity and exhaust loss, may be approximated by multiplying the weight flow to the condenser by the specific volume at the exhaust flange and dividing by the annulus area of the last blade row. If A_o = area of last blade annulus, sq. ft.; W = lb. of steam per sec. to condenser; v_{so} = specific volume and quality at pressure at exhaust flange, cu. ft.

per lb.; the average annulus velocity, $V_o = Wv_{so}/A_o$. The approximate leaving velocity and exhaust loss $h_L = 1.25\ (V_o/223.8)^2$. The condition of the steam at the true end-point in Fig. 34 may be assumed as $h_{Bo} = h_o - h_L$.

EXAMPLE: The leaving velocity and exhaust loss at most efficient load of the 35,000-kw. unit is 10 B.t.u. $\therefore\ h_{Bo} = 986.1 - 10 = 976.1$ B.t.u. per lb.

This gives an assumed quality leaving the last row of blades of 88.65% or 11.35% moisture. Leaving velocity and exhaust loss at full load, neglecting specific volume change, equals

$$(324{,}100/246{,}960)^2 \times 10 = 17.2 \text{ B.t.u. per lb.}$$

This method gives lower values than the actual leaving loss at loads below about 1/3 load, due to too low entering steam velocities. These calculated values may be increased arbitrarily 25 to 50% at 1/4 load and less.

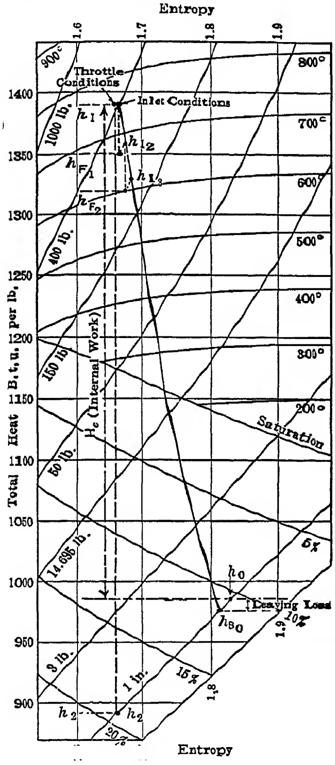

FIG. 34. Condition Curve

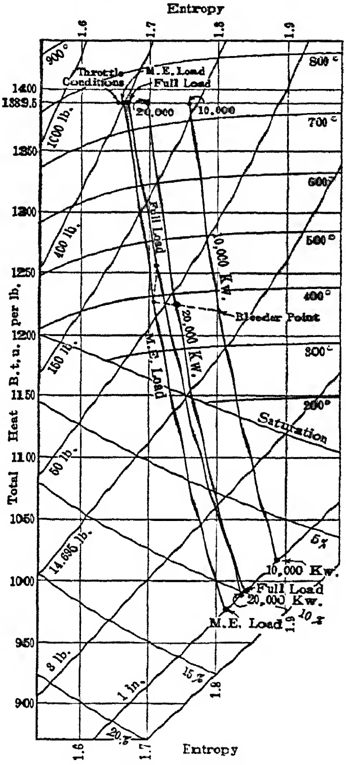

FIG. 35. Conditions Curves for Various Loads

The true end points are the lower ends of the condition curves for the various loads. The exact form of the curve between the initial point and the end point depends upon the design and efficiency of the various sections of the particular machine. For purposes of performance analysis, the curve can be approximated with sufficient accuracy on the Keenan-Mollier diagram by laying a straight edge between the two end-points and mid-way marking a point to the left of the straight edge and 3/8 in. distant. A smooth curve through the initial point, this marked mid-point and the end-point can be taken as the approximate condition curve.

In the case of a turbine with nozzle governing, the first nozzle is throttled until the load requires its full capacity, then the next nozzle is throttled, etc. As each nozzle

reaches full capacity, the initial point of the condition curve for the first stage becomes the same. The end-points for the condition curve of this first stage will vary, depending upon the efficiency and capacity of the turbine. When one nozzle is throttling the steam and one or more other nozzles are giving full delivery, there must be two expansion lines for the first stage. Thereafter a single condition curve suffices. But the turbine efficiency must be known in order to plot the complete condition curve.

To find the leaving velocity and exhaust loss on bleeder turbines, the total steam to the condenser and its condition must be known. This condition generally is not known unless data are available from the manufacturer on the relative efficiencies of various sections of the turbine.

The moisture in the exhaust steam and at the true end point can be estimated from the Mollier diagram. European designers aim to keep this moisture content less than 10%. American turbines have operated with moisture contents as high as 14%.

Table 24 presents the calculations necessary to find the true end points at a series of loads for the 35,000-kw. turbine considered in the examples given above.

These data of initial points and end points are plotted on a Mollier diagram in Fig. 35, and condition curves have been drawn for the various loads.

Table 24.—Calculation of End Points of Condition Curves

Load, kw.	Full, 35,000	Most Efficient, 28,000	20,000	10,000
1. Total steam (from Willans Line), lb. per hr.	324,100	246,960	182,260	101,380

THE CONDITION CURVE EFFICIENCY, η_{cc}, of a turbine with no extraction or reheating, is the ratio of the heat to work, as shown by the condition curve, to the total heat drop. In Fig. 34 the condition curve efficiency

$$\eta_{cc} = (h_1 - h_{B_O})/(h_1 - h_2)$$

THE INTERNAL EFFICIENCY, η_I of such a turbine is the ratio of the heat to work on the shaft, just inside the casing, to the total heat drop. In Fig. 34 the internal efficiency

$$\eta_I = (h_1 - h_o)/(h_1 - h_2) = \eta_{cc} - L_L$$

where L_L is the leaving loss expressed as a percent of the total heat drop.

EROSION of the inlet edges of blades by water droplets in the low pressure steam frequently has been encountered. Christie and Colburn (Turbines, N.E.L.A., 1932) show that in a pure impulse turbine, the moisture content of the steam entering the last blade row is greater than at the outlet or true end-point condition. In a Parsons turbine the reverse is the case, with moisture content highest at the true end-point. Since the last blade rows on most large impulse turbines now are given a certain degree of reaction, it generally may be assumed that the moisture content at the true end-point is the greatest that prevails in the turbine.

STAGE EFFICIENCY is the ratio of the heat to work in a stage of a turbine, measured on the shaft, to the isentropic heat drop for that particular stage. Nozzle and blade losses together with disc and idle blade loss and leakage must be considered. In general $\eta_s = \eta_n\eta_b\gamma$, where η_s = stage efficiency; η_n = nozzle efficiency; η_b = diagram efficiency; η_{cc} = condition curve of efficiency; γ = a factor to cover disc, idle blade leakage, and radiation losses. In large turbines γ is large, about 98%, for units with full peripheral admission and moderate blade speeds when labyrinth packings are tight. On small machines with partial admission, high wheel speeds and large leakage, γ is smaller. In Fig. 34 the stage efficiency $\eta_s = (h_1 - h_{I_2})/(h_1 - h_{F_1})$ for the first stage, and similarly for other stages.

It is well known from thermodynamics that the heat returned as reheat in a stage (as

for instance $(h_{I2} - h_{F1})$ in the first stage of Fig. 34) increases the available heat to produce work in succeeding stages. Hence the total heat available to produce work in the several stages, $\Sigma(h_1 - h_{F1}) = \Sigma h_r$ will exceed the total heat drop $(h_1 - h_2)$.

The ratio, $\Sigma h_r/(h_1 - h_2)$ is known as the *Reheat Factor*, *R*.

$$(h_1 - h_2) \qquad (h_1 - h_2) \qquad (h_1 -$$

where η_s = average stage efficiency.

Also $\eta_I = \eta_{cc} - L_L = \eta_s R - L_L$. Hence, with the condition curve found, it is possible to estimate the average stage efficiency, provided the reheat factor R is known. The calculation of R is difficult, since the stage efficiency in the saturation region generally is assumed to decrease 1% for each 1% of additional wetness. Kraft (The Modern Steam Turbine) suggests that the stage efficiency at any point in the saturated region can be found by multiplying the efficiency for the superheated region by the quality at the given point, and that tests have verified this assumption. Hence step-by-step methods must be used to find exact reheat factors. Table 25 has been taken from Report on Reheat Factors, E. L. Robinson (*Mech. Engg.*, Feb., 1928, pp. 1155–6). These reheat factors may be used for estimating purposes. The table is calculated for constant stage efficiency of 80% and initial superheats, 0 to 400° F. It is closely approximate for initial pressures from 20 lb. per sq. in., abs. to 700 lb. per sq. in., abs. These factors are based on Keenan's Steam Tables and Mollier Diagram. The table gives reheat factors R for various isentropic heat drops for steam expansion with an infinite number of stages.

Table 25.—Values of Reheat Factors, *R*

Isentropic Heat Drop, B.t.u. per lb.	Saturation	100° F. Superheat	200° F. Superheat	300° F. Superheat	400° F. Superheat
	Reheat Factor				
50	1.006	1.013	1.011	1.010	1.009
100	1.011	1.021	1.024	1.021	1.019
150	1.017	1.023	1.036	1.034	1.030
200	1.022	1.026	1.038	1.048	1.042
250	1.027	1.030	1.039	1.051	1.056
300	1.033	1.035	1.041	1.052	1.065
350	1.038	1.040	1.044	1.053	1.064
400	1.043	1.045	1.048	1.054	1.064
450	1.049	1.050	1.052	1.057	1.065
500	1.054	1.055	1.057	1.060	1.066
550	1.060	1.061	1.062	1.064	1.068

$$\text{Reheat Factor} = \frac{\text{Actual Heat to Work on Condition Curve}}{\text{Average Stage Efficiency} \times \text{Isentropic Heat Drop}} = \frac{}{\eta_s (h_1 - h_2)}$$

With any particular number of stages the heat recovery $(R - 1)$ is decreased by a fraction nearly equal to the reciprocal of the number of stages, *i.e.*, by a fraction $(n - 1)/n$, where n = number of stages. Thus with 500 B.t.u. adiabatic heat drop and 300° F. superheat, with 80% stage efficiency, the reheat factor for a 17-stage machine would be $R_{17} = 1 + \{16\,(R - 1)/17\} = 1 + \{16 \times 0.060/17\} = 1.056$. Also with any other stage efficiency, the heat recovery is greater or less, nearly in direct proportion, as the stage loss is greater or less. If the stage efficiency were 70% instead of 80% the reheat factor with an infinite number of stages with 500 B.t.u. adiabatic heat drop and 300° F. superheat is $R_{70\%} = 1 + \left(\frac{- 0.70}{- 0.80}\right)(R_{80\%} - 1) = 1 + \frac{0.3}{0.2} \times 0.060 = 1.090$. On a 17-stage machine this becomes 1.085.

CUMULATIVE HEAT.—In a multi-stage turbine the sum of the isentropic heat drops Σh_r in the individual stages is greater than the adiabatic heat drop $(h_1 - h_2)$, from initial conditions to final pressure, by the reheat factor R. That is, $\Sigma h_r = R(h_1 - h_2)$. This is called the cumulative heat. In steam turbine design, it is often necessary to determine the heat actually available for work at any point on the condition curve. When the stage efficiency is known and H_s is the total heat to work from initial conditions to the given point, then cumulative heat $H_c = H_s/\eta_s$. This cumulative heat then is distributed among the various stages and leads to a proper design. See Goudie Steam Turbines, p. 581, for methods of distributing cumulative heat and for determining specific volumes at the various points.

Extraction Calculations

Most large turbines now are provided with extraction points from which steam is bled for regenerative feedwater heaters. These heaters vary from one to five in number. If economizers are used, only one or two feed heaters are added. If air preheaters only are installed, usually three or more heaters are used.

When steam is thus extracted at intermediate stages from a turbine, more steam must enter the throttle for a given generator output than if the turbine were operating straight condensing. Reynolds (Factors Affecting the Gain from Feedwater Heating, *Elec. Jour.*, June, 1929) gives in Table 26 such increases, expressed as percent of throttle flow for the same output for non-extraction operation, due to stage extraction for feedwater heating, and steam extracted for feedwater heating as a percent of total throttle flow when operating with extraction. Steam conditions: throttle pressure, 300 lb. per sq. in., gage; throttle temperature 622° F.; vacuum, 29 in. Hg.

Table 26.—Increase in Steam Flow and Steam Required for Extraction Heating
Expressed as Percentage of Throttle Flow for Non-extraction Operation

Final Feed-water Temp., ° F.	Extraction Stages					Extraction Stages				
	1	2	3	4	5	1	2	3	4	5
	% Increase in Steam Flow					Steam Extracted—% of Throttle Flow				
180	4.0	3.5	....	....	....	9.6	9.9	....	....	....
200	5.5	4.5	4.2	....	....	11.3	11.6	11.9	....	....
220	7.5	6.0	5.5	5.0	....	13.0	13.2	13.5	13.8	....
240	9.0	7.5	6.5	6.0	5.5	14.6	14.9	15.2	15.5	15.7
260	11.0	9.2	8.0	7.5	7.0	16.0	16.4	16.8	17.1	17.3
280	....	11.0	10.0	9.2	8.5	....	18.0	18.3	18.6	18.9
300	....	13.2	11.7	11.0	10.0	....	19.3	19.8	20.1	20.4
320	....	....	13.5	13.0	12.0	....	....	21.4	21.7	22.1
340	....	....	17.0	15.5	14.5	....	....	22.8	23.2	23.6
360	....	....	....	18.5	17.0	....	....	....	24.7	25.1
380	....	....	....	21.5	20.0	....	....	....	26.0	26.5
400	....	....	....	25.0	23.5	....	....	....	27.6	28.1

The percent increase in steam flow will be slightly lower with higher steam pressures and slightly higher with lower steam pressures. For estimating purposes, the values in Table 26 may be multiplied by 1.05 for 200 lb., by 0.95 for 400 lb., by 0.915 for 600 lb., and 0.88 for 1200 lb.; all pressures in lb. per sq. in. gage. Similar corrections apply to the percentage of steam extracted. The latter data may be used to estimate steam to condenser, the leaving losses, and condenser capacity.

The condition curve is modified by this additional throttle steam, as increased steam flow through the high-pressure stages leads to increased efficiency in these sections. Also decreased flow to the condenser results in lesser leaving loss. The general result of bleeding a turbine for regenerative reheating is to increase its overall efficiency, provided the stages are designed for operation under extraction conditions.

To plot exact condition curves, manufacturers can furnish data on the pressures, temperatures, or quality, and heat contents at the various extraction points and at exhaust or true end-point. With leaving losses also given, the condition curves at the various loads can be plotted. Lacking such data, an approximation to the condition curves can be made, as outlined in preceding sections, by assuming the efficiency of a similar size of turbine operating under the same steam and exhaust conditions.

Performance data generally are expressed in terms of final feedwater temperature leaving the last heater. The choice of this temperature in the design of a plant depends upon the number of heaters and the personal judgment of the engineer. In general, at most efficient load this is about 70% to 80% of the saturation temperature at boiler pressure when no economizer is used.

Hendrickson and Vesselowsky (A Thermal Study of Available Steam-power-plant Heat Cycles, *Trans.* A.S.M.E., FSP–56–4, April, 1934) present thermodynamic formulas and methods for computing the performances of 30,000-kw. units on various cycles and with different pressures and temperatures at throttle. Their results are shown by curves from which deductions on performance can be drawn.

R. L. Reynolds (Calculation of the Gain from Feedwater Heating, *Elec. Jour.*, April, May, June, 1929) presents simple methods of calculation and many data on performance. He has recomputed these data on the basis of Keenan's Steam Tables and Mollier Diagram, also considering more recent power plant developments. Tables 27 to 32, which will prove useful in making plant estimates, are taken from the Reynolds' curves.

Table 27 shows the final feedwater temperature from the last heater, which gives

maximum reduction in heat consumption with multi-stage extraction. Steam conditions: Throttle pressure, 200 to 1200 lb. per sq. in., gage; throttle temperature, 750° F.; vacuum, 29 in. These temperatures vary only a few degrees with changes in throttle temperature.

Table 27.—Final Feedwater Temperatures with Extraction Heating

Steam Pressure, lb. per sq. in., gage	Number of Stages of Extraction							
	1	2	3	4	5	6	8	10
	Deg. F.	Deg. F.	Deg. F.	Deg. F.	Deg. F.	Deg. F.	Deg. F.	Deg. F.

1200	302	361	390	411	428	442	463	481

The reduction in heat consumption with multi-stage extraction, in percent of that with no extraction, and with the feed temperatures of Table 27, are given in Table 28, using the same steam conditions as given for Table 27.

Table 28.—Reduction of Heat Consumption with Extraction Heating

Expressed as a percentage of the heat consumption with non-ext

Steam Pressure, lb. per sq. in., gage	Number of Stages of Extraction							
	1	2	3	4	5	6	8	10
	Percent	Percent	Percent	Percent	Percent	Percent	Percent	Percent
200	5.15	6.80	7.70	8.35	8.85	9.20	9.70	9.90
300	5.60	7.35	8.35	9.05	9.55	9.95	10.50	10.70
400	5.90	7.80	8.90	9.65	10.25	10.65	11.20	11.45
500	6.25	8.25	9.40	10.20	10.80	11.20	11.80	12.10
600	6.55	8.65	9.85	10.65	11.30	11.75	12.35	12.65
700	6.70	9.00	10.25	11.10	11.75	12.20	12.85	13.15
800	6.90	9.35	10.60	11.50	12.15	12.60	13.30	13.65
900	7.25	9.65	10.95	11.85	12.50	13.00	13.70	14.05
1000	7.45	9.90	11.25	12.10	12.80	13.30	14.00	14.40
1100	7.60	10.15	11.50	12.30	13.05	13.60	14.35	14.80
1200	7.75	10.30	11.75	12.65	13.30	13.85	14.60	15.10

The effect of a rise in steam temperature is to decrease these gains slightly; a decrease in steam temperature increases the gain slightly. For estimating purposes, deduct 0.2% for each 100° F. rise above 750° F., and add 0.23% for each 100° F. decrease below 750° F. The percent reduction in heat consumption does not vary much for a range of feed temperature on either side of those given in Table 27. This is shown by the values in Table 29. In practice the tendency is to choose feed temperatures below the maximum rather than above.

Table 29 indicates the reduction in heat consumption due to feedwater heating to various final temperatures expressed as a percent of non-extraction performance.

Table 29.—Reduction in Heat Consumption Due to Feedwater Heating

Expressed as a percentage of non-extraction operation. Steam conditions: Throttle pressure, 400 lb. per sq. in., gage; throttle temperature, 750° F.; vacuum, 29 in.

Final Feed Temperature, deg. F.	Number of Stages of Extraction				Final Feed Temperature, deg. F.	Number of Stages of Extraction			
	1	2	4	10		1	2	4	10
	Percent	Percent	Percent	Percent		Percent	Percent	Percent	Percent
180	5.20	5.65	5.90	6.30	320	5.05	7.65	9.65	11.00
200	5.60	6.40	6.80	7.25	340	....	7.45	9.65	11.25
220	5.85	7.00	7.55	8.10	360	....	7.10	9.55	11.40
240	6.00	7.45	8.25	8.85	380	....	....	9.35	11.45
260	5.95	7.70	8.80	9.55	400	....	....	9.00	11.35
280	5.75	7.85	9.20	10.10	420	....	....	....	11.20
300	5.45	7.80	9.50	10.60	440	....	....	....	10.95

Since stage pressures increase or decrease with the amounts of steam passing through the stage, the saturation temperature of the steam at the extraction points, and consequently the final feedwater temperature, will increase or decrease with load. The aver-

age large turbine has its feed heating system designed to give best performance at a most efficient load of 75 to 80% of rating. Reynolds gives in Table 30 the figures for a unit designed for most efficient load at 75% rating. Table 30 shows the influence of load on the reduction in heat consumption as compared with non-extraction conditions with 4-stage feed heating. Steam conditions are the same as given for Table 29.

Table 30.—Influence of Load on Reduction of Heat Consumption, 4-stage Heating

Expressed as a percentage of the heat consumption with non-extraction operation

Load on turbine, percent of rating	30	40	50	60	70	75	80	90	100
Percent reduction in heat consumption	4.85	6.35	7.60	8.55	9.30	9.65	9.85	10.25	10.55

Since the heat consumption in non-extraction operation increases above most efficient load, operation with extraction heaters as indicated by the above gains will lead to heat consumptions at full loads, relatively less in proportion to most efficient load than in the case of non-extraction performance. This leads to a flatter heat consumption curve.

Reynolds shows that a decrease in vacuum from 29 in. to 27 in. decreases the gain from extraction operation, but increases the most favorable final feed temperature. Table 31 shows the influence of vacuum on the reduction in heat consumption as compared to non-extraction operation when using 4-stage feed heating. Steam conditions, same as given for Table 29.

Table 31.—Influence of Vacuum on Reduction of Heat Consumption with 4-stage Heating

Expressed as a percentage of the heat consumption with non-extraction operation

332	....	....	9.70	....					

SELECTION OF HEATERS.—The economic selection of the proper number of heaters requires an evaluation of the savings, giving consideration to average use factor and average load throughout the useful life of the turbine, the cost of fuel, and whether or not economizers are used. Against this are charged the fixed costs on the investment in the added heater, valves, and piping, repairs and maintenance on this equipment, and the cost of added power for pumping due to the friction head added by the heater. In many cases this balance will indicate that the savings from adding more than 3 or 4 heaters are not warranted by the returns on this investment.

When the final feed temperature from the last heater is fixed, the temperatures leaving other heaters can be selected. The easiest method is to divide the temperature rise equally between heaters. But in actual cases, the feed heating system is complicated by drainage from previous heaters, by evaporators and their condensers, by steam jet air pumps, and by the heat from the boiler feed pump. These modify the amount of steam bled at the various heaters, and particularly tend to decrease that bled at No. 1 heater. Reynolds shows a curve from which Table 32 is taken to indicate that best performance is obtained when equal quantities of steam are bled at all heaters. Table 32 shows the effect of location of heaters on heat consumption for 4-stage extraction by indicating the quantity bled at various heaters.

Table 32.—Effect of Location of Extraction Heaters on Heat Consumption

Steam conditions: Throttle pressure, 300 lb. per sq. in., gage; throttle temperature, 622° F.; vacuum, 29 in.

Stage of Extraction	Heat Consumption, B.t.u. per kw-hr. 11,962	11,944	11,925	11,953
	Steam Bled, lb. per hr.			
4	15,560	13,520	11,100	7,980
3	12,440	12,300	11,100	10,820
2	9,250	11,180	11,100	10,530
1	7,530	7,750	11,100	15,360

There is no rule to determine the distribution of bleeder points and trial and error must be employed. Several approximate methods are in use.

If generator air coolers, oil coolers, heat exchangers on drips, and the exhaust of steam

jet air pumps, all are used to heat the feed, the temperature entering the first heater will be considerably higher than hotwell temperature. It may be assumed for preliminary calculations at most efficient load and 29 in. vacuum to be about 100° F. Having chosen the number of heaters and the desired final feed temperature, the temperature leaving each heater can be fixed, or if equal quantities of steam are bled, the feed temperature is found by calculation.

The terminal differences in feed heaters varies from 5° to 10° F., depending on the amount of heater surface, and usually is 6° F. With this fixed, the saturated steam temperature can be determined and hence the saturated steam pressure in the heater. Some feed heaters for the high-pressure bleeder points, where superheated steam is bled from the turbine, have been furnished with a counter-current section to utilize the superheat, which in some cases has heated the feedwater to the saturation temperature of the steam in the heater or even higher.

A Pressure Drop occurs in the piping, non-return valves, and gate valves between turbine casing and heater, and in the turbine between the blading and the extraction nozzle. This frequently has been assumed to be 10% of the absolute pressure at the bleeder point at all loads. An analysis of N.E.L.A. test data indicates that pressure drops, shown in Table 33, between extraction points on the condition curve and the heaters may be assumed at most efficient load.

Table 33.—Pressure Drop between Extraction Points and Heater

Pressure at extraction point on condition curves, lb. per sq. in., abs.		10	20	30	40	50		70			100	120	140	160
Percent of pressure drop	15.6	14.5	12.8	11.6	10.6	9.7	9.0	8.1	7.5	7.0	6.4	5.8	5.4	5.

The major portion of the pressure drop is caused by the non-return valve, and this becomes a factor of decreasing importance with increase in pressure.

At other loads the pressure drop from the extraction points on the condition curve to the heaters, can be found by the formula $p = K w^2 v$, where p = pressure drop, lb. per sq. in.; w = steam flow, lb. per hr.; v = specific volume at extraction point on condition curve, cu. ft. per lb.; K = a constant determined by applying the above formula to the assumed pressure drop, flow and specific volume at most efficient load. Such computations are somewhat involved, and for estimating purposes, approximate pressure drops in percent can be estimated at other than most efficient loads as proportional to the total steam flow through the throttle. Thus in the preceding example, if the pressure at a given extraction point on the condition curve at most efficient load is 60 lb. per sq. in., the pressure drop to extraction point, from Table 33, is $60 \times 0.09 = 5.4$ lb. per sq. in., when 246,960 lb. per hr. are flowing through the throttle. At full load, the throttle flow is 324,100 lb. per hr. The pressure on the condition curve at the extraction point would be $60 \times 324{,}100/246{,}960 = 78.7$ lb. per sq. in. The approximate pressure drop to the heaters, in percent, would be $9 \times 324{,}100/246{,}960 = 11.8\%$. For preliminary calculations the pressure drop at full load may be taken as $78.7 \times 0.118 = 9.3$ lb. per sq. in.

Reynolds (Calculation of the Gain from Feedwater Heating, *Elec. Jour.*, April, 1919) uses a different approximate method by allowing for a pressure drop between extraction point and heater, which he assumes as equivalent to 2° F. drop in saturation temperature.

The pressure of the steam in the turbine casing now can be computed, and when plotted on the condition curve, the total heat in the steam at the extraction point can be found.

The pressures at other loads at the high-pressure extraction point are proportional to the total steam flows at the throttle, and for estimating purposes may be assumed in the same proportion at the other bleeding points. The true pressures at bleeder points below the high-pressure heater are proportional to the actual flows at each point, but these cannot be determined until later computations have been made. Slight errors in extraction point pressures have comparatively little effect upon the final unit performance.

The location of these pressures on the respective condition curves indicates the heat content of the steam at the various bleeder points. The computations now can be reversed and the temperatures of feed leaving each heater at each load can be found.

Table 34 shows these calculations for the 35,000-kw. turbine assumed above and similar calculations for other loads. It also shows the method of finding the actual pressure in the heater. These pressures on the condition curve are marked on Fig. 35.

Standard practice numbers the heaters from the exhaust. Thus No. 1 heater is the first one that the condensate enters.

The heaters may be drained: *a*, Through traps to the succeeding heater in *Cascade*, and finally to the condenser; *b*, by a return pump to the feed system at each heater; or *c*, by cascading to No. 2 heater, which is often made a deaerating heater, and mixing with the feed; the drains from No. 1 heater pass through a heat exchanger to the condenser. H. L. Guy (Tendencies in Steam Turbine Development, *Proc.* Inst. Mech.

Engrs., 1931) shows that (*b*) will decrease heat consumption over (*a*) with 600 lb., 700° F. steam conditions by about 0.87%; while (*c*) betters (*a*) by 0.7%. With 350 lb., 700° F. steam conditions, the gains of (*b*) and (*c*) over (*a*) are 0.97% and 0.69%, respectively, for the conditions assumed. System (*b*) involves many small drip pumps, often of low capacity, and at the high-pressure heaters these must pump against full boiler feed pressure. These added auxiliaries decrease the reliability and availability factors of the turbine. Scheme (*c*) or a modification of this arrangement is generally preferred.

Table 34.—Steam Conditions in 35,000-kw. Turbine

Load, kw.	Full, 35,000	Most Efficient, 28,000	20,000	10,000
Total Steam (from Willans Line), lb. per hr.	324,100	246,960	182,260	101,380
Pressure on condition curve at extraction point, lb. per sq. in., abs.	78.7	60	44.2	24.6
Percent pressure drop to heater	11.8	9	6.6	3.7
Pressure drop to heater, lb. per sq. in.	9.3	5.4	2.9	0.9
Pressure in heater, lb. per sq. in., abs	69.4	54.6	41.3	23.7

The Calculation of the Steam Extracted at each bleeder point is a heat balance calculation. Thus assume, for example, No. 3 heater of a series of four heaters.

$$b\,(h_3 - m_3 - h_{f3}) + a\,(h_{f4} - h_{f3}) = (x + w)\,(h_o - h_i)$$

Solve for b = lb. of steam per hr. to be bled, where h_3 = total heat at bleeder point on the condition curve; m_3 = radiation loss, B.t.u. per lb. of bled steam (usually 3 to 5 B.t.u.); h_{f3} = heat of saturated liquid at bleeder heater pressure; a = lb. of steam per hr. cascaded from previous heater; h_{f4} = heat of saturated liquid at pressure of preceding heater; x = make-up feedwater, lb. per hr.; w = lb. of steam per hr. entering turbine; h_o= heat of feedwater at temperature leaving No. 3 heater; h_i = heat of feedwater at temperature entering No. 3 heater; all heat quantities are in B.t.u. per lb.

In the above calculation the temperature of the drips was assumed to be saturation temperature at that heater pressure. Some counter-current heaters reduce this temperature considerably below saturation temperature and these lower temperatures can be used in the heat balance equations.

Where pumps lift the drip back into the feed line, w must be correspondingly decreased on the heater from which the drips are pumped, as well as on lower-temperature heaters.

Heat Transfer Rates in Bleeder Heaters depend upon the velocity of the water through the tubes. As shown by Yellott's statement (Turbines, N.E.L.A., 1932) heat transfer rates in a given heater may vary from 400 B.t.u. at 2 ft. per sec. water velocity; 600 B.t.u. at 4 ft. per sec., to 750 B.t.u. at 6 ft. per sec. High water velocities permit the use of less heater surface. Regarding the effect of average film temperatures, if the heat transfer rate at 4 ft. per sec. velocity is taken as 400 B.t.u. at 100° F. average film temperature, the rate should be 500 B.t.u. at 150° F., 600 B.t.u. at 200° F., and 700 B.t.u. at 250° F. Usual water velocities vary from 4 to 6 ft. per sec. The pressure drop on the feedwater side of the heater varies from 4 to 12 lb. per sq. in. per heater.

Bleeder heaters with an outlet temperature up to 250° F. generally are installed on the suction side of the boiler-feed pump. The condensate pump is selected to deliver the condensate through these heaters at a suitable pressure to the suction of the boiler-feed pump. Non-return valves in the bleeder steam connections prevent flooding the turbine if a tube ruptures in one of the closed heaters.

Frequently, one of the feedwater heaters serves as a *deaerating heater* to remove oxygen and gases from the feedwater. In case this is an open mixing heater, the temperature of the condensate leaving this heater will be the saturation temperature corresponding to the heater pressure. When boiler pressures do not exceed 600 lb., the boiler-feed pump removes the water from No. 2 when this is an open heater. Heaters beyond this point must be designed on the water side to withstand full boiler pressure. With 1500 lb. boiler pressure, a booster pump is placed at No. 2 heater and the boiler-feed pump may be placed beyond the final heater.

Allowance must be made for the heat added to the feedwater from the losses in centrifugal condensate, booster, and boiler-feed pumps. It may be assumed that 10% of the losses disappear as radiation and 90% is carried away by the feedwater. On this assumption, the temperature rise in deg. F. due to pump losses is

$$\left(\frac{1}{\eta_p} - 1\right)$$

where η_p = pump efficiency as a decimal; P = total pressure added by pump, lb. per

sq. in.; d = specific volume of feedwater entering pump, cu. ft. per lb.; w_1 = total feedwater pumped, lb. per hr.

The Efficiency of Centrifugal Condensate Pumps may vary from 25 to 60%, depending upon working conditions. Centrifugal boiler-feed and booster pumps have efficiencies, at full load, of 50 to 75% depending upon pressure and temperatures. These efficiencies decrease at partial loads.

The Evaporator to provide distilled water for boiler-feed make-up usually forms an element in the extraction system. A single-stage evaporator generally is used, taking steam from No. 2 or No. 3 extraction point, and exhausting into an evaporator condenser placed on the feed line between the preceding heater and the heater at the extraction point from which steam is taken. Aside from radiation losses, the evaporator and its condenser merely serve as the first stage of feed heating at the extraction point from which steam is taken to the evaporator. (See pp. 3–36 to 3–48 for evaporator data and calculation.) Make-up in a modern station varies from 0.5 to 2% of the total steam to the turbine. In industrial plants, it may be much higher and may even exceed possible evaporator capacity when all condensate does not return from the bleeder services.

Heat transfer in evaporator coils depends both upon temperature head and on the vapor temperature and degree of purity of the water evaporated. Thus with 25° F. temperature head, heat transfer rates of 425 B.t.u. at 100° F. vapor temperature, 500

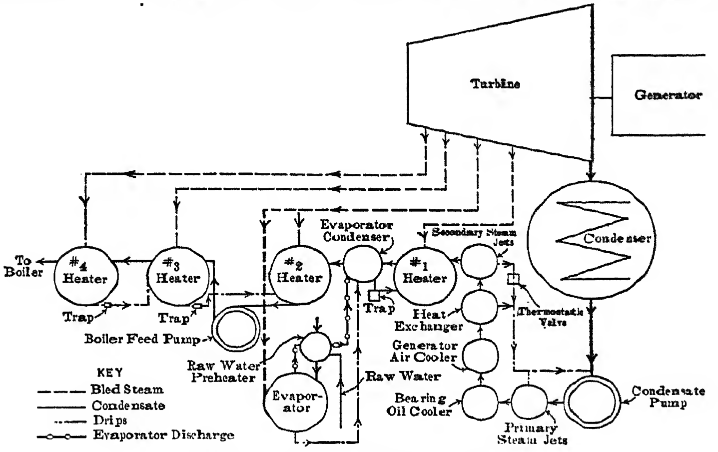

Fig. 36. Typical Extraction Plant Layout.

B.t.u. at 200° F. and 550 B.t.u. at 300° F. might be expected. Generally the total heating surfaces in all stages of multiple effect evaporators are made the same. See Yellott's statement in Turbines, N.E.L.A., 1932.

In some plants, steam is withdrawn at bleeder points to furnish station heating, to operate steam-jet air removal pumps on the condenser, to operate steam-driven booster pumps, etc. These cases can be computed by giving careful consideration to all heat quantities involved.

Generally, the feed leaving the condensate pump passes first through the condenser for the primary steam jets of the air pump. Knowing the total steam required by the jets and the total heat in this steam, the temperature rise of the feedwater can be computed.

The feed next passes through the *generator air cooler* where the use of clean condensate is desirable, as it eliminates the need of cleaning and will not corrode tubes. Few data have been published to show the relation which the heat recovered in the generator air cooler bears to the heat equivalent of the total electrical losses. Schoenherr's statement in Turbines, N.E.L.A., 1932, indicates that at 29.5 in. vacuum, 92.5% of the electrical losses are recovered by the feedwater; at 29 in. vacuum, 84.5%; at 28.5 in. vacuum, 76%. Passing the condensate through the generator air cooler reduces the steam bled at the first bleeder point, and results in a final saving in heat rate of unit of 0.25 to 0.5%.

The feedwater next passes through the *oil cooler*. Data indicate that heat equivalent

to the total mechanical losses is absorbed by the feedwater in this heater. Undoubtedly some of the missing heat in the generator losses and heat from the turbine itself passes by conduction to the bearings and is removed by the oil.

If a *heat exchanger* is used on drips, this can be calculated by assuming a terminal difference of 10° F. between the cooled drips and entering condensate, and calculating the resultant temperature rise of the condensate.

The feed finally passes through the condenser of the secondary air jets of the vacuum pump, where temperature rise can be calculated as for the primary jets.

At light loads, there may be insufficient condensate to properly cool the generator air. In such a case a thermostatically controlled valve may by-pass feedwater beyond the oil cooler to the condenser, where it flashes and thereby increases the flow to the generator air cooler to obtain the desired generator air temperature. Fig. 36 shows a typical extraction layout. Further information upon the computation of the heat balance on extraction turbines can be found in the following:

Jour.*, April, 1919; Wheeler, A Typical Power Plant Heat Balance Layout, *Powerfax*, Autumn, 1931. A Thermal Study of Available Steam-Power Plant Heat Cycles, Hendrickson and Vesselowsky, *Trans.* A.S.M.E., FSP–56–4, April, 1934.

OPERATION OF EXTRACTION TURBINES.—Extraction turbines are started, operated, and shut down with all bleeder heaters connected in service. The connection to the turbine usually contains a gate valve and a non-return check valve. Some turbines have been designed so that at the time of peak load, bleeder heaters may be shut off and all of the steam passed to the exhaust, increasing the leaving loss and decreasing the plant efficiency by feeding colder water to the boilers. Christie and Viessman (Low Cost Peak-Load Capacity Bleeder Turbines, *Mech. Engg.*, Feb., 1931) show that the use of hot water accumulators to provide feed to the boilers over the peak when the bleeder heaters are cut off, leads to increases in station capacity of about 10% with 3 bleeders, 17% with four bleeders, and 21% with 5 bleeders. These gains are obtained with no increase in boiler or furnace capacity over those when the bleeders are in service. Station economy is also maintained nearly constant. These installations require a low investment, are simple and reliable in operation, and are economical in fuel consumption.

16. REHEATING TURBINES

REHEATING the steam from the high-pressure section of a turbine before admitting it to the low-pressure section has two objects: 1. To decrease moisture at exhaust; 2. To increase overall plant efficiency. Warren and Blowney (The Increase in Thermal Efficiency Due to Resuperheating, *Trans.* A.S.M.E., xlvi, p. 563, 1924) show that the stage efficiency of the saturated section of a turbine decreases 1.15% for each additional 1% of moisture in the steam. Reheating provides more expansion in the superheat region with corresponding gains in efficiency. Reheating is done with live steam, with boiler flue gases, or with a combination of these two methods. Station economy is highest when reheating is done by boiler flue gases. The need of reheating becomes less as permissible initial steam temperatures increase. For instance with 700° F. throttle temperature, reheating is necessary at all pressures above 500 lb. per sq. in., gage, to maintain moisture at exhaust at 12%. With 850° F., reheating is not necessary until above 700 lb. per sq. in. pressure is reached. With 1000° F. and 85% engine efficiency, reheating is unnecessary below 1250 lb. per sq. in. gage pressure.

Reynolds has shown (Reheating, *Southern Power Jour.*, 1932) that the efficiency of a turbine has little effect on the gain to be expected from reheating. The number of stages

Table 35.—Reduction in Heat Consumption Due to Reheating

Steam Conditions: 1200 lb. per sq. in., gage; 750° F. inlet temp.; 750° F. reheat temp.; 29-in. vacuum.

Operating Condition	Pressure entering reheater which produces maximum reduction, lb. per sq. in., abs.	Reduction in heat consumption, percent
Straight condensing	170	6.75
1-Stage feed heating	195	5.65
2-Stage feed heating	210	4.95
3-Stage feed heating	215	4.65
4-Stage feed heating	220	4.55
5-Stage feed heating	225	4.45

of extraction does affect the gains. Table 35 shows the reduction in heat consumption due to reheating.

The Pressure Drop over the Reheater is assumed as 5% of the absolute pressure leaving the high-pressure section. Table 35 indicates that 4- or 5-stage extraction reduces the gain about $^1/_3$, but this does not include the gain due to regenerative feed heating. The gain from both reheating and regenerative feed heating may be taken as 95% of the sum of the individual gains. This maximum gain is obtainable only over a narrow range of reheating pressure. For example, with 4-stage bleeding, the gain is 4.5% or better with reheat pressures of 175 to 225 lb. per sq. in., abs. Usually the pressure entering the low-pressure section varies with load. The efficiency of the low-pressure section is a maximum at only one load and reheating pressure, and this load is the most efficient load for the complete unit. Hence for loads above or below most efficient load, the improvement due to reheat will be lessened. While further gains might be obtained by additional stages of reheating, these add to the expense of the plant and involve operating complications. More than one stage of reheating is not warranted with pressures of 2000 lb. per sq. in., abs., or less, and 850° F. at throttle.

THE GAIN FROM REHEATING depends upon the temperature to which the steam is reheated. See Table 36, by Reynolds.

Table 36.—Reduction of Heat Consumption Due to Reheating—4-stage Feed Heating

Steam conditions: 1200 lb. per sq. in. gage; 750° F. inlet temperature; 29-in. vacuum; 5% pressure drop over reheater.

Temperature of reheat, deg. F.	Pressure entering reheater which produces maximum reduction in heat consumption, lb. per sq. in., abs.	Reduction in heat consumption, percent	Reduction in steam flow to condenser due to reheat, percent	Reduction in heat absorbed by condenser circulating water due to reheating, percent
850	250	6.4	20.0	10.5
750	220	4.55	16.0	7.7
650	200	2.75	11.8	4.7
550	175	1.35	7.9	2.35
450	150	0.40	4.3	0.70

The temperature of saturated steam at 1200 lb. per sq. in. gage is about 569° F. Allowing a terminal difference in a live-steam reheater of 19° F., the reheat temperature to the low-pressure section would be 550° F., on which the maximum reduction of heat consumption with 4-stage extraction is 1.35% at most efficient load. At other loads the gain is less. This gain may be entirely wiped out if the pressure drop through the reheater should reach 17%. All gains are affected by this pressure drop through the reheater. Hence the need of large piping and passages and of few baffles.

Reynolds states that the maximum gain from reheating decreases but slightly with increased pressure. Thus, with 4-stage extraction, 750° F. inlet and reheat temperatures, and with 29 in. vacuum, the maximum gain with 600 lb., gage, steam pressure is 4.9%; at 1200 lb., gage, it is 4.55%. The decrease appears less rapid at higher pressures.

Since more heat per pound is converted into work with reheating, less steam enters the throttle for a given load, and less passes to the condenser. The percent reductions at the stated reheat pressures are given in Table 36. A corresponding reduction can be made in the size of the condensate pump, feedwater heaters, feedwater piping and boiler feed pump. But reheating involves the rejection of more heat per pound of steam to the condenser. The percent reduction in the heat absorbed by the circulating water also is shown in Table 36 for reheat effect only. A corresponding reduction can be made in condenser and circulating pump sizes.

Reheating introduces problems of reheat temperature control, of regulation when load suddenly is removed and of complicated station layout. With increased steam temperatures, simple regenerative plants are preferred, despite the thermal advantages of reheat.

For further information see: Guy, Tendencies in Steam Turbine Development, *Proc.*, Inst. Mech. Engrs., 1929; Guy, The Economic Value of Increased Steam Pressure, *Proc.* Inst. Mech. Engrs., 1927; Baumann, Some Considerations Affecting the Future Development of the Steam Cycle, *Proc.* Inst. Mech. Engrs., 1930.

17. ECONOMIC SELECTION OF OPERATING CONDITIONS

PRESSURES AND TEMPERATURES for steam turbines have changed greatly over the last fourteen years (1921 to 1935), and are being increased. Steam temperatures of 750° F. to 850° F. are in use and turbines are offered for 925° F. As the result of a two-year experience with a 10,000-kw. turbine, operating with initial temperature of 1000° F., Thompson and Van Duzer (High Temperature Steam Experience at Detroit, *Trans.* A.S.M.E., FSP-56-9, July, 1934) state that a plant now can be built to operate on 1000° F.

and that reliable service can be expected. Carter and Ellenwood (The Thermal Performance of the Detroit Turbine Using Steam at 1000° F., *Trans.* A.S.M.E., FSP–56–8, July, 1934) estimate that a 50,000-kw. turbine with 1200 lb. per sq. in., 1000° F., 29 in. vacuum, no reheating, and about 12% moisture at exhaust, should operate close to 8600 B.t.u. per kw.-hr. of net generator output. Turbines form only 15 to 20% of total station cost, and consideration must be given to load factor, coal cost, and cost of complete plant in making the selection. In general, the larger the capacity, the lower the unit cost. Boilers now operate at 3200 lb. per sq. in., and pressures of 6000 lb. per sq. in. are being tried experimentally.

While stage efficiencies tend to decrease with high pressures, the reheat factor increases and the overall efficiency of the turbine changes but little. F. Hodgkinson (Steam Turbine and Condensing Equipment, *Elec. Jour.*, Dec., 1924) gives engine efficiencies of 80.5% for 400 lb. unit with no reheat, and 79.5% for 1500 lb. unit with reheat. These values are increased in present day units.

EXHAUST CONDITIONS.—The lowest exhaust pressure gives the greatest heat drop and largest potential power per pound of steam. It also entails long low-pressure blading, or in a given casing either limits output or increases leaving velocity and exhaust losses. In any specific case the weighted average cooling water temperature should be determined from an analysis of water temperatures throughout the year and the loads at such times. This weighted average temperature may vary from the mean temperature by several degrees. When the weighted temperature is found, the corresponding vacuum may be estimated by allowing for a temperature rise (usually 10 to 15° F.) and a terminal difference leaving the condenser (usually 9 to 12° F.). When this vacuum is found the economic rating of a given casing can be chosen or blade lengths adjusted to the steam volume.

METALS FOR HIGH TEMPERATURE.—Steel and other metals decrease rapidly in tensile strength at temperatures above 750° F. Data have been published in many papers and books on this decrease of strength. Besides the references on creep given below, see also Symposium on Effect of Temperature on the Properties of Metals, A.S.M.E. 1931, and bibliography included in this symposium.

A further factor is *creep,* the name given to that indefinite elongation that occurs at higher temperatures under constant load at stresses much below the elastic limit of the material. This rate of flow is stated in terms of hours. S. H. Weaver (The Effect of Temperature on Materials Required in Turbine Design, *Gen. Elec. Rev.*, Nov., 1930) shows that the limiting creep stress on a 0.23% carbon steel at 900° F. is 14,200 lb. per sq. in. A load of 10,300 lb. per sq. in. produces a flow of 1% in 10,000 hrs.; a 1% flow results from 8,000 lb. per sq. in. load in 100,000 hrs. while a 6000 lb. per sq. in. load produces an elongation of 0.1% in 100,000 hrs. Certain designers have chosen the allowable rate of creep as 0.01% per year. This permits turbines to be built safely with material now available for 900° F. and possibly for 1000° F.

Particular attention must be given to the matter of creep in bolting material, in disc and diaphragm construction and in piping connections. Data on various materials can be found in Norton's The Creep of Steel at High Temperatures, McGraw-Hill Book Co.; Kanter & Spring's Long Time or Flow Tests of Carbon Steels at Various Temperatures, A.S.T.M., 1928; McVetty, Working Stresses for High Temperature Service, *Mech. Engg.*, Mar., 1934; Baumann, Some Considerations Affecting the Future Development of the Steam Cycle, *Proc.* Inst. Mech. Engrs., 1930. In this article, Baumann gives permissible creep rates per hr. as follows: 1. Turbine discs pressed on shafts 10^{-9}. 2. Bolted flanges of turbine cylinders 10^{-8}. 3. Steam piping, welded joints, boiler tubes 10^{-7}. 4. Superheater tubes, 10^{-6}. These stresses must be well below the yield point. He suggests a factor of safety of 3 based on the yield point at the working temperature.

PROBABLE STATION CONDITIONS will be: With no reheat, 450 lb. per sq. in., 750° F. for stations with 10,000- to 50,000-kw. units, with $4 per ton coal, and with load factor under 50%. Single-cylinder units with up to 4 stages of bleeding will be used. For stations with 1- and 2-cylinder units of from 25,000 to 125,000 kw., and no reheating, 750 lb. per sq. in., 850° F. Newer stations of this type may use 1000° F. and no reheat. For certain high-pressure stations with high load factor, 1200 lb. per sq. in., 800° F., and reheat to 950° F., with 4 to 5 bleeders. This plant costs from 5 to 10% more than a 400-lb. plant, but is about 13% more economical in fuel. If fuel cost and load factor are such in 450-lb. plant that fuel charges equal fixed charges, it pays to consider high-pressure plant.

Single-cylinder units in sizes up to 100,000 kw. are preferred, and are economic for 750 lb. per sq. in., 850° F. When cross-compound units are used, the high-pressure units generally operate at 3600 r.p.m. The capacity of the high-pressure unit depends on whether steam or gas reheat is used.

G. A. Gaffert (High-pressure Steam and Binary Cycles as a Means of Improving

Power Station Efficiency, *Trans.* A.S.M.E., FSP–56–11, Oct., 1934) considers the possibilities of these various cycles. His results, given in Table 37, are based on the following assumptions: *a.* An overall efficiency ratio of 82% for turbines of 30,000 to 50,000 kw. capacity; *b.* a maximum of 11% moisture at exhaust at full load; *c,* terminal differences on feedwater heaters of 5 to 20° F. for feed temperatures of 100 to 525° F.; *d,* steam generator efficiencies of 85%, including air preheater (if used); *e,* pressure drops of 10% between boiler and turbine, bleed points and their respective heaters, reheater piping and reheater; *f,* radiation loss of 2% from bleed point to heater, and 3% for reheating lines; *g,* normal auxiliary power allowances, with 20 kw.-hr. per ton as power for pulverizing coal; *h,* feedwater heated in equal temperature steps to a maximum of 75 to 80% of saturation temperature corresponding to throttle pressure when most economical number of feedwater heaters is employed; *i,* an overall efficiency ratio of 75% for the mercury vapor turbine; *j,* a terminal difference of 30° F. across the mercury condenser-boiler between mercury condensate and steam vapor temperatures. With diphenyloxide, a difference of 30° F. was assumed for the condenser-boiler at 25 lb. exhaust pressure for the diphenyloxide.

§ Exh. = Exhaust pressure in lb. per sq. in. or inches of mercury, absolute.

Gaffert concludes that higher steam pressures economically are justified, and that the steam cycle has not reached its limit; that when metals become available for temperatures over 1000° F., the mercury-steam binary cycle is the only feasible one; and that when thermal advantages and capital costs are considered, there is little choice between mercury-steam, diphenyloxide-steam and high pressure steam cycles, assuming low fuel costs and 800° F. initial temperature.

VARIABLE-PRESSURE OPERATION is possible with boilers operating at or above the critical pressure at constant temperature, such as the Benson. A description of this boiler appears in *The Engr.*, April 21, June 23, 1933. The specific volume at approximately constant temperature varies inversely as the pressure. A turbine for 2250 lb. pressure will pass about four times as much steam as one for 550 lb. pressure and the same temperature, with some loss in vacuum. The heat drop and heat utilized remain nearly constant in both cases. Hence, it appears possible to govern the load on the turbine by varying the boiler pressure and thus the inlet pressure. This would eliminate the use of throttling or nozzle governing valves.

THE LIMITING FACTOR IN TURBINE CAPACITY is the permissible area of the annulus of the last blade row. The amount of steam that can be discharged to the condenser is determined by the allowable leaving loss, and hence the allowable leaving velocity from this last row.

Kearton (Steam Turbines, p. 258) develops a formula for the mean diameter at the

exhaust end of an impulse turbine with no extraction from which the following is derived:

$$D = 21.46\sqrt{\frac{-}{\eta}} \qquad \times$$

where D = mean diameter, in.; x_E = quality of steam at outlet of blade; v_E = specific volume of steam at exhaust pressure, cu. ft. per lb.; ρ = ratio of blade speed to steam speed for last row; η_g = engine efficiency referred to generator output; $(h_1 - h_2)$ = isentropic heat drop from initial conditions to final pressure; m = allowable ratio of blade length to mean diameter (maximum value in 1934, $m = 0.35$); c = thickness coefficient, *i.e.*, ratio of clear opening at outlet of blades to pitch of blades (often assumed = 1.0); α = nozzle angle for last stage; kw. = kilowatt output of generator; N = r.p.m.

For a Parsons turbine, $D =$

where w = total pounds of steam per sec. passing last blade row, and α_1 = outlet angle of last blade row, other notation being as before.

The maximum permissible annulus area largely is determined by the permissible tip speed and blade length, with maximum tip speed of 1257 ft. per sec. (1934). Increased tip speeds contribute to increased economy.

Blade length depends upon blade strength, and the method of blade fastening. Improved blade designs permit higher tip speeds, and thereby increase area of the annulus.

Baumann blades are used by several companies to increase the capacity of the last row. One or more partitions are placed across both orifices and blades of several of the last rows. The outer section in each case expands the steam to exhaust pressure and delivers it to the exhaust pipe. The inner sections by-pass the steam to the succeeding orifices where expansion takes place. By this means the actual last row annulus area may be increased 60% by one extra Baumann row, 120% by two extra rows and 180% by three extra rows.

The greater the allowable leaving loss the greater is the turbine capacity. For instance, if the leaving loss can be doubled, the turbine capacity is increased about 40%. Doubling the leaving loss does not signify an equivalent decrease in turbine efficiency, for increased steam flow decreases disc, gland, and leakage losses, and increases the high-pressure blade lengths, while the mechanical losses per lb. of steam also decrease. Hence, the turbine itself may decrease in efficiency by only half the amount of the added leaving losses. The selection of the economic leaving loss for a given turbine, and hence its economic rating, depends on certain factors extraneous to the turbine, as load factor, daily and annual load curves, coal cost, station cost, and cooling water temperatures. The load factor should be the average throughout the whole useful life of the turbine. N.E.L.A. records show that this is comparatively low. Daily and annual load curves determine the nature of the loading, the point of best economy, and the permissible sacrifice of efficiency at occasional full load. Coal costs are highly important, as they fix the value of increased efficiency with decreased leaving loss. Station cost influences the amount of money that may be spent on the turbine. Water temperatures influence vacuum. For instance, if 28-in. vacuum only can be obtained, practically twice the weight of steam can be passed through the last blade row as with 29-in. vacuum and the same leaving velocity.

A given turbine casing can have a low rating for low leaving loss and maximum economy, or a high rating with high leaving loss and decreased economy. Foreign practice favors low leaving loss, not exceeding 15 B.t.u. per lb. American design formerly followed this practice. Turbines, N.E.L.A., 1932, gives a table which shows that at full rating, leaving losses vary from 6.6 to 33 B.t.u. per lb. Balcke and Alden (Steam Turbine Plant Practice in the U. S., *Trans.* A.S.M.E., FSP-55-3*a*, 1933) suggest for maximum load, winter conditions, and a 29 in. vacuum, a leaving loss of 25 to 30 B.t.u. per lb. of steam. American practice in last row annulus varies from 1.2 to 2.5 sq. ft. per 1000 kw. rated capacity, with the trend towards the lower figure. Bleeding for regenerative heating of the feedwater tends to decrease the steam to exhaust, and thereby increase possible rating of a given casing. Reheating has a similar effect in decreasing leaving loss.

Part of the kinetic energy of the leaving velocity is converted into pressure in the exhaust passage to the condenser. Practice allows area of exhaust openings to be 2.5 to 5 sq. ft. per 1000 kw. of rated capacity. With high leaving losses, large condenser outlets are not necessary, and a saving may be effected in the cost of this item.

INCREMENT LOADING.—The incremental rate of a turbine at any given output is the slope of the input-output curve at the point corresponding to the output. The

best combined efficiency of turbines carrying load in parallel is obtained when these are operated at outputs corresponding to equal incremental rates. See The Theory of Incremental Rates, Stienberg and Smith, *Elec. Eng.*, March-April, 1934.

THE ECONOMIC SELECTION OF A LARGE STEAM TURBINE is based on the above considerations of economy and cost. The extra costs of decreased unit efficiency, resulting from increased leaving loss, must be balanced against the fixed charges on the added cost of units of higher efficiency with lower leaving loss. This is fully discussed and a method of computation outlined by Christie (Economic Considerations in the Application of Modern Steam Turbines to Power Generation, *Mech. Engg.*, Aug.-Sept., 1930).

FLOOR AREA in sq. ft. per 1000 kw. is given in Christie's and Warren's papers, World Power Conference, Berlin, 1930, and presented in Table 38.

THE SELECTION OF INDUSTRIAL TURBINES depends upon the power demand, the efficiency warranted, use factor of unit, and its cost. If the plant has large low-pressure steam requirements, a high-pressure turbine may serve as a reducing valve from high-pressure boilers. When all steam is utilized in industry, the electric energy is generated at all loads under average conditions at about 4600 B.t.u. per kw.-hr., or roughly, $1/3$ lb. of coal per kw.-hr. A complete analysis of this problem is given by Flanders in Turbine Arrangements for Supplying Industrial Power (*Power*, June 7, 1932).

Limited cooling water at the industrial plant may warrant a turbine for an extra high pressure to lessen the heat to condenser per kilowatt of plant output. These, and other economic influences, indicate increasing use of higher pressures and temperatures in industrial plants. Many old industrial turbines, of uneconomical design, could be replaced by modern efficient units with the old alternator. Savings up to 17% are possible with no change in steam conditions. An additional saving of 5% may be effected by regenerative feedwater heating with new units. With same quantity of steam as used by the old turbines, a greater electrical output can be obtained.

The Selection of a Bleeder Turbine involves a careful study of the conditions in the plant for which it is intended. The calculation of the performance of a bleeder turbine is somewhat complicated and can be represented best by a set of performance curves, based on the local plant conditions. These curves must be supplied by the builder of the turbine. See Campbell, The Field and Limitations of Extraction Turbines, *Elec. Jour.*, Nov., 1927; Gove, Picking the Turbine to Fit the Job, *Elec. Jour.*, Mar., 1933.

18. MERCURY TURBINES

Mercury, as a power generating fluid, has high boiler temperatures for moderate pressures (see Table 8, p. 5-16) and does not decompose at any reasonable temperature. Mercury vapor can be utilized in a properly designed turbine, where it is expanded in stages to the exhaust pressure. The condensing temperatures at usual vacua (see Table 8, p. 5–16) are so high that it can be used to evaporate water at a pressure suitable for

steam turbine operation. Hence stations can be built to operate upon the mercury vapor-steam cycle. This combination leads to high economy in the plant. See data in Table 37.

The mercury vapor-steam plant of the Hartford Electric Light Co., of 10,000 kw. capacity, developed power at the switchboard for a year at an average fuel consumption of 10,250 B.t.u. per kw.-hr.

The mercury-turbine at Hartford is a 5-stage impulse unit, and operates at 70.7 lb. per sq. in. gage pressure, 28.5 in. vacuum. More stages will be used on new units with higher mercury pressures. The wheel speed of the Hartford unit is about 300 ft. per sec. The turbine wheels are overhung on the outer end of the generator shaft in order to save gland. The engine efficiency, based on shaft horsepower of the Hartford mercury bine, is said to be about 77% at full load, and only a little less at half load.

The mercury condenser is arranged for a temperature head of 20° F. between condensing mercury and boiling steam.

Besides the Hartford station, two other plants have been installed (1934). One at Schenectady, N. Y., of 20,000 kw. capacity delivers power to the New York Power and Light Co. and sends 325,000 lb. of steam per hr. to the works of the General Electric Co. The other plant, also of 20,000 kw. capacity, is being built at the Kearny Station of the Public Service Electric and Gas Co. of N. J., and delivers steam to turbines now in place, in which 33,000 kw. will be generated, thus making a total output of 53,000 kw. for the combined mercury-steam unit. Table 40 gives comparative operating conditions for the three stations.

Table 40.—Operating Conditions of Mercury Vapor-Steam Turbine Stations

	Hartford	Kearny	Schenectady
Load on mercury turbine, kw.	10,000	20,000	20,000
Speed of mercury turbine, r.p.m.	720	900	900
Total steam from unit, lb. per hr.	129,000	325,000	325,000
Steam pressure, lb. per sq. in., gage	275	365	400
Steam temperature, deg. F.	680	750	760
Mercury vapor, pressure at turbine, lb. per sq. in., gage	70.7	125	125
Mercury vapor temperature at turbine, deg. F.	884.5	958	958
Vacuum of mercury condenser, in. Hg, abs.	1.5	3.0	3.0
Temperature of mercury vacuum, deg. F.	440	485	485

The mercury-vapor plant appears to be economically justified on a system where fuel costs are high or where the unit with its accompanying steam turbine can be given a constant heavy loading throughout the year.

CONDENSING AND COOLING EQUIPMENT

By Robert Thurston Kent

TABLE OF CONTENTS

CONDENSING EQUIPMENT

COOLING EQUIPMENT

CONDENSING AND COOLING EQUIPMENT

By Robert Thurston Kent

CONDENSING EQUIPMENT

TYPES OF CONDENSERS.—The two general types of condensers are: 1. Direct contact condensers, in which the steam to be condensed comes in direct contact with the condensing water. They include jet, barometric, and ejector condensers. 2. Surface condensers, in which steam and condensing water circulate on opposite sides of a metallic condensing surface.

1. DIRECT CONTACT CONDENSERS

THE JET CONDENSER, Fig. 1, comprises a head into which the steam is delivered and where it is condensed by water sprays, a pump for the removal of condensate and condensing water, and a vacuum pump or steam-air jet ejector for removing air and non-condensible gases. Sometimes the same pump is used for removing both air and water. The jet condenser may be used where there is an ample supply of condensing water, particularly if this is of the proper quality for boiler feeding. Condensing water is drawn into the head by means of the partial vacuum therein, and no circulating pump is required.

Vacuum Breakers are required on jet condensers to admit air to the condenser body if water rises in it to a predetermined level. If permitted to rise above this level, the water might flood and damage the prime mover. The vacuum breaker consists of a float that opens an air valve, thereby destroying the vacuum and stopping the flow of condensing water.

Cost.—The jet condenser is low in first cost, but its operating expense is higher than that of other types of condensers.

Maximum Suction Lifts for the condensing water should be from 15 to 18 ft. If greater, an overload on the condenser would tend so to decrease the vacuum that insufficient condensing water would be drawn for operation. Fig. 4 is a chart issued by the Elliot-Erhart Company showing permissible condenser overloads at various suction lifts

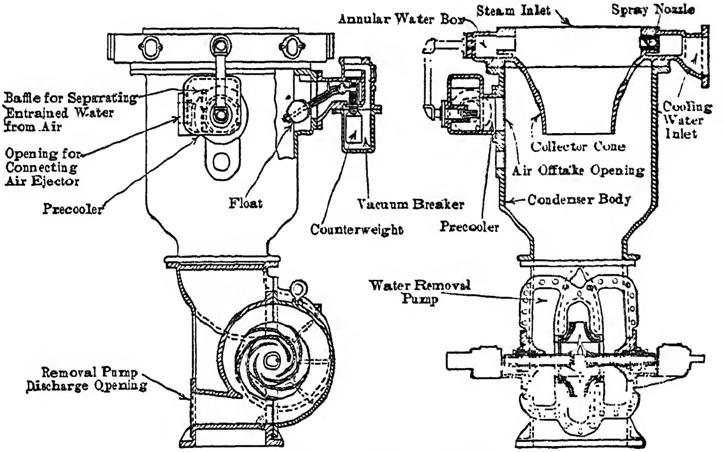

FIG. 1. Westinghouse Jet Condenser

The chart is based on condensing water at 70° F. At lower temperatures the permissible overload is greater.

The use of the chart is as follows: Let L = load on condenser, lb. of water per hr., at suction lift m and vacuum v; l = proportionate load at lift m and vacuum v; X and X_a = actual load on condenser at incipient and absolute instability, respectively; x and x_a = proportionate load at point of intersection of curve of suction lift m, with lines of incipient and absolute instability respectively. Then

$$X = L(x/l) \quad \text{and} \quad X_a = L(x_a/l).$$

Example.—Load L = 50,000 lb. per hr.; vacuum, 27 in.; suction lift 18 ft. Proportional load (v = 27; m = 18) = 140; proportional load of incipient instability (m = 18) = 199. Load of incipient instability X = 50,000 (199/140) = 71,071 lb.

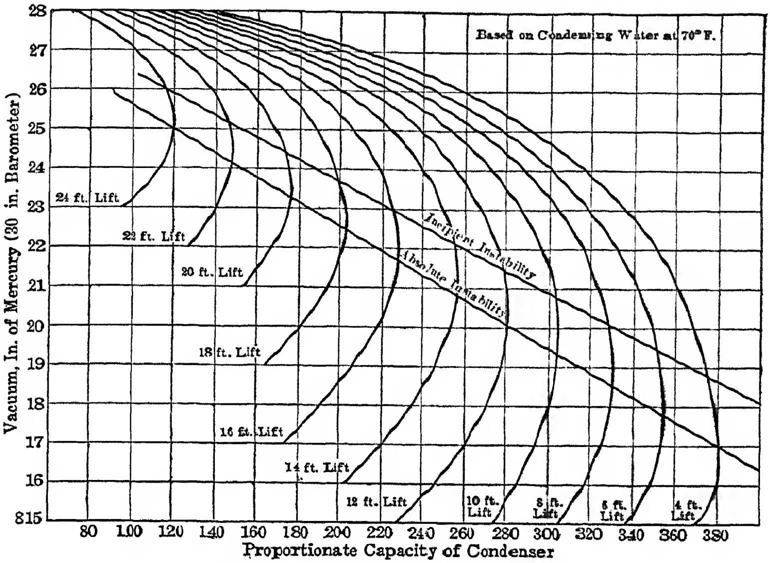

FIG. 4. Stability Chart for Jet Condensers

THE BAROMETRIC CONDENSER consists of a condenser head similar to that of a jet condenser, mounted at the top of a discharge pipe whose length is at least 34 ft. above the level of the hotwell. The condensate and condensing water falling into the tail pipe draw out the entrained air. As a rule, no vacuum pump is required with this type of condenser although sometimes a dry air-pump may be used to remove such air as may not be removed by the descending water column. If the condensing water inlet is not over 20 ft. above the source of supply, condensing water will be drawn into the condenser by the partial vacuum, as in a jet condenser, and no circulating water pump will be necessary.

Fig. 5 shows the Schutte & Koerting multi-jet barometric condenser. The condensing water is discharged through a series of small nozzles *A* into a combining tube *B* and an extension *C*, consisting of several sets of tapered rings. The water jets are directed into the throat *D* where they unite to form a single jet. The vapors flow through the annular passes of the combining tube and there are condensed. The water jets entrain the air and non-condensible gases and discharge them into the barometric tail pipe. This type of condenser has had wide application in connection with evaporators, vacuum pans, dryers, stills, etc. Table 2 gives dimensions and capacities.

THE EJECTOR CONDENSER operates in a manner similar to a steam ejector. In the Koerting Eductor condenser, built by Schutte & Koerting Co., Philadelphia, condensing water enters through a series of nozzles at a pressure of 5 to 9 lb. per sq. in. and condenses the steam. The condensate and steam enter the discharge pipe at high velocity and discharge at atmospheric pressure, air and non-condensible gases being entrained and discharged with the jet. Water capacities of these condensers range from 15 to 750 gal. per min. Steam capacities, at 26-in. vacuum, range from 150 to 750 lb. per hr. Condensing water is supplied by a circulating pump, no vacuum pump being required.

QUANTITY OF CONDENSING WATER REQUIRED.—Let H = B.t.u. in exhaust steam at temperature T_s; h = B.t.u. in condensate at temperature T_c; W = weight of exhaust steam per hr., lb.; Q = quantity of condensing water required per hr., lb.; T_i = initial temperature of condensing water, deg. F.; T_c = temperature of condensate deg. F.; T_f = final temperature of condensing water. Heat surrendered by the steam = $W(H-h)$. Heat absorbed by the condensing water = $Q\,(T_f - T_i)$, and $Q = W(H-h)/(T_f - T_i)$. Theoretically $T_c = T_s$, but due to the presence of air and to imperfect mixing T_c should be taken from 10 to 15 deg. lower than T_s. $T_f = T_c$, whence

$$Q = W\,(H-h)/(T_c - T_i) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

The value of $(H-h)$ may be taken as 943 B.t.u. when exhaust steam is assumed to contain 10% moisture with 29-in. vacuum, and 933 B.t.u. with 28-in. vacuum. For approximate calculations $(H-h)$ frequently is assumed as 1000 B.t.u., but the use of the actual values of H and h is more accurate.

2. SURFACE CONDENSERS

The standard type of surface condenser comprises a chamber containing a large number of brass tubes, from $^5/_8$ to $1\,^1/_4$ in. diam., through which flows the condensing water. Steam flows around the tubes at high velocity and is condensed. Condensate, air, and other non-condensible gases are removed by a vacuum pump. For high vacuums, air and other gases are removed by a dry vacuum pump, and the condensate by a separate hotwell pump. The tubes are arranged so that the water makes usually one or two passes through them, although in some cases it may make as many as five passes. Air coolers usually are provided to further cool the entrained air and reduce its volume, and to condense any condensible gases present. These may be placed in the condenser chamber or be external to it.

CONDENSING SURFACE REQUIRED.—Let S = outside area of condenser tubes, sq. ft.; Q = quantity of condensing water, lb. per hr.; T_1 and T_2 = respectively, initial and final temperatures of condensing water, deg. F.; U = overall coefficient of heat transfer per sq. ft. per hr. per deg. F. temperature difference; t_m = mean temperature difference, deg. F., between temperature T_s of the steam and temperature of the condensing water. Then

$$\div \log_e \frac{}{(T_s - T_2)} \quad . \quad . \quad [3]$$

G. A. Orrok (*Trans.* A.S.M.E., xxxviii, 1916, p. 467) gives for the value of U the empirical formula

$$U = 325V^{0.6}/T_m^{1/8} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [4]$$

where V = velocity of water through the tubes, ft. per sec., other notations as above.

W. H. McAdams (*Trans.* A.S.M.E., xlviii, 1926, p. 1233) in an analysis of Orrok's data derived the empirical formula $1/U = r_v + r_t + r_s + (1/BV^{0.8})$, where r_v, r_t, and r_s = respectively, the individual thermal resistance, per unit area of condensing surface on the vapor side, of the tube itself, and of any scale or other deposit on both sides of the tube, and V = a coefficient depending on the dimensions of the tube and on the temperature. On a clean tube of Admiralty metal, 1 in. outside diameter, with a steam temperature of 136° F. and an average water temperature of 66° F. this formula reduces to

$$1/U = 0.000401 + (1/248V^{0.8}) \quad [5]$$

In practice V ranges from 4 to 10 ft. per sec. Corresponding values of $V^{0.6}$ and $V^{0.8}$ are

V = 4	4.5	5	5.5	6	6.5	7	7.5	8	8.5	9	9.5	10
$V^{0.6}$ = 2.31	2.47	2.63	2.77	2.93	3.07	3.21	3.35	3.48	3.61	3.74	3.86	3.98
$V^{0.8}$ = 3.03	3.33	3.62	3.91	4.19	4.47	4.74	5.01	5.27	5.54	5.80	6.16	6.31

Values of t_m and $t_m^{1/8}$ are given in Table 6.

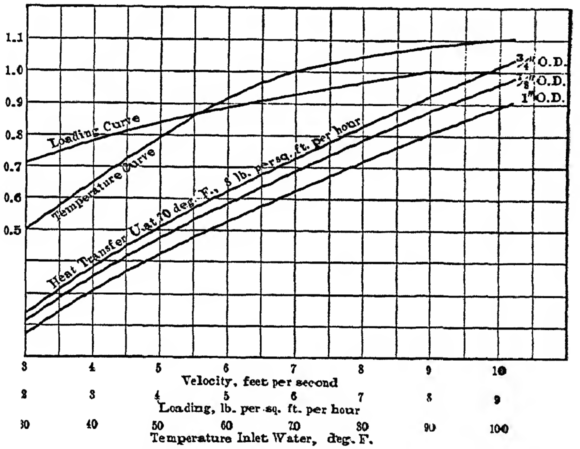

FIG. 6. Curves of Values of U for Surface Condensers

The curves, Fig. 6 (*Power*, Sept., 1932) have been adopted by the leading condenser manufacturers for values of U that can be used on a commercial basis for the design of surface condensers for use with steam turbines. They take into account the effect on the value of U of the velocity and temperature of the inlet water, tube diameter, and fouling of the tubes. Figs. 7 and 8 are curves adopted by the same manufacturers for determining loss of head in the tubes and water box losses, the latter including entrance and exit losses of the tubes. The curves of Fig. 6 give lower values of U than does the Orrok formula.

Number and Size of Tubes.—Geo. A. Orrok (*Trans.* A.S.M.E., xxxviii, 1916, p. 467) gives the following: Let N = number of passes in the condenser, n = number of tubes in one pass, d = outside diam. of tubes, in., t = thickness of tubes, in., l = total length of all passes, *i.e.*, total length of water travel in the condenser, ft., a = full area through tubes for the passage of water, sq. ft. Then

$$a = {}^1/_4\pi(d - 2t)^2/144 = 0.00545\,(d - 2t)^2, \quad [6]$$

$$V = Q/(3600 \times 62.4 \times na), \quad [7]$$

$$n = Q/1223V(d - 2t)^2. \quad [8]$$

The number of passes N depends on the ratio $(l/d) = R$. Values of R in practice range from 25 to 50, and $N = l/R$.

Tube diameters range from $^3/_4$ in. to $1\,^1/_4$ in. The smaller diameters are preferable as the rate of heat transfer is higher in a small tube. With 1-in. tubes, 1 sq. ft. of condenser cross-section will contain from 40 to 80 tubes, depending on tube spacing and

gement. If B = number of tubes per sq. ft., A = area of condenser cross-section, and L = length of condenser, ft. $A = Nn/b$, and $L = l/N$ + length of water boxes.

EXAMPLE.—Determine the dimensions of a surface condenser to condense 175,000 lb. of steam per hr. at a vacuum of 28.5 in.; inlet water temperature t_i, 75° F.; velocity, V = 8 ft. per sec. in the tubes; loading, 5 lb. per sq. ft. per hr. Assume temperature of condensate, t_c = 81.75° F., diam. d of tubes = $^3/_4$ in., thickness t, No. 18 B.W.G. = 0.049 in.

Solution.—From Table 3, T_s = 91.75; H = 1100.6; t_s = 91.75, h = 49.75.

$$Q = 175{,}000 \times (1106.5 - 49.75)/(81.75 - 75) = 27{,}244{,}250$$

From Fig. 6, $U = 762 \times 1.03 \times 0.88 = 690.7$. From formula [3],

$$t_m = \frac{81.75 - 75}{\log_e \{(91.75 - 75)/(91.75 - 81.75)\}} = 13.086$$

Surface = $S = Q\,(t_c - t_i)/Ut_m$ = 27,244,250 (81.75 − 75)/690.7 × 13.086 = 20,346 sq. ft.
No. of tubes = $n = Q/1223\ V\,(d - 2\,t)^2$ = 27,244,250/1223 × 8 (0.75 − 0.098)² = 6550
Length = l = 3.82 S/dn = 3.82 × 20,346/0.75 × 6550 = 15.82 ft.
If ratio of length to diameter of tubes R = 25,
Number of passes $N = l/R$ = 15.82/25 = 0.632, indicating one pass.
If tubes per sq. ft. of condenser cross section B = 110,
$A = Nn/B$ = 1 × 6550/110 = 59.55 sq. ft.

CONSTRUCTION DETAILS.—Shells usually are made of steel for land service, and of steel or copper for marine service. Shells are ribbed on the outside to resist collapsing pressure, and steel or copper shells are stiffened with angles.

Tubes usually are of brass, Muntz metal or Admiralty metal. The latter is used for salt water. A more recent development (1935) is arsenical copper. Tube thickness ranges from No. 16 to No. 20 B.W.G. and diameters from $^5/_8$ to 1 $^1/_4$ in. The larger tubes are used where water is dirty and liable to clog the tubes. Usual practice has been to set the tubes in brass ferrules screwed into the tube plates, and packed with lacing or wicking. In other cases, tubes were set in ferrules at one end and expanded into the tube sheet at the other end. Current practice (1935) tends toward expanding the tubes into the tube sheet at both ends, and allowing for expansion by flexure of the tubes, a special arrangement of the intermediate supporting plates being necessary. Another construction uses one fixed tube plate and one floating tube plate, an expansion joint being placed between the tube plate and the shell.

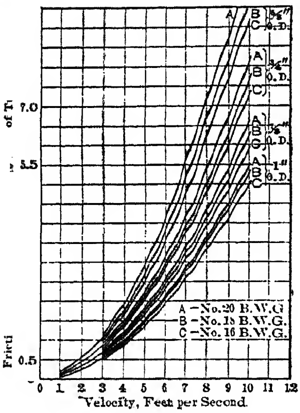

FIG. 7. Loss of Head in Tubes of Surface Condensers

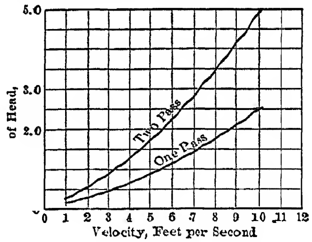

FIG. 8. Water Box Losses in Surface Condensers

Tube Spacing must provide room for ferrules, if these are used, and leave sufficient metal between holes for strength. The maximum number of tubes per square foot of tube sheet is

Pitch of tubes, in.	1	1 $^1/_{16}$	1 $^1/_8$	1 $^3/_{16}$	1 $^1/_4$	1 $^5/_{16}$	1 $^3/_8$	1 $^7/_{16}$	1 $^1/_2$	1 $^9/_{16}$	1 $^5/_8$

2	1.095	10	1.334	18	1.435	26	1.503	34	1.554
4	1.189	12	1.364	20	1.454	28	1.517	36	1.565
6	1.251	14	1.391	22	1.472	30	1.530	38	1.576
8	1.298	16	1.414	24	1.488	32	1.542	40	1.586

Tube Sheets usually have been of rolled Muntz metal or brass. Where tubes are expanded into both tube sheets the Foster-Wheeler Corp. recommends the use of copper-bearing steel tube sheets. Thickness of tube sheets ranges from 1.1 to 1.5 tube diameters. Large areas should be stayed to prevent collapse.

Supporting Plates for the tubes, usually of cast iron, should be spaced about 60 to 70 tube diameters. The holes should be 1/8 in. larger diameter than the tubes.

Water Passages.—Dimensions of water connections should be based on a velocity of 8 ft. per sec., and of hotwell pump suction on a velocity of 4 ft. per sec. Air pump connection should be twice the size of the hotwell pump suction.

Setting.—Condensers should be set with a slope of 1 in. in 10 to 15 ft. to drain the tubes when shut down. A small hole should be drilled in the water box partition to enable the water boxes to drain. Circulating water outlet should be above the highest point of tubes. The air pump should be as close as possible to the condenser with short, direct pipe connections. Air suction should be connected at the coldest part of the condensers and steam flow directed to it.

Condenser design should be such that the steam penetrates every portion of the tube bank. Both longitudinal and transverse distribution must be considered. Dead air pockets, and blanketing of tubes by air are to be avoided. Steam passages should be of decreasing area toward the suction, to maintain practically uniform velocity of steam throughout the tube bank. The construction should be such as to cause the temperature of the condensate to be as close as practicable to the vacuum temperature. Baffles or special arrangements of tubes should protect the lower tubes from excessive condensate dripped from the upper ones.

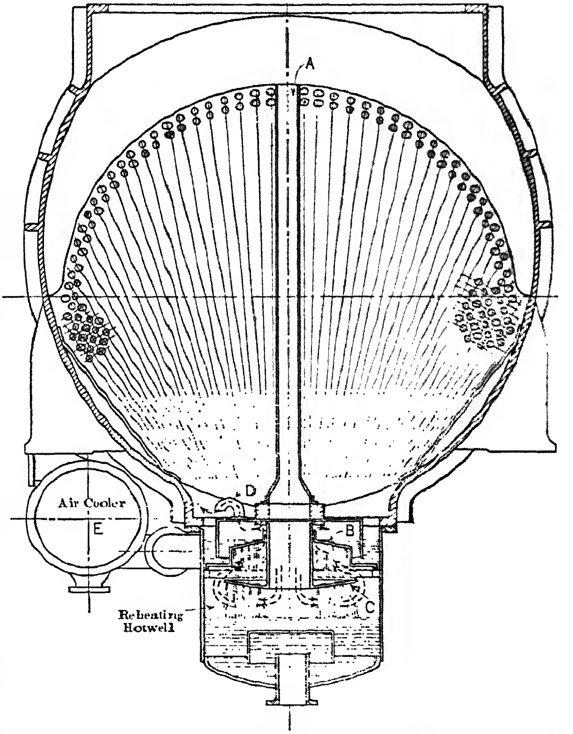

Fig. 9. Cross Section of Foster-Wheeler Single Pass Surface Condenser with Reheating Hotwell and External Air Cooler

Fig. 9 shows sections of a Foster-Wheeler condenser with a reheating hotwell and external air cooler. The tubes are arranged in straight lines diverging from the bottom. Steam enters at the top into a steam belt surrounding the upper part of the tube bank and flows through the straight lanes of diminishing area to the air off-takes at the bottom. A pipe *A* between the two tube banks conveys a portion of the steam to the hotwell, where it flows through two curtains of condensate falling from perforated plates *B* and *C*, being condensed thereby and raising the temperature of the condensate to within about 1° F. of vacuum temperature. Entrained air is vented through pipe *D*. The air off-takes are connected to the external air cooler *E*, the cooling surface of which ranges from 5 to 15% of the cooling surface of the main condenser. The water velocity in the air cooler is less than 1 ft. per sec.

Table 7 shows dimensions of standard small and medium size surface condensers

installations of 1000 kw. and over usually are designed for the conditions

to be

AIR IN SURFACE CONDENSERS.—In addition to air entrained in the feedwater, surface condensers contain air due to leakage through joints subject to vacuum. This leakage may range from 1 to 25% of the volume of the feedwater, but average leakage is from 5 to 10%. G. A. Orrok (*Trans.* A.S.M.E. xxxiv, 1912, p. 713) shows the effect of leakage on the vacuum of three units as follows.

Leakage, cu. ft. of air per min. . .	10	20	30	40	50
Size of unit		Vacuum In. of Mercury			
8700 kw	28.25	27.85	27.4	27.0	26.6
8500 kw	28.4	28.1	27.8	27.5	27.2
4000 kw	28.7	28.35	28.0	27.65	. . . .

The air leakage was measured at atmospheric pressure. Mr. Orrok says that the leakage in condensers of from 20,000 to 50,000 sq. ft. should be less than 5 cu. ft. of free air per min. Sources of greater leakage should be found and corrected. The leakage should be added to the air entrained in the feedwater when determining the size of air pump.

The vacuum in condensers may be increased by the application of deaerators, which remove practically all the air entrained in the feedwater. The air in the condenser then is limited to that introduced by leakage.

CLEANLINESS FACTOR IN CONDENSER PERFORMANCE.—As deposits on the surface of condenser tubes greatly affect heat transmission through them, and hence affect the performance of the condenser, a determination of the cleanliness of the condenser is essential in evaluating its performance under given conditions. This is particularly important in tests to determine conformity with guarantees. P. H. Hardie and W. S. Cooper (*Trans.* A.S.M.E. RP-55-3, 1933) define cleanliness factor as the ratio of heat transmission of a fouled tube to that of a new tube through which water has passed only during the time necessary to start the test, the tubes being supplied with water at the same inlet temperature and subjected to the same conditions on the steam side. Also.

water velocities through the tubes must be equal. In determining cleanliness factor, representative groups of tubes throughout the condenser are selected, and independently supplied with water from the same source as the main supply. Inlet and exit temperatures are measured for each tube, and the velocity in each tube is calculated from the discharge of calibrated nozzles on each tube. The heat transmission of old and new tubes is computed by

$$U = (WC/S)\,\log_e\,(T_a/T_b) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [9]$$

where U = heat transmission, B.t.u. per hr. per sq. ft. per deg. F. log mean temperature

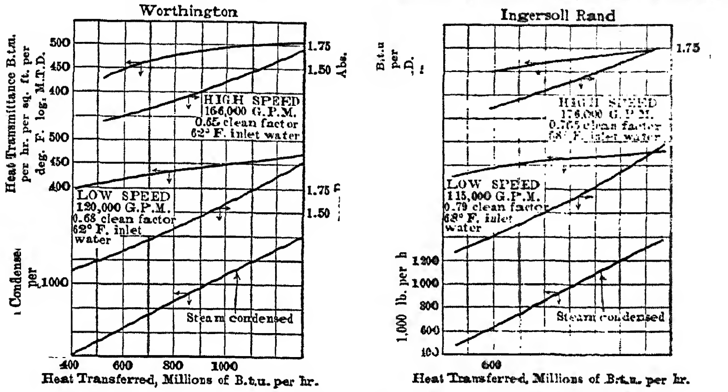

FIG. 11. Results of Tests of Two 101,000 sq. ft. Surface Condensers

difference; W = water flow, lb. per hr.; C = specific heat of water; S = surface area of tube, sq. ft.; T_a and T_b = initial and final temperature differences, respectively, deg. F. The average cleanliness factor for the entire condenser at any velocity is determined by averaging the heat transmission of all old tubes under test, and of all new tubes, and then computing the ratio of these two averages. The performance of the tubes under test should be referred to the saturated vapor temperature immediately adjacent to them, otherwise a higher cleanliness factor than the true one may be obtained.

The cleanliness factor varies inversely as some power of the velocity, that is

$$c = f(1/v)^n \quad . \quad . \quad . \quad . \quad . \quad . \quad [10]$$

where c = cleanliness factor; v = velocity in any unit; and n = velocity exponent for c. With velocities v_1 and v_2 and cleanliness factors c_1 and c_2,

$$n = \log\,(c_1/c_2) \div \log\,(v_1/v_2).$$

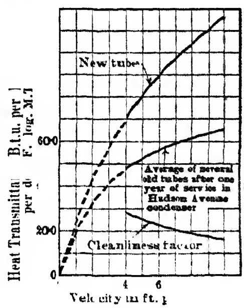

FIG. 12. Effect of Velocity on Variation of Cleanliness Factor and Heat Transmission in Old and New Tubes

See J. N. Landis and S. A. Tucker (*Trans.* A.S.M.E., FSP-56-3, 1934) for test data of two 101,000 sq. ft. condensers at the Hudson Ave. plant of the Brooklyn Edison Co. In these tests cleanliness factors were determined in accordance with the foregoing method. Results are summarized in Fig. 11. An explanation of the difference in cleanliness factors at high and low speeds in both sets of curves is given in Fig. 12, which shows that foul tubes do not respond to increases of velocity as do clean tubes. The increase of velocity reduces only the resistance to heat flow of the water film. This is a much smaller proportion of the total resistance in a foul tube than in a clean one.

Chlorination of the circulating water tends to improve the cleanliness factor, particularly if the water contains organic matter tending to promote the growth of algae. V. M. Frost and W. F. Rippe (*Trans.* A.S.M.E. FSP-53-10, 1931) describe experiments on chlorinating the water used in a condenser at the Kearney, N. J., station of the Public Service Elect. and Gas Co. Two 50,000-sq. ft. 2-pass condensers were used in the test

the water to one being with rubber plugs. T] 0.2 in. of mercury over

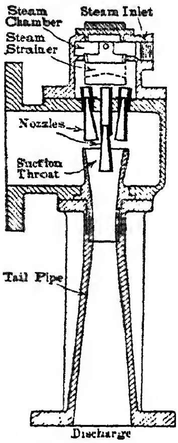

FIG. 13. Multiple Nozzle Ejector

320 to 72 lb. per day, depending on the ... Chlorine must be used with caution, for aside from its hazard as a toxic gas, it has a tendency, when present in excess, to cause corrosion of condenser tubes (see report of A.S.M.E. Research Comm. on Condenser Tubes, *Trans.* A.S.M.E., FSP-53-18, 1931). The report of the Kearny tests, however, states that no corrosion was evident after one year of operation with chlorine. The maximum residual chlorine at Kearny was found to be 0.3 part per million, at the condenser inlet.

3. AIR PUMPS

Air usually is removed from condensers by steam-jet pumps. These almost universally have replaced the mechanical pumps formerly used. Single-stage pumps are adapted to vacua under 26 in. of mercury; 2-stage pumps are used for vacua between 26 and 29 in.; 3-stage pumps for vacua above 29 in.

Multi-stage condensers usually have an inter-condenser between stages, and an after-condenser after the final stage. Condensate is used as cooling water. All of the heat in the steam jet thus is recovered, when the inter- and after-condensers are of the surface type. Fig. 13 shows a multiple nozzle ejector. Fig. 14 shows a 2-stage steam-jet air pump with surface inter- and after-condensers (Foster-Wheeler Corp.). Fig. 15 shows a 2-stage pump with jet inter-condenser.

CAPACITY OF STEAM-JET PUMPS depends on the area of jet in contact with the air. A pump with multiple nozzles will ...uch greater steam-jet surface than a single nozzle passing the same amount ... A single-stage pump will operate economically only within a compression ratio about 8 to 1. Beyond this range, high vacuum can be obtained only at the cost of

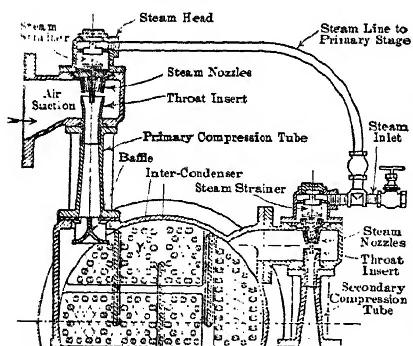

FIG. 14. Two-Stage Steam Jet Air Pump with Surface Inter- and After-Condensers

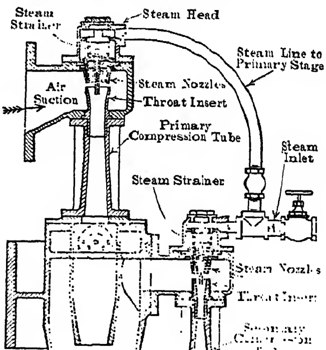

FIG. 15. Two-Stage Steam Jet Air Pump with Jet Inter-Condenser

excessive steam consumption, and a 2- or 3-stage pump is indicated. Fig. 16 shows the relative capacity of a 2-stage and a 3-stage Foster-Wheeler steam-jet pump using the ...ount of steam.

Commercial steam-jet air pumps range in capacity from about 10 lb. of dry air per hour to 100 lb. per hr. for single units. Twin units have double the capacity of single units.

The steam consumption may be taken approximately as 15 lb. per 1 lb. of dry air per hr., based on a mixture temperature of 7.5 deg. lower than the temperature of the steam at the condenser pressure.

Capacity of Air Pump Required for Surface Condensers is based generally (1935) on 29 in. vacuum and a temperature depression at the pump suction of 7.5° F. below the temperature of the steam at the pressure in the condenser. Under these conditions, the mixture of air and vapor in the condenser comprises about 2.2 lb. of vapor per 1 lb. of dry air. The air to be removed is that which leaks into the system. The quantity may cover a wide range, depending on the construction, tightness of joints and character of maintenance. Fig. 17 represents outside values that may be assumed for surface condensers, based on 29 in. vacuum and 7.5° temperature depression. In general, the actual leakage in well-maintained systems will be lower than the figures given by Fig. 17.

For conditions of vacuum and temperature other than those given above the necessary pump capacity can be estimated as follows: Let V_a = volume of atmospheric air leaking into condenser, per hr., cu. ft.; V_c = volume of air to be removed from condenser, cu. ft.; v_a = specific volume of air at temperature T_a, cu. ft. per lb. (see Table 10, page 1–08); v_s = specific volume of steam at temperature T_m, cu. ft. per lb. (see Table 3); T_a = temperature of atmosphere, deg. F.; T_m = temperature of mixture of air and vapor in condenser at pump suction, deg. F.; P_a = pressure of atmosphere; P_c = total pressure in condenser; P_s = pressure of vapor in condenser; all pressures in in. of mercury; W_a = weight of air to be removed per hr., lb.; W_s =

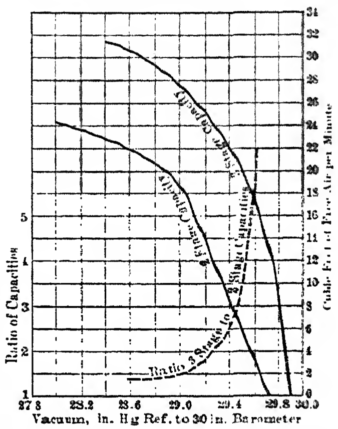

Fig. 16. Comparative Capacity Curve of 2- and 3-stage Steam-jet Pumps using same amount of Steam.

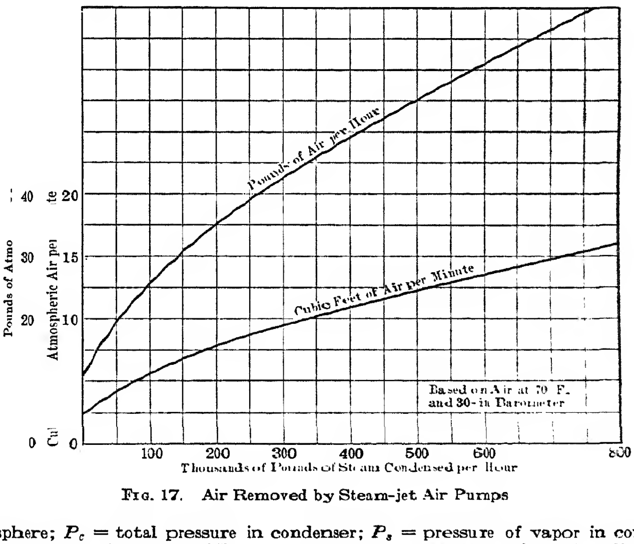

Fig. 17. Air Removed by Steam-jet Air Pumps

weight of vapor to be removed per hr., lb.; W_m = weight of mixture of vapor and air to be removed per hr., lb. Then

$$V_c = \frac{V_a P_a (T_m + 460)}{(P_c - P_s)(T_a + 460)} \quad [11]$$

$$W_a = V_a / v_a \quad [12]$$

$$W_s = V_c \times (1/v_s) \quad [13]$$

$$W_m = W_a + W_s \quad [14]$$

Values of V_c and W_s for the usual range of condenser pressures and temperatures are given in Tables 4 and 5.

Capacity of Air Pump for Jet Condensers may be estimated for preliminary calculations by assuming double the values given by Fig. 17. If the actual volume of air in the injection water is known, this figure should be used instead of the value from Fig. 17.

EXAMPLE—Required the capacity of pump to remove air from a surface condenser condensing 250,000 lb. of steam per hr. Temperature of atmosphere, 65° F.; barometer, 29.6 in.; vacuum, 28.5 in.; temperature of condensate, 87° F. *Solution.*—From Fig. 17, W_a = 39.0; the specific volume v_a of air at 65° F. is 13.22, whence V_a = 13.22 × 39.0 = 515.58 cu. ft. P_a = 29.6; P_c = 1.5; T_m = 87; T_a = 65. From Table 3, P_s = (30 − 28.708) = 1.292, or by interpolation in Table 5, $(P_c - P_s)$ = 0.208.

Then from formula [11],

$$V_c = \frac{515.58 \times 29.6 \times (87 + 460)}{0.208 \times (65 + 460)} = 76{,}445.5 \text{ cu. ft. per hr.}$$

Interpolating in Table 4, 1 lb. of dry air at 28.5 in. vacuum and 87° F. will have a volume of 1982 cu. ft. and contain 3.871 lb. of vapor. The weight of vapor to be removed, therefore, will be

$$W_s = (76{,}445.5/1982) \times 3.871 = 149.3 \text{ lb.}$$

$$W_m = 39.0 + 149.3 = 188.3 \text{ lb. per hr.}$$

COOLING EQUIPMENT

Water is cooled in a tower or pond by: *a*. Sensible heat flow from the water to the air, by radiation and conduction. *b*. Flow of latent heat to the air by evaporation of a portion of the water. The flow by radiation and conduction may range from 0 to 15% of the total flow. The evaporation of 1 lb. of water will absorb about 1000 B.t.u. from the body of the water to be cooled, thus reducing its temperature. The speed of evaporation depends on: 1. Difference in temperature of water and air. 2. Vapor tension differential between water and air. 3. Relative velocity of water and air.

A cooling tower is largely independent of climatic conditions. Ordinary air is not saturated, and when brought into contact with water will absorb sufficient moisture to saturate it. Even if saturated, and brought into contact with warmer water, the temperature of the air will be raised and a portion of the water will pass into the form of vapor and be absorbed by the air. The main body of water will be reduced in temperature by the loss of heat necessary to raise the temperature of the air and to evaporate the portion passing into vapor.

1. COOLING TOWERS

In a cooling tower, the water is broken into fine drops, or into thin films, and brought into contact with a current of air, induced by natural draft or mechanical means. For the various arrangements used to break up the water consult the catalogs of manufacturers.

TYPES OF COOLING TOWERS.—Cooling towers are classified by the method of producing the air current through them as:

1. Atmospheric Towers, depending on natural winds blowing horizontally across the tower. Louvres on the sides prevent water from being blown out of the tower. This type combines maximum thermal efficiency with minimum cost of construction, operation and maintenance. Its performance depends on the wind velocity, and therefore may vary widely.

2. Chimney Towers.—A chimney is superposed on the cooling surfaces, and draft is produced by the column of air in the chimney heated by its passage through the hot water in the tower. This type is well adapted to high temperatures and limited space.

3. Mechanical Draft Towers.—Draft is supplied by a fan, and may be either induced or direct. Since the air supply is absolutely controlled, this type is very flexible in operation, and the maximum of cooling capacity can be placed in a given area. The practical limit to the cooling capacity of a given mechanical draft tower is the horsepower required

to operate it. As the quantity of water is increased, both the volume of air required and the pressure against which the fan must operate increase. This necessitates larger fans and motors, and increased operating expense. A point is reached at which the increased cost of fans and motors, and the increased operating expense, is greater than the cost of building and operating a larger tower.

COOLING TOWER CALCULATIONS are based on the fact that the heat carried into the tower by the inflowing water and air is equal to the heat carried out by the outflowing water and air. Formulas covering the several variables involved are given below. The formulas and tabular data accompanying them should be used with caution, since the performance of a tower will vary widely with a relatively small change in any of the several variables involved. The tabular data are exact only for the conditions stated, and serve as a guide to the performance within a range of conditions. For other conditions than those stated, the performance should be calculated, and calculations should be based on the most unfavorable climatic conditions, *i.e.*, highest atmospheric temperatures and highest relative humidity. Table 1 gives the average temperature and humidity in July for a large number of places in the U. S., and will serve as a guide for conditions to be met. It should be borne in mind that the figures in Table 1 are averages and provision should be made for more unfavorable conditions. Thus, it would be wise to increase both temperature and humidity by 5%, and in certain localities by at least 10%. Otherwise, in very hot, humid weather, the tower may fail to give the desired range of cooling. Furthermore, while theoretically a tower can cool to the wet-bulb temperature, such a degree of cooling would be exceedingly costly. Cooling to within 5 deg. of wet-bulb

temperature represents good practice. Manufacturers of cooling towers should be consulted before a final decision is reached as to the size and type of tower advisable for any specified conditions.

ATMOSPHERIC COOLING.—An empirical formula for average temperature reduction in summer weather is

where T_1 = temperature of entering water; T_2 = temperature of leaving water; t_1 = temperature of dry bulb thermometer; t_2 = temperature of wet bulb thermometer, all in deg. F. A more exact formula, including wind variation, given by the Cooling Tower Co. is

$$T_{\cdot} = \left[\left\{ \frac{1.9385}{\quad} + 1. \right\} - \quad t_2 \right] \div \left[\left\{ \left(\quad 1.9385 \quad + 1.53 \right) \frac{\quad}{100} \right. \right. \qquad [2]$$

where, in addition to above notation, R = cooling range, deg. F.; A/W = ratio of air to water by weight. Let V = wind velocity, mi. per hr.; J = a constant depending on the of the tower; H = height of tower, ft.; B = width of distributing deck, ft.;

at various rates of loading per sq. ft. of horizontal deck area of atmospheric cooling towers.

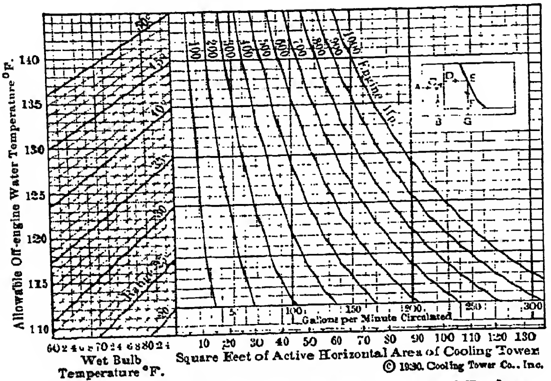

FIG. 1. Atmospheric Cooling Tower Chart for Diesel Engines

Fig. 1 is a chart for determining the size of tower for cooling the jacket water of Diesel engines for various atmospheric conditions, cooling ranges and engine horsepowers. The method of using the chart is shown by the inset. Find the intersection C of the allowable off-engine water temperature and of the wet bulb temperature B. Follow to the right to D, the diagonal range line from this intersection and then horizontally to the curve of engine horsepower E. At the bottom of the chart read the required gallons per minute F, and the square feet of active horizontal area G.

* Active horizontal area is the horizontal area occupied by each deck.

AIR REQUIRED IN MECHANICAL DRAFT COOLING TOWERS.—Let A = pounds of air required per pound of entering water; T_1 = temperature of entering water; T_2 = temperature of leaving water; t_1 = temperature of entering air; t_2 = temperature of leaving air, all in deg. F.; m_1 and m_2 = moisture in 1 lb. of saturated air, at temperatures t_1 and t_2 respectively (see Table 6); e_1 and e_2 = total heat, B.t.u., per lb. of water vapor, at temperatures t_1 and t_2 respectively; z = relative humidity of entering air. H_w = heat, B.t.u., entering tower in the water, per 1 lb. of water; H_a = heat, B.t u , entering tower in the air, per 1 lb. of water; h_w = heat, B.t.u., leaving tower in the water per 1 lb. of water; h_a = heat, B.t.u., leaving tower in the air, per 1 lb. of water.

$$H_w = (T_1 - 32);\ H_a = 0.2375\,A\,(t_1 - 32) + A\,(m_2 e_2);$$

$$h_w = 1 - (m_2 - m_1 z)\,(T_2 - 32);\ h_a = 0.2375\,A\,(t_2 - 32) +$$

Neglecting radiation losses, $H_w + H_a = h_w + h_a$, whence

$$A = \frac{[\text{illegible}]}{0.2375\,(t_2 - t_1) + m_2 e_2 - m_1 e_1 z - (m_2 - m_1 z)\,(T_2 - 32)} \qquad [3]$$

This formula assumes the leaving air to be saturated. If it is not saturated, the value of m_2 must be multiplied by a factor z_2 = relative humidity of the leaving air. Table 7 has been calculated from this formula. See also paper by C. S. Robinson, *Trans.* A.S.M.E., vol. xliv, p. 669, for formulas that take into account the diffusion of water vapor.

EXAMPLE.—Required the air to cool 475,000 lb. of water from 110° to 80° F. Temperature of entering air, 70° F., relative humidity 70%. Temperature of leaving air 100°; relative humidity 98%.

Solution.—T_1 = 110; T_2 = 80; t_1 = 70; t_2 = 100; z_1 = 0.70; z_2 = 0.98; from Table 6, m_1 = 0.1553; m_2 = 0.4305; from steam tables, e_1 = 1090.8; e_2 = 1104.2. Then $m_1 z_1$ = 0.01087; $m_2 z_2$ = 0.04044;

$$A = \frac{110 - 80}{0.2375(100 - 70) + (1104.2 \times 0.04044) - (1090.8 \times 0.01087) - (0.04044 - 0.01087)\,(80 - 32)}$$
= 0.7257 lb. of air per lb. of water.

From Table 10 p. 1-08, 1 lb. of dry air at 70° F. = 13.35 cu. ft. and 1 lb. of saturated air = 13.69 cu. ft. Volume of vapor = 13.69 − 13.35 = 0.34 cu. ft. Volume of 1 lb. of air at 70° F. and 70% relative humidity = 13.35 + (0.70 × 0.34) = 13.59 cu. ft. Cu. ft. of air required per lb. of water = 13.59 × 0.7257 = 9.862. Total air required = 0.7257 × 475,000 = 344,707.5 lb. = 9.862 × 475,000 = 4,684,450 cu. ft.

WATER EVAPORATED IN A COOLING TOWER per pound of air is represented by the expression $(m_2 - m_1 z)$ in formula [3] above. If A = lb. of air per lb. of water circulated (see Table 7), W = lb. of water circulated per hr. and w = amount of water evaporated per hr., $w = AW\,(m_2 - m_1 z)$. This represents the quantity of make-up water required for surface condensers. Table 8 has been calculated from the above formula.

ATMOSPHERIC COOLING TOWER CAPACITY FOR REFRIGERATION.—Cooling towers are used not only for refrigerating plants for ice-making and food cooling, but also for those used in connection with air conditioning equipment. The heat discharged per minute per ton of refrigeration, which must be eliminated by the cooling tower is:

Compression Plants.—Straight refrigeration, 250 B.t.u.; distilled water ice, 1250 B.t.u.;

refrigeration for gas refrigerating machines. For steam refrigeration, it recommends 3.20 sq. ft. per ton. The air requirements are 300 cu. ft. per min. per ton of refrigeration.

Mechanical refrigeration requires 30 gal.-deg. of water per min. per ton of refrigeration; *i.e.*, if but 1 gal. of water per min. per ton of refrigeration is circulated through the tower, the cooling range will be 30° F.; if 3 gal. per min. are circulated, the cooling range will be 10° F.; if 6 gal. per min. are circulated, the cooling range will be 5° F. Steam refrigeration (see p. 10–27) requires the circulation of at least 3 times the above quantities.

ECONOMY OF COOLING TOWERS.—Gustav J. Bischof (*Power*, Sept., 1933) presents a series of curves showing the relative cost of city water, at $1.00 per 1000 cu. ft. and the cost of operating a cooling tower for ammonia condensers for refrigerating plants, for condensers for steam turbines, and for Diesel engine jacket water. These curves are combined in Fig. 2. The ammonia condenser curve is based on 3 gal. per min. per ton of refrigeration and 10° F. cooling range. The steam turbine condenser curve is based on a steam rate of 20 lb. per kw.-hr., 28-in. vacuum, 940 B.t.u. dissipated per lb. of steam condensed, and a temperature difference of 8° F. between outlet water and vacuum temperature. The city water charges are based on 63° F. temperature. The Diesel engine curve is based on a 50° F. temperature rise in the city water, a 40° F. rise in the cooling tower water and a heat absorption by the cooling water of 3400 B.t.u. per brake-Hp.

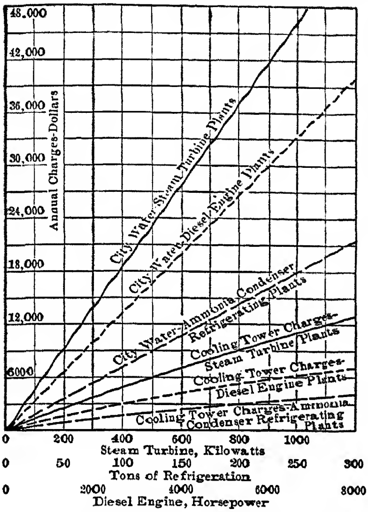

FIG. 2. Comparison of Cost of City Water with Cost of Cooling Tower Operation

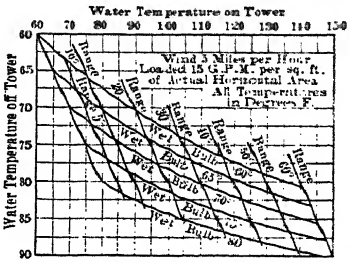

FIG. 3. Type of Guarantee Curve for Cooling Towers

COOLING TOWER GUARANTEES.—Cooling tower capacity sometimes is guaranteed on the basis of a given number of degrees of cooling with a given atmospheric temperature and relative humidity. Unless the stated temperature and humidity coincide, which may not occur over a period of years, the guarantee cannot be verified and the purchaser has no legal relief. A series of curves, similar to Fig. 3, furnished with the cooling tower, permits its performance to be checked under a wide range of conditions of temperature and humidity. The wind velocity in the case of atmospheric towers, the air velocity in mechanical draft towers, and also the loading per sq. ft. of active horizontal deck area, upon which the curves are based should be stated.

2. COOLING PONDS

EVAPORATION FROM PONDS.—In ponds, cooling is mainly by evaporation and is independent of the depth. Box (Treatise on Heat) gives for the rate of evaporation from a pond, in still air,

$$W = (240 + 3.7\,t)\,(P - p)/7000 \qquad [4]$$

where W = moisture evaporated per sq. ft. per hr., lb.; t = average temperature of water, deg. F.; P = saturation pressure of vapor at temperature t, in. of mercury; p = actual vapor pressure of air, in. of mercury. See also p. 3–48.

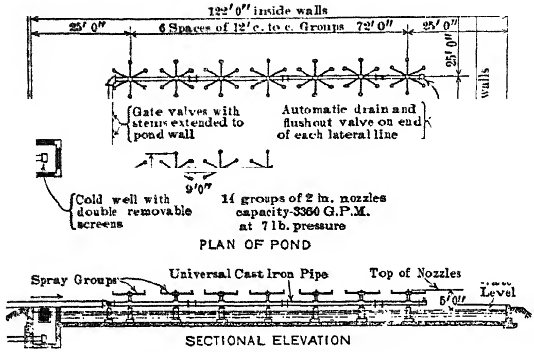
Area of Pond Required.—If the water is not sprayed into the pond, the theoretical area A sq. ft., required to cool Q lb. of water to a final temperature of t_2, deg. F., is

$$A = Q\,(t_1 - t_2)/H. \qquad [5]$$

where t_1 = initial temperature of water entering pond; t_2 = final temperature of water in

pond; H = heat dissipated per sq. ft. per hr., B.t.u., = Wh; h = latent heat of water at temperature t_1; W = weight of water evaporated as given by formula [4]. The value of A so found may be smaller than is usual in practice. Heat dissipation is modified by variations in wind velocity, air temperature and relative humidity. Actual values of H range from 4 B.t.u. per hr. per sq. ft. per deg. temperature difference in summer, to 2 B.t.u. in winter. A good practical average is 3.5 B.t.u.

SPRAY PONDS.—The heat-dissipating capacity of ponds may be increased greatly by spraying the water into them through nozzles which break the water into fine spray, increasing the evaporation and the cooling effect. Final temperatures depend on the cooling range, atmospheric conditions, arrangement of nozzles and storage capacity of pond. A lower final temperature is obtainable with moderate cooling ranges (10° to 20° F.) than with ranges of 30° to 40°. At the same relative humidity, final temperatures will be lower in warm weather than in cold, due to the greater moisture-absorbing power of warm air. Table 9 compiled from curves published by the Cooling Tower Co. gives average final temperatures that may be expected under various conditions.



G. 4. Typical Spray Cooling Pond

The quantity of water stored greatly exceeds the quantity sprayed per minute. Its average temperature is lower than that of the sprayed water, decreasing as the quantity stored increases. Fig. 4 is a layout of a typical spray pond.

Table 9.—Average Final Temperatures of Spray Cooling Ponds

Temp. of Water Entering Nozzles, deg. F.	Ammonia Condenser Service					Steam Condensing Service				
	Wet-bulb Temperature, deg. F.					Wet-bulb Temperature, deg. F.				
	60	65	70	75	80	60	65	70	75	80
	Temperature of Pond, deg. F.					Temperature of Pond, deg. F.

130	83.75	86.5	89.25	91.75	94.50	92.5	94.5	96.5	98.75	101.0

Nozzle pressures of 7 to 10 lb. per sq. in. are usual. Higher pressures produce a finer spray that may be blown away by the wind; lower pressures produce larger drops which retard cooling. Nozzles should be spaced 8 to 12 ft. The pond area should be 1 sq. ft. per 250 lb. of water sprayed per hour for plants of 1000 Hp. or over, and 1 sq. ft. per 150 lb. of water per hour for plants under 1000 Hp. Depth need not exceed 3 ft. Power required to circulate the water ranges from 1% to 2% of the power developed by the prime mover under high vacuum. Table 10 gives the capacities of one type of spray nozzle.

REFRIGERATION AND ICE MAKING

By Louis A. Harding

TABLE OF CONTENTS

REFRIGERATION

REFRIGERATION AND ICE-MAKING

By Louis A. Harding

References.—An elaborate discussion of the thermodynamic theory of the various fluids used in the production of cold was published by M. Ledoux in the *Annales des Mines*, and translated in *Van Nostrand's Magazine* in 1879. This work, revised and additions made by Profs. Denton, Jacobus and Reisenberger, was reprinted in 1892 (Van Nostrand's Science Series No. 46). The work is largely mathematical. Other references are numerous papers in *Trans.* A.S.M.E. and *Trans.* A.S.R.E., and the following books: Siebel, Compend of Mechanical Refrigeration; Lorenz, Modern Refrigerating Machinery, translated by Pope; Gardner T. Voorhees, Refrigerating Machines; J. Wemyss Anderson, Refrigeration; Harding and Willard, Power Plants and Refrigeration; W. R. Woolrich, Refrigerating Engineering; H. J. McIntire, Refrigerating Engineer's Handbook; Refrigerating Data Book of A.S.R.E.; A. J. Wallis-Taylor, Refrigeration, Cold Storage and Ice-making. For Properties of Ammonia and Sulphur Dioxide, see papers by Profs. Wood and Jacobus, *Trans.* A.S.M.E., vols. ix and xii, 1888 and 1891; Univ. of Ill. Bulletin No. 66, Goodenough and Mosher; U. S. Bureau of Standards, Circular No. 142. The Data Book of A.S.R.E. gives thermal properties of a number of refrigerants.

For illustrated descriptions of refrigerating-machines, see catalogs of builders, as Frick & Co., Waynesboro, Pa.; De La Vergne Machine Co., New York; Vilter Mfg. Co., Milwaukee; York Mfg. Co., York, Pa.; Henry Vogt Machine Co., Louisville, Ky.; Carbondale Machine Co., Carbondale, Pa.; and others. See also articles in *Ice & Refrigeration*, *Power*, *Power Plant Engineering*, *Heating, Piping & Air Conditioning*.

REFRIGERATION

1. REFRIGERATION UNITS OF CAPACITY

MEASURE OF REFRIGERATING EFFECT AND STANDARD TON.—The quantity of heat abstracted or absorbed is measured in British thermal units. In the following discussion, 1 B.t.u. will be taken as equivalent to 778 ft.-lb. = 0.2930 watt-hr.

The commercial unit of refrigeration or *standard ton of refrigeration* as adopted by A.S.R.E. is the heat required to *melt* 1 ton (2000 lb.) of pure solid ice, *i.e.*, the heat absorbed by 2000 lb. of pure ice melting to water at 32° F. The 144 B.t.u. absorbed is the latent heat of ice. One ton of refrigeration, therefore, equals $(144 \times 2000) = 288{,}000$ B.t.u. per 24 hr. = 12,000 B.t.u. per hr. = 200 B.t.u. per min. All refrigeration calculations are made on a 24-hr. or day basis.

RATING OF REFRIGERATING MACHINES.—Refrigerating machines are rated in tons of refrigeration per 24 hours with a statement of the temperature and pressure range through which they operate while performing this duty.

A refrigerating machine using liquefiable gas or vapor is rated by the number of *standard tons* it is capable of producing under pressures which correspond to a saturated temperature of 5° F. for inlet or suction pressure, and 86° F. for condenser pressure, with 9° F. subcooling of the liquid entering the throttling or regulating valve, and 9° F. superheating of vapor entering the compressor. These pressures and temperatures are to be measured outside of and within 10 ft. of the machine.

The Ice-making Capacity of a machine in tons of ice is assumed as approximately one-half its refrigerating capacity. The production of 1 ton of ice necessitates reducing the temperature of the water to 32° F., the extraction of its latent heat, and reducing the temperature of the ice to the mean temperature of the brine tank (approximately (11° to 16° F.). The average temperature of the manufactured ice harvested is $(16 + 32)/2 = 24°$ F. Heat extracted to freeze 1 lb. of ice (initial temperature of water, 75°) is:

To lower temperature of water, $1 \times (75 - 32) \times 1$ (specific heat of water) =	43 B.t.u.
To freeze 1 lb. of water, 1×144 (latent heat of ice) .... =	144 "
To reduce temperature of ice, $1 \times (32 - 16) \times 0.5$ (specific heat of ice) ... =	8 "
Total..	195 B.t.u.
20% of 195 (heat transmission losses of brine tank, ice storage room, heat introduced by warm ice cans, etc.)	39 "
Total heat required to manufacture 1 lb. of ice.......................	234 B.t.u.

The heat required to manufacture 1 ton of ice from water at 75° F. is $2000 \times 234 = 468{,}000$

B.t.u. The refrigerating capacity of the machine required for 1 ton of ice, working through the above temperature range, is 468,000/288,000 = 1.625 tons of refrigeration.

REFRIGERATING LOAD.—The refrigerating load of a cold storage or other refrigerating plant consists of heat abstracted for the following purposes: 1. To cool the goods

Table 1.—Composition and Specific Heat of Food Products and Storage Temperatures

stored, depending on initial and final temperatures of the goods, their weights and specific heats. 2. To offset heat transmission of the cold storage room walls, depending on the difference in temperature between the inside and outside of the room and the character of wall construction. 3. For ventilation including heat to be extracted from air passing into the room for ventilating purposes, and that required for lowering the temperature of and precipitating moisture contained in the entering air, depending upon initial and final temperatures of the air and its relative humidity. 4. To offset heat inside the room, including that generated by men working, by motors, fans, etc., and lights in the room.

1. Heat abstracted to cool the goods stored = $sw(t_1 - t)$, where s = specific heat of goods; w = weight, lb.; t_1 = outside temperature, deg. F.; t = inside temperature, deg. F. If the goods are to be frozen, *i.e.*, carried at a temperature below 32° F., the B.t.u. required = $(t_1 - t_2)\ sw + (Pw \times 144)$, where P = percentage of water contained in the goods. Tables 1, 2, 3, 4 and 5 give data for estimating the above quantities.

2. Heat transmission of walls may be estimated from Tables 6 and 7.

3. If a fan is used to circulate cold air in the room or through the cold room, the heat generated by the fan will be introduced into the circulation and extra refrigeration must be provided on the basis of 1 Hp. = 2546 B.t.u. per hr. The brake-Hp. required for a fan will be B.Hp. = $5.2\,pQ/(E \times 33{,}000)$, where p = total pressure of the air, in. of water, at the fan outlet; Q = cu. ft. of air circulated per min.; E = mechanical efficiency of fan = 0.50 for a steel plate ventilating fan, and 0.60 for a multiblade fan (approximate). In a well-proportioned system of ducts and cooling chamber, p ordinarily should not exceed 1 in. of water, equivalent to a pressure of 5.2 lb. per sq. ft.

4. The heat abstracted to offset the heat generated inside the cold storage room may be estimated from the following data: Heat given off per workman per hr., 500 B.t.u.; heat given off by one gas light per hr., 3600 B.t.u.; heat given off by incandescent lights, 3.41 B.t.u. per watt.

Example.—Required the refrigeration to cool 50,000 lb. of meat from 95° to 35° F. per 24 hr.; outside temperature 85° F. and 70% humidity. Size of room 40 × 60 × 12 ft. Ventilation, 10 changes of air per 24 hr., based on inside temperature. Walls, 13 in. brick; roof, 1 1/2 in. wood with large air space and 1 in. ceiling. Floor construction, 6 in. concrete on cinder fill. Insulation on all walls, floor and ceiling, 3-in. corkboard.

1. *Refrigeration Load.*—To cool the goods stored,

$$sw(t_1 - t) = 0.8 \times 50{,}000 \times (95 - 35) = 2{,}400{,}000 \text{ B.t.u. per 24 hr.}$$

2. *Heat Transmission.*—B.t.u. = area × transmission coefficient × temperature difference.

12-in brick walls + 3-in. corkboard, 2400 sq. ft. × 1.75 × 50	210,000 B.t.u.
6-in. concrete floor + 3-in. corkboard, 2400 sq. ft. × 1.97 × 15	71,000 "
1-in. wood ceiling + 3-in. corkboard, 2400 sq. ft. × 1.99 × 50	238,800 "
	519,800 B.t.u.

3. *Ventilation.*—Cu. ft. of air introduced per 24 hr. = 40 × 60 × 12 × 10 = 288,000 cu. ft. Weight of moisture contained in air at 85° F. and 70% humidity (0.026 × 0.70) = 0.0182 lb. of vapor per lb. of air. The air will be reduced to a saturated state of 35° F. on entering the room and will then carry 0.00427 lb. of moisture per lb. of air introduced. Latent heat of the vapor at 35° F. = 1074.4 B.t.u. Specific heat of vapor = 0.46. Weight of air per 24 hr. = 23,040 lb.

To lower temperature of air, 23,040 × 0.24 (85 − 35)	276,480 B.t.u.
To lower temperature of vapor, 23,040 × 0.018 × 0.46 (85 − 35)	9,539 "
To condense vapor, 23,040 × (0.0182 − 0.00427) × 1074.4	346,558 "
	632,577 B.t.u.

The precipitated moisture deposited on the cooling coil will be frozen. The coil temperature is approximately 10° lower than room temperature; in this case it is 25°. The heat abstracted per lb. of moisture precipitated is as follows:

Reducing temperature from 35° to 32°	3 B.t.u.
Freezing	144 "
Reducing temperature of ice from 32 to 25 = 0.5 (32 − 25)	3.5 "
	150.5 B.t.u.

Total heat thus abstracted, 150.5 × 0.014 × 23,040 = 48,545 B.t.u.
Total heat abstracted by ventilation = 632,577 + 48,545 = 681,122 B.t.u.

Total Refrigeration Required.

(1) To cool the goods stored	2,400,000 B.t.u.
(2) Heat transmission	519,800 "
(3) Ventilation	681,122 "
	3,600,922 B.t.u.

1 ton of refrigeration = 288,000 B.t.u.; refrigeration required is 3,600,922/288,000 = 12.5 tons

HEAT TRANSMISSION OF BUILDING CONSTRUCTION.—The method, including conductivities of the materials and surface coefficients, used in calculating heat transmission of building construction is given in Section 11, p. 11–03. Data in Table 6 were calculated as therein described. The heat transmission of a compound wall for any combina-

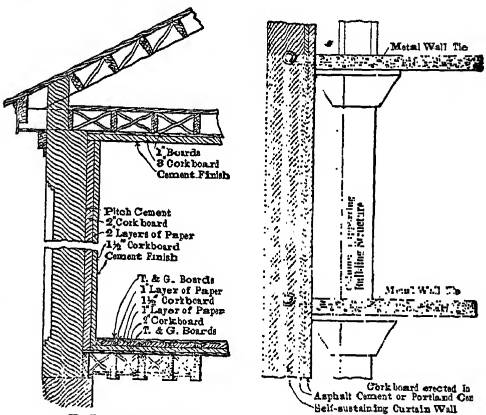
tion of materials may be found when the conductivities and surface coefficients of the materials are known.

The following conductivities C were used in the calculations for data given in Table 6; Brick, $C = 5$; concrete, $C = 8$; tile, 6-in., $C = 0.54$; 8-in., $C = 0.49$; 10-in., $C = 0.46$; cork board, $C = 0.30$; plaster, $C = 2.32$; $^7/_8$-in. boards, $C = 1.0$; one air space, $C = 1.1$. Outside wall surface coefficient, $K = 1.34$; inside wall surface coefficient, $K = 4.02$. The value of u as determined by the heat transmission formula was multiplied by 24 to obtain heat transmission per 24 hr.

2. COLD STORAGE

Relative Humidity for Cold Storage Rooms.—If air in a cold storage room is recirculated only, it soon is devoid of moisture, which is condensed on cold coil surfaces. The ultimate result is evaporation of moisture from stored product, with a loss of weight and value, which is to be avoided if possible. The proper relative humidity for each product stored has not been definitely ascertained. In general, it is safe to maintain a percent relative humidity equal to the moisture percentage in the stored product. Table 4 (H. Vetter) gives recommended data for several products.

C. E. Baker gives the optimum temperature for apple storage as 31° to 33° F. with relative humidity of 80 to 85%. Approximate control of relative humidity in rooms cooled by the direct method may be obtained by relatively large coil surfaces proportioned on a basis of 10° to 12° temperature difference.



Built-up Insulation Continuous Insulation

FIG. 1. Methods of Insulating Walls

While the method of approximately controlling relative humidity usually is satisfactory for small or medium size rooms, large rooms are best served by a central refrigerating and air conditioning system, rooms being refrigerated by cold air fan circulation. The circulated air is cooled and saturated by a spray type dehumidifier. Water for sprays is cooled by refrigeration. See Section 11, p. 11–55. Table 5, giving operating conditions for meat storage rooms cooled by a central cooling and air conditioning plant is from Sulzer *Tech. Rev.*, No. 3, 1927, translated by J. D. Blake in *Aerologist*, June, 1928.

Provision must be made to heat saturated cooled air leaving dehumidifier or cooling chamber by passing it through a heater to obtain complete and satisfactory control of relative humidity in rooms being cooled.

CORK PIPE-COVERING is a molded covering, manufactured in three types, *viz.*, ice water thickness, brine thickness, and heavy brine thickness. Ice water thickness, used for temperatures above 25° F., is $1^1/_2$ to 2 in. thick. Brine thickness, used for temperatures from 0° F. to 25° F., is 2 to 3 in. thick. Heavy brine thickness, used for temperatures below 0° F., is 3 to 4 in. thick.

THE BRINE SPRAY BUNKER system of room cooling is used principally in hog or beef chill rooms of meat packing plants. It consists of spraying cold brine in spray bunkers or lofts near the ceiling. The brine spray induces rapid circulation of air and maintains a fairly high relative humidity, which rapidly chills meat without "case hardening" and without appreciable loss of weight or shrinkage. Pressure of 8 to 20 lb. per sq. in. is maintained at the spray nozzles, spaced 1 to 5 ft. centers. At each end of the bunker is a large gravity air circulation duct. Air circulation is in direction of the spray. This system is cheaper than a cold air fan circulating system.

THE FORCED AIR CIRCULATION SYSTEM uses a fan to recirculate air over cooling coils located in a small room called a cooler. The air is piped from the cooler to

the cold storage rooms, and returned from them to the fan by a return duct. A coil with fan (unit cooler) is becoming a popular method of room cooling. The advantages of the system are: Centralizing of brine or refrigerant piping; moisture precipitation all occurs in the cooler; cold storage rooms are dry and free from cooling coil drip.

If air is cooled by a spray type dehumidifier, relative humidity in the rooms also may be controlled. It must be possible to heat the air leaving the dehumidifier to obtain complete control of relative humidity in the cold storage rooms.

Example.—Assume a forced air circulation system to be used in the previous example, the air leaving the cooler at 20° F., and returning at 35°. The fan must handle

$$3{,}600{,}922/(0.24 \times 15 \times 60 \times 24) = 694 \text{ lb. of air} = 8710 \text{ cu. ft. of air per min.}$$

With an air velocity of 500 ft. per min., through the face area of cooling coils, the total pressure rating of the fan should not exceed 1 in. of water. This will require a steel plate fan, 42 in. wheel, 475 r.p.m. and 4.58 brake-Hp., or a multiblade fan, 36 in. diam., 300 r.p.m. and 3.3 brake-Hp. Using the multiblade fan, the heat equivalent of the power required to move the air, which is intro- nto the circulation is 3.3 × 2545 × 24 = 201,564 B.t.u. per 24 hr., equivalent to [illegible] = 0.70 ton of refrigeration, which must be added to the amount previously calcu- The total refrigeration required then is 12.5 + 0.70 = 13.2 tons.

TESTS OF SMALL REFRIGERATORS.—Table 8 gives results of tests made by the author to determine the heat transmission of the walls of three well-known makes of small ice-cooled refrigerators. The figures are an average of several tests run in still air with the boxes empty and doors made tight with felt and kept closed during the tests. The boxes were cooled to constant temperature conditions before the tests were started.

REFRIGERATION REQUIRED FOR SMALL BOXES AND ROOMS.—In large rooms the heat losses may be analyzed with some degree of certainty when conditions of operation are known. For small refrigerators as in hotels, kitchens and private homes, etc., the following data are recommended as giving better results than a more elaborate analysis. Heat loss, B.t.u. per cu. ft. per 24 hr.: Pantry refrigerator, 300; kitchen refrigerator, 600 to 900; butchers' display refrigerators, 200 to 250; long storage, 150 to 200. An allowance of from 200 to 225 B.t.u. is made per lb. of ice. In applying the data, as- a refrigerator temperature of approximately 45° F. and an average summer tem-

perature of 72° F. For pantry and kitchen refrigerators, outside dimensions are used in figuring volumes. Each lineal foot of insulated brine pipe requires approximately the same refrigeration as 1 cu. ft. of box. The approximate refrigeration required for large boxes and rooms, together with the pipe or coil surface necessary, is given in Table 9.

EXAMPLE.—Required the amount of refrigeration and brine pipe surface for a pantry refrigerator, $4 \times 2 \times 6$ ft.; average inside temperature 45° F.; average brine temperature in cooling pipes, 20° F. Allow for 50 ft. of insulated brine pipe. Total cu. ft. $= (4 \times 2 \times 6) + 50 = 98$. Tons of refrigeration per 24 hr. $= (300 \times 98)/288{,}000 = 0.102$, equivalent to $0.102 \times 12{,}000 = 1224$ B.t.u. per hr. Taking the coefficient of heat transmission $K = 2$, the amount of pipe surface required will be $S = (300 \times 48)/24 \times 2\ (45 - 20) = 12$ sq. ft. or 34 lineal feet of 1-in. pipe. See Heat Transfer in Room Piping, p. 10–10.

APPROXIMATE REFRIGERATION IN TONS REQUIRED FOR VARIOUS PURPOSES.—The following data are from a bulletin issued by Am. Carbonic Machy. Co. These data will guide preliminary estimates and check more refined calculations after operating conditions are known.

General Cold Storage Buildings

Desired temp., deg. F.	0	5	10	20	32	36
Cu. ft. per ton, rooms up to 1000 cu. ft.	500	1000	2000	3000	4000	5000
" " " over " "	1000	2000	3000	5000	7000	8000

One ton of refrigerating machine capacity is required for the quantities given in each class in the following services:

Apartment Buildings.—16–20 apartment refrigerators; 1000 cu. ft. of restaurant refrigerator.

Bakeries.—800 cu. ft. of air circulated for air-conditioned dough mixing room*; 1000 cu. ft. of air through high speed 3-bbl. dough mixer*; 1000 gal. water cooled per day.*

Candy Factories.—2000 cu. ft.*; 1500 cu. ft. of fruit and nut storage*; 2 chocolate enrobers.

Creameries.—3000 gal. of milk cooled per day; 1000 cu. ft. of butter and milk storage.

Drinking Water.—1000 gal. per day cooled from 75° to 40° F.*; 200 persons in office building*; 150 persons in factories.*

Fur Storage Vaults.—1500 cu. ft. for vault space.*

Hotels.—1000 cu. ft. of kitchen service and storage refrigerators; 5–10 ice-cream cans in serving counters; drinking water cooling, 60 rooms*; ice-making, 125 rooms; air conditioning and cooling dining-rooms, 10–12 seats*; ball rooms, 500 cu. ft. of air circulated.*

Ice Cream Factories.—120 to 150 gal. of ice cream made and hardened per day.

Ice Plants.—1000 lb. of ice per day.

Meat Markets.—1000 cu. ft. storage refrigerator space; 50 lineal ft. display counter.

Pipe Line Losses.—1000 lineal ft. drinking water piping; 750 lineal ft. brine mains.

Theater Cooling.—10–15 seats* (see Sect. 11, p. 11–60).

Ice Skating Rinks.—The following averages are based on 9 rinks in the U. S.: Sq. ft. of ice surface per ton of machine capacity, 169.3; lineal feet of 1 1/4-in. pipe per sq. ft. of ice surface, 2.85, 4-in. pipe centers, pipes across the arena. For good skating conditions, about 0.40 B.t.u. per min. per sq. ft. must be absorbed. Brine temperature, approximately 18° F. for bare pipe; 10° to 12° F. for embedded pipe. Ice surfaces removed one day and replaced the next require nearly twice as much refrigeration as a surface that remains frozen. Brine storage tanks always are used, but tank capacity is relatively small.

3. HEAT TRANSMISSION

HEAT TRANSMISSION OF PIPING IN REFRIGERATING PRACTICE.—The coefficient of heat transmission K = B.t.u. transmitted per sq. ft. per deg. F. difference in temperature per hr. It varies with the velocity of the gas or liquid in contact with the surfaces. The following formulas are given (*Trans.* A.S.R.E., 1907) for the heat transmission of double-pipe ammonia condensers: $K = 130\sqrt{w_w}$; $Q = KS \times \Delta t$, where Q = heat transmitted, B.t.u. per hr. $= K \times S \times \Delta t$; S = sq. ft. of surface; t_1, t_2 = initial and final temperatures of cooling water or brine, respectively, deg. F.; Δt = mean temperature difference; w_w = velocity of water over the pipe surface, ft. per sec.

For double-pipe brine coolers $K = 84\sqrt{w_b}$, where w_b = velocity of brine through the pipe, ft. per sec., $Q = K \times S \times \Delta t$, and $\Delta t = \{(t_1 + t_2)/2\} - t_0$, where t_0 = temperature

* Required capacity of compressor for daily operating periods of 24 hr. or less; allowances not marked (*) are based on 24-hr. operation of compressor. For less than 24-hr. operation (brine circulation), size of plant is $(24 \times Q)/h$, where Q = size as determined from above allowances and h = hours operated.

of gas maintained in evaporating coil. The York Mfg. Co., York, Pa., gives the heat transmission obtained with circulating water and brine at different velocities as follows:

For 1 1/4-in. and 2-in. double-pipe ammonia condensers:

Velocity of water in coil, ft. per min	100	150	200	250	300	400
B.t.u. per hr. per sq. ft. per deg. mean temperature difference	150	198	240	260	300	338

For 2-in. and 3-in. double-pipe brine coolers:

Velocity of brine in coil, ft. per min	100	150	200	250	300	400	500	600	700	800
B.t.u. per hr. per sq. ft. per deg. mean temperature difference	95	112	130	145	158	177	191	205	215	220

The above figures were obtained in tests. For ordinary practice the heat transmission is taken as 30 to 40% less.

The York Mfg. Co. gives for the surface required in ammonia condensers

$$S = [HA + \{AC(t - t_1)\}] \div \{K(t_1 - t_2)\} \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

where S = surface, sq. ft.; H = heat of vaporization at condensing pressure, B.t.u. A = ammonia circulated per min. per ton of refrigeration, lb.; C = specific heat of vapor; t = temperature of gas entering condenser, deg. F.; t_1 = temperature due to condensing pressure; t_2 = mean temperature of water on and off condenser; K = B.t.u. transmitted per hr. per sq. ft. per deg. mean temperature difference.

Various tests made on shell-tube type condensers indicate the following values for K for various water velocities through tubes:

Velocity, ft. per min	100	150	200	250
K	170	190	210	230

HEAT TRANSMITTED FROM LIQUID TO LIQUID.—Hausbrand gives for the quantity of heat transmitted from liquid to liquid, the formula

$$K = 60/[\{1/(1 + 3.33\sqrt{w_1})\} + \{1/(1 + 3.33\sqrt{w_2})\}] \quad . \quad . \quad . \quad . \quad . \quad [2]$$

where w_1 and w_2 = velocities on opposite sides of the pipe surface. If $w_1 = w_2$, then $K = 30(1 + 3.33\sqrt{w})$, and $Q = KS \times \Delta t$, where Δt = mean temperature difference between the two liquids. This formula is applicable to the "heat exchanger" used in the absorption system.

MEAN TEMPERATURE DIFFERENCE.—The mean temperature difference Δt between two fluids which alter their temperatures during an exchange of heat, may be determined by the constant in Table 10. If D_e and D_a = smallest and greatest temperature difference, respectively, and D_e/D_a = ratio of smallest to greatest difference (see column 1) and M = a constant (see column 2), then $\Delta t = M \times D_a$ is the mean temperature difference.

HEAT TRANSMITTED FROM STEAM TO BOILING WATER.—Prof. Greene gives from the experiments of Jelinck, the formula

$$K = 953/\sqrt{ld} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

d = diam of pipe or tube, ft ; l = total length of pipe, ft.

HEAT TRANSFER IN ROOM PIPING.—The rate of heat transfer per deg. difference in temperature between ammonia or brine and air, circulated by gravity in cold-storage rooms as interpolated from a diagram by C. H. Herter (*Refrig. Wld.*, Oct., 1915) are:

D =	6	8	10	12	14	16	18	20
K =	1.20	1 50	1.75	2.00	2.17	2.30	2.40	2.48

D = temperature difference between room and refrigerating medium; K = heat transfer,

Table 10.—Mean Temperature Difference Δt. (Hausbrand)

B.t.u. per hr. per sq. ft. per deg. temp. diff. These values are to be applied to room piping fairly free from frost. Table 11, condensed from one by O. Gueth in the Refrigerating Engrs. Manual, presumably represents practice of various makers of refrigerating machines. See also series of papers, Basic Laws and Data of Heat Transmission, by W. J. King, *Mech. Engg.*, Mar.-Aug., 1932, for a comprehensive survey of this subject.

The method used in the following example, to ascertain coil surface required for a given amount of work is due to C. D. Fehl.

EXAMPLE.—5000 lb. of beef are stored per day of 24 hr. in a room 31 × 12 × 15 ft. high, exposed on all sides to outside temperature of 90° F. Beef enters the room at 90° F. and is cooled to room temperature of 33° F. Using 4-in. corkboard on all parts of room, allows a heat leakage of 1.5 B.t.u. per sq. ft. per 24 hr. per deg. temperature difference. Specific heat of beef assumed as 0.77. Total exposed surface = 1980 sq. ft.

Heat transmitted through wall, $\{1980 \times 1.5 \times (90 - 33)\}/24$	=	7,054 B.t.u.
Heat abstracted from beef, $\{5000 \times 0.77 \times (90 - 33)\}/24$	=	9,144 "
Two workmen at 500 B.t.u., each	=	1,000 "
Three 16-cp. incandescent lights, at 254 B.t.u., each	=	762 "
Total B.t.u. per hr.	=	17,960 B.t.u.
Add 20% for opening doors, etc.	=	3,592 B.t.u.
Net heat to be abstracted per hr	=	21,552 B.t.u.

The surface required in the room is based on the assumption that the brine enters the room coils at 15° and leaves at 20° F. The least difference in temperature is $(33 - 20) = 13$, and the greatest is $(90 - 15) = 75$. Using Hausbrand's method (see above) $13/78 = 0.173$, and from Table 10, by interpolation, the coefficient corresponding to 0.173 is $M = 0.47$; whence $0.47 \times 75 = 35.25$ mean temperature difference. If the arithmetical mean temperature difference is used, it is

$$\{(90 + 33)/2\} - \{(20 + 15)/2\} = 44° \text{ F.}$$

The surface required is $21{,}552/(2 \times 35.25) = 305.7$ sq. ft., assuming that the pipe is frosted and transmits 2 B.t.u. per hr. per sq. ft. per deg. of temperature difference. Lineal feet of 1 1/4-in. pipe required is $305.7 \times 2.301 = 703.4$.

The above method may be used to calculate all coil surfaces, where velocities of liquids or gases as well as the heat transmission at the different velocities are known. It is advisable to add 20% to the calculated surface, since in practice the brine may rise to a higher temperature than assumed.

4. METHODS OF PRODUCING ARTIFICIAL REFRIGERATION

Low temperatures may be produced by a comparatively rapid absorption of heat by certain substances during either a chemical or a physical change of state. Chemical changes require, and are accompanied by, a heat transfer. The tendency of certain salts in combination with water, acid or ice, to pass into a liquid state is so great that the heat energy required for the change cannot all be supplied from outside the mixture. The deficiency is supplied by the heat of the mixture itself, with a consequent lowering of the temperature. The salts used in so-called freezing mixtures are those alkalies which possess the property of solubility at comparatively low temperature. Refrigeration by a chemical change is not commercially possible, as the energy expended to change the state of the resultant mixture back to its original constituents is excessive. The high cost of the materials used render imperative a continuous cycle of operation. The most common form of freezing mixture is ice and common salt Other mixtures use snow and calcium chloride, snow and sulphuric acid, snow and hydrochloric acid, sulphate of sodium and hydrochloric acid or sulphuric acid, etc. See p. 3–23 for freezing mixtures.

PHYSICAL CHANGE OF STATE.—Artificial refrigeration is produced commercially by apparatus causing a physical change of state only by mechanical process. The fol-

lowing systems are at present (1935) in use: 1. Cold air machines, using air as the refrigerating medium. 2. Vapor compression machines, using a volatile liquid, as ammonia (NH_3), sulphur dioxide (SO_2), carbon dioxide (CO_2), Dielene ($CH_3 Cl_2$), Carrene ($CH_2 Cl_2$), etc., as the refrigerant. 3. Steam jet vacuum machines, using water vapor as the medium. 4. Absorption machines, using ammonia as the refrigerant.

Cold-Air Machines

The operation of the cold-air machines is based on the first law of thermodynamics. If a compressed gas or air, cut off from the source of supply, expands in a cylinder, moving a piston and performing external work, heat is abstracted from the working substance, since heat and work are mutually convertible. If the expansion occurs in a non-conducting cylinder, it is adiabatic and the temperature of the air expanded in the cylinder falls. The cold expanded air is circulated through the space to be cooled, absorbing heat and producing the refrigerating effect desired. The excessive size of compressor cylinders and their relatively low efficiency, as compared with machines using saturated vapor for a refrigerating medium, has practically limited cold-air installations to shipboard. The low specific heat of air requires the circulation of large volumes and the use of bulky apparatus. The compressor cylinder capacity is approximately 16 times that required for equal duty with ammonia used as a refrigerant.

Cold-air systems should be worked on a closed cycle, the air being recirculated to keep the working temperature range low and also to avoid the loss and operating difficulty caused by freezing of moisture in outside air taken into the system. If air introduced to make up leakage loss is chilled below its dew point before introduction, its water vapor will be precipitated and the system will operate practically with dry air.

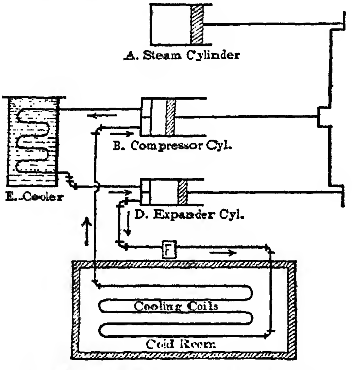

Fig. 2. Diagram of Cold Air Machine

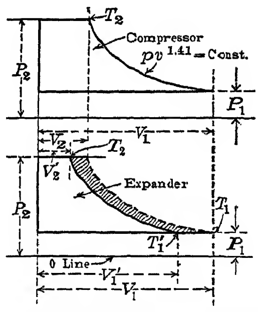

Fig. 3. Indicator Cards, Cold Air Machine

THE ALLEN DENSE AIR MACHINE.—The operating cycle above indicated is accomplished in the Allen dense air machine, Fig. 2. Air is drawn into the compressor B from the refrigerator coil at a gage pressure of from 60 to 70 lb. per sq. in. It is compressed (single stage) to from 210 to 240 lb. per sq. in., gage, and passes through a cooling coil E surrounded by water, which removes the heat of compression. The air leaves the coil at about 10° F. higher than the final temperature of the cooling water. The reduced volume of cooled air expands in the cylinder D which has an adjustable cut-off gear The air, in expanding, assists in driving the compressor, thereby recovering a large portion of the external work of compression. The expansion of the air causes its temperature to fall, and it then passes to the coils of the room to be refrigerated, returning thence to the compressor cylinder. An oil extractor F in the discharge line permits the frozen oil to be collected and melted. Make-up air required to keep the system fully charged is compressed in a small cylinder and discharged into cooler E, where its temperature is lowered and moisture precipitated before it is introduced into the system.

The operation of the cold-air system is explained by formulas below. Compression of the air and its re-expansion are assumed to take place adiabatically (Fig. 3).

Compression.—Let v_1 = volume of air drawn into compressor cylinder per min.; T_1 = absolute initial temperature of this air and p_1 = its initial pressure. T_1 is about

Table 12.—Tests on Cold-air Machines

(Linde, *Trans.* A.S.M.E., xiv, p. 1416)

	System		
	Bell-Coleman	Lightfoot

Temp. of air entering compression cylinders, deg. F	65.5	62.0	
Temp. of air after expansion, deg. F	−52.6	−82.0	−85.0
I.Hp. in compression cylinder	124.5	43.1	346.4
I.Hp. in expansion cylinder	58.5	28.0	176.2
I.Hp. in steam cylinder	84.4	24.6	332.7
B.t.u. abstracted per hour per I.Hp. of steam cylinder, at 20° F	668.0	1554.0	954.0

10° below the temperature to be maintained in the refrigerator. Let v_2, p_2 and T_2 be the volume, pressure and absolute temperature, respectively, of the air after compression All pressures are lb. per sq. in., absolute. Then

$$T_2 = T_1 (p_2/p_1)^{0.29};\ v_2^{1.41} = p_1 v_1^{1.41}/p_2 \quad [4]$$

Work of compression, ft.-lb. per min., is $w = 3.45 (p_2 v_2 - p_1 v_1) \times 144$ . . . [5]

Cooling.—Volume v_2 is reduced to volume v'_2 in the cooler at constant pressure.

$$v'_2 = v_2(T'_2/T_2) \quad [6]$$

The B.t.u. imparted to the cooling water per lb. of air circulated is

$$H = C_{pa}(T_2 - T'_2) \quad [7]$$

where $C_{pa} = 0.24$ = specific heat of air at constant pressure.

Expansion Cylinder.—The reduced volume v'_2 expands adiabatically to v'_1 and pressure p'_1. Then

$$(v'_2)^{1.41} = p_1(v'_1)^{1.41}/p'_2 \quad [8]$$

Work recovered by expansion, ft.-lb., is $w' = 3.45(p_2 v'_2 - p_1 v'_1) \times 144$, . . [9]

Final absolute temperature is $= T'_1 = T'_2(p_1/p_2)^{0.29}$. . . . . . [10]

Expansion in Refrigerator Coils.—Volume v'_1 expands in the refrigerator coil at constant pressure p_1, returning to original volume v_1 and temperature T_1. $v_1 = v'_1(T_1/T'_1)$ . . [11] The shaded portion of Fig. 3 gives the refrigerating effect (heat removed = H) per cu. ft. of piston displacement.

$$H = C_{pa}\, d(T_1 - T'_1)\ \text{B.t.u.} \quad [12]$$

where d = density, lb. per cu. ft. of air at temperature T_1 and pressure p_1. The density for any pressure is given by the characteristic equation of gases $PV = MRT$, where P = absolute pressure, lb. per sq. ft., T = absolute temperature, and R = 53.35 for air. If M is 1 lb. and v is the volume, cu. ft., $Pv = Rt$ or $1/v = P/RT$. But $1/v = d = P/RT$ which gives the density in terms P, R and T.

Compressor Displacement Required per Ton of Refrigeration.—Let D = displacement of compressor per 24 hr. per ton of refrigeration, cu. ft., E = volumetric efficiency of compressor (80% approximately). Then

$$D = 288{,}000 \div \{d \times C_{pa}(T_1 - T'_1) \times E\} \quad [13]$$

and the net horsepower required is

$$33{,}000 = \frac{\{3.45(p_2 v_2 - p_1 v_1 - p_2 v'_2 + p_1 v'_1) \times 144\}}{33{,}000} \quad [14]$$

Vapor Compression Machines

The media generally used in compression machines, ammonia, sulphur dioxide, and carbon dioxide, etc., exist only as a gas or vapor at atmospheric pressures and ordinary temperatures, but they are liquefied when compressed to a sufficiently high pressure and cooled. The heat absorbed in re-evaporating the liquid at a reduced pressure constitutes the refrigerating effect. To periodically return the refrigerating medium to its original liquid state, the system must comprise the following parts: 1. Evaporating coils, wherein the liquid is evaporated, absorbing heat from its surroundings and producing the refrigerating effect. 2. The compressor, in which vapor from the evaporating coils is compressed into the condenser at a terminal pressure corresponding to the temperature of the saturated vapor obtainable with the cooling water available. 3. The condenser, in which the latent heat and heat of compression is removed and the vapor liquefied by cooling water circulated through or over the condenser pipes or tubes.

MEDIA.—The choice of vapor depends on: 1. Pressure range corresponding to temperature to be maintained in condenser and evaporator. 2. Volume of medium to be

drawn into compressor to produce a given amount of refrigeration. This determines the displacement of the compressor used.

Table 13 (condensed from Data Book, A.S.R.E., 1933 ed.) gives data on commonly used refrigerants. The Data Book contains tables of thermal properties of isobutane, butane, methyl chloride, ethane and dichlorodifluoromethane (freon, F-12).

Ammonia (NH_3) is used most generally in cold storage and ice-making plants; for the temperature range in practice between evaporator and condenser it does not require the compressor to handle large volumes of gas, and condensing pressure is approximately 180 lb. per sq. in. for usual condensing water temperatures. Ammonia gas from a safety standpoint, in case the gas escapes, is not favored for cooling auditoriums, installations on ships, etc., where an odorless refrigerating equipment may be required; carbon dioxide (CO_2) often is preferred.

Carbon Dioxide operating pressures are relatively high, about 1000 lb. per sq. in. for usual condensing water temperatures; steel compressor cylinders are required. CO_2 machines are used in chemical processes requiring low temperatures, which NH_3 machines cannot meet without going below atmospheric pressure on suction (evaporation) side of machine, allowing air and its contained vapor to enter. Air, being non-condensible at temperatures and condenser pressures available, would lower efficiency and capacity.

Compressed CO_2, so-called *dry ice*, is used as a refrigerant in shipment of ice cream, fish and meats It completely disappears when vaporized and has high refrigerating effect for its weight.

Sulphur Dioxide (SO_2) is not used for evaporator temperatures below about 20° F. Another objection is that SO_2 forms highly corrosive sulphurous acid on contact with moisture in in-leaking air. For usual temperature ranges, however, SO_2 is very satisfac-

tainers. Dielene is slightly combustible; its flame generally is self-extinguishing. Carrene, which may be interchangeably used in the same system, is non-combustible. The relatively large volume of gas necessary to produce refrigerating effect makes their use in reciprocating machines impractical. These refrigerants always operate below atmospheric pressure, and the apparatus requires more or less continuous removal of air, which carries with it some refrigerant. The loss is not serious, and replacement cost probably does not exceed that of other refrigerants which operate above atmospheric pressure. Freon, F-12 (CCl_2F_2) is used in connection with surface-type, direct expansion coolers, used for air conditioning. Ordinarily, condensing pressure does not exceed 120 lb. per sq. in. with usual available condenser cooling water temperatures.

Water-vapor, used with a turbo-compressor or a steam-jet ejector-type thermo-compressor, is used to cool water for industrial uses and air conditioning. Its application is limited to cooling to approximately 40° F. minimum when steam is available. As a large volume of water-vapor is drawn from the evaporator, a reciprocating compressor is impractical.

TOTAL-HEAT-ENTROPY DIAGRAMS FOR AMMONIA, CARBON DIOXIDE, SULPHUR DIOXIDE, METHYL CHLORIDE AND FREON (Figs. 4 to 8, by the author, *Heating, Piping & Air Conditioning Magazine*, Aug., 1935) may be used to approximate refrigerating effect R and the value of M_m or M_r, heat equivalent of the work of compression $(h_c - h_s)$ or $(h_c - h_1)$, and horsepower per ton of refrigeration. To compress the diagrams to fit the page, the heat content scale has been shortened. Upper scale is for vapor and lower scale is for liquid. On the NH_3 diagram, standard conditions (5° evaporator temp. and 86° condenser temp.) for the theoretical Rankine cycle are shown; also standard machine rating conditions with 9° subcooling of liquid and 9° superheat for suction vapor.

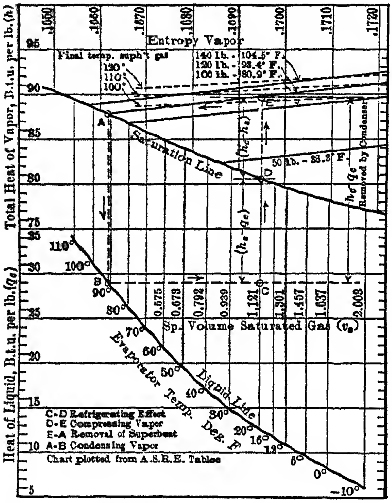

FIG. 8. Total-heat-Entropy Diagram for Freon

For NH_3, and theoretical Rankine cycle, evaporator pressure for 5° is 34.27 lb. per sq. in., abs.; condenser pressure for 86° is 169.2 lb. per sq. in., abs. $q_c = 138.9$ B.t.u.; $h_s = 613.3$ B.t.u. $v_s = 8.15$ cu. ft.; $h_c = 711.3$ B.t.u. $M_r = 200/(613.3 - 138.9) = 0.422$ lb. per ton per min.

Hp. $= 0.422 \times (711.3 - 613.3)/42.5 = 0.973$ per ton. Volume of saturated vapor to be pumped per min. per ton is $V = Mv_s = 0.422 \times 8.15 = 3.44$ cu. ft.

For SO_2 and theoretical Rankine cycle, evaporator pressure for 5° is 11.81 lb. per sq. in., abs.; condenser pressure for 86° is 66.45 lb. per sq. in., abs.; $q_c = 42.12$; $h_s = 183.49$; $v_s = 6.421$; $h = 213$; $M_r = 200/(183.49 - 42.12) = 1.414$ lb. per ton per min.; Hp. $= 1.414\ (213 - 183.5)/42.5 = 0.98$ per ton; $V = 1.414 \times 6.421 = 9.08$ cu. ft. of saturated vapor to be pumped per min. per ton.

For CO_2, and theoretical Rankine cycle, evaporator pressure for 5° is 332 lb. per sq. in., abs.; condenser pressure for 86° is 1043 lb. per sq. in., abs.; $q_c = 83.3$; $h_s = 138.75$; $v_s = 0.266$; $h = 159$; $M_r = 200/(138.75 - 83.3) = 3.60$ lb. per ton per min.; Hp. $= 3.60\ (159 - 138.75)/42.5 = 1.70$ per ton; $V = 3.60 \times 0.266 = 0.958$ cu. ft. of saturated vapor to be pumped per ton per min.

The lines joining points $ABCDE$ in Figs. 4 to 8 represent various states of the refrigerant as it passes through the apparatus for the theoretical Rankine cycle with no subcooling or superheat in the suction gas. The lines $ABFGDHK$ are for the same cycle with 9° F. subcooling of liquid and 9° superheat in suction gas. The following description refers to cycle without subcooling or suction superheat $(ABCDE)$:

Liquid at 86° F. and corresponding condenser pressure p_c, point B, is throttled to the lower pressure p_e, point C, corresponding to evaporator temperature (5° F.), as it passes the expansion valve. Heat-content during throttling remains constant. The remaining liquid evaporates to dry saturated vapor in the expansion coils and absorbs the difference

between heat content at saturation for 5°, point C, and heat content of mixture at point D, which is the refrigerating effect R per lb. of refrigerant circulated. Compression begins at D; it is complete when condenser pressure p_c is reached at E. Adiabatic compression is assumed, and the heat equivalent of the work done in compressing 1 lb. of vapor is difference between heat content at D and E. Entropy remains constant at an adiabatic change of state. The compressed vapor condenses at constant condenser temperature 86° and corresponding pressure p_c due to removal of heat of compression and its latent heat by the condenser cooling water. Heat to be removed per pound of refrigerant is difference between heat content of superheated vapor at E and heat content of liquid at B.

Using the heat-content-entropy diagrams, the values of Table 19 were obtained for standard machine rating conditions.

VAPORIZATION OF A LIQUID AND "REFRIGERATING EFFECT" R.—The liquid to be used as a refrigerating medium should evaporate at a relatively low temperature (low boiling point) in order to extract heat from its surroundings during the evaporating period. Let t_c = temperature of condensed liquid in the receiver (Fig. 9); t_s = temperature of saturated vapor in the evaporating coils; v_s specific volume of saturated vapor at temperature t_s; q_c = heat of the liquid for temperature t_c; h_s = heat content at temperature t_s. Then the heat R_1 in B.t.u. per lb., which the medium is capable of extracting from the surroundings will be the refrigerating effect, and $R_1 = (h_s - q_c)$, the initial state being liquid and the assumed final state dry saturated vapor. The volume, in cubic feet, of dry saturated vapor leaving the evaporating coil per ton of refrigeration per minute is $V = (200 \times v_s)/R_1$. If the vapor is allowed to superheat in the evaporator, heat content becomes h_1, and the refrigerating effect is $(h_1 - q_c)$ B.t.u. per lb. Superheating increases the refrigerating effect.

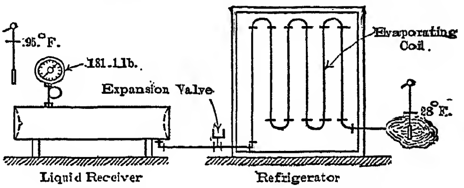

FIG. 9. Diagram of Refrigerating Effect

EXAMPLE.—If 1 lb. of liquid ammonia at the temperature of the outside air, 95° F., flows through a needle valve from a drum into the evaporating coil, Fig. 9, one end of which is open to the atmosphere, the liquid will evaporate into dry saturated vapor at atmospheric pressure. The pressure existing in the drum (Table 14) will be 181.1 lb. per sq. in., gage, and the heat of the liquid q_c at this temperature will be 149.4. From Table 14, the boiling point of the liquid is −28° F. and the heat of the saturated vapor is 602.1 B.t.u. per lb. = h_s. The refrigerating effect

$$R_1 = (602.1 - 149.4) = 452.7 \text{ B.t.u.}$$

Refrigerating effect of 1 cu. ft. of vapor is $R_2 = R_1/v_s = 452.7/18 = 25.2$ B.t.u.

THE WEIGHT OF REFRIGERANT M_r to be circulated per minute per ton of refrigeration per 24 hours is $M_r = 288{,}000/R_1 \times 24 \times 60 = 200/(h_s - q_c)$ lb. The volume of saturated vapor to be pumped per ton per min. is $G = (M \times v_s)$ cu. ft. Actually the volume may be somewhat greater, as the vapor usually enters the machine with some superheat. If the liquid is subcooled below the temperature of the saturated vapor corresponding to the condenser pressure, the weight to be pumped is less, due to greater refrigerating effect of the vapor.

VAPOR COMPRESSION CYCLE.—The four essential parts of a vapor refrigerating system are shown in Fig. 10. The complete system comprises: 1. An expansion or regulating valve through which liquid refrigerant is throttled from condenser pressure to evaporator pressure. 2. The evaporator, pressure in which corresponds to that tempera-

ture of saturated vapor as may be required for refrigeration. 3. The compressor, where vapor from evaporator is compressed to pressure required for liquefaction. This corresponds to temperature of the condenser cooling medium, usually water, although air often is used for small house refrigerators with certain refrigerants. 4. The condenser, where superheat due to temperature rise of the vapor during compression is removed, and the vapor condensed. Sometimes a liquid cooler is added to further cool (subcool) liquid below saturation temperature corresponding to condenser pressure.

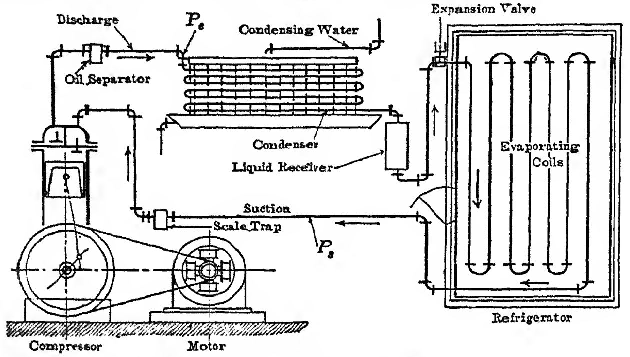

FIG. 10. Diagram of Vapor Compression System

The theoretical Rankine cycle, Fig. 11, assumes vapor to enter the compressor dry and saturated, corresponding to temperature t_s and pressure p_s of evaporator. The compression assumed is adiabatic (constant entropy) to pressure p_c corresponding to temperature of liquid leaving the condenser t_c. Let h_s = heat content (enthalpy) of the saturated vapor corresponding to t_s and p_s, B.t.u. per lb.; h_c = heat content of superheated vapor at end of compression, B.t.u. per lb.; heat equivalent Q of external work of compression is $(h_c - h_s)$ per lb. Theoretical horsepower of the compressor, based on the Rankine cycle is, Hp. = $M_r\ (h_c - h_s)/42.5$, where M_r = weight of refrigerant circulated per min.; 42.5 (or 33,000/778) is the B.t.u. heat equivalent per min. of 1 Hp. The expected B.Hp. of the compressor may be assumed as approximately 30% more than the theoretical. The values of h_s and h_c are taken from the saturated and superheated vapor tables or from a Mollier diagram for the refrigerant used. The value of h_c may be approximated by $\{h + C_p(t - t_c)\}$, where C_p mean specific heat of vapor at constant pressure for the superheated vapor between temperature t_s and final temperature t at the end of compression. h = heat content of saturated vapor corresponding to p_c. The temperature t at end of compression may be approximated by the equation

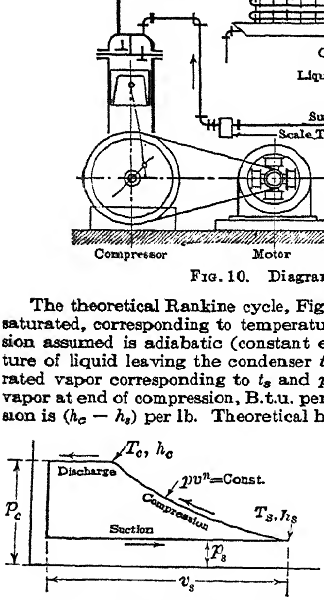

FIG. 11. Theoretical Rankine Cycle

$$t + 460 = (t_s + 460)\ (p_c/p_s)^{(n-1)/n} \quad . \ . \ . \ . \ . \ . \ . \ . \ [15]$$

See Table 13 for value of n for various refrigerants, and Fig. 12 for mean specific heat of superheated ammonia gas.

The heat equivalent of the work of compression per lb. of refrigerant circulated may be approximated by

$$Q = h_c - h_s = (n/n - 1)\ p_s v_s[1 - (p_c/p_s)^{(n-1)/n}] \times (144/778) \text{ B.t.u. per lb.} \quad . \ [16]$$

where p_s and v_s are respectively the pressure, lb. per sq. in., and volume, cu. ft. per lb., of saturated vapor entering compressor. Table 13 gives values of n for various refrigerants. See standard works on thermodynamics for derivation of equations for t and Q.

HEAT BALANCE FOR VAPOR COMPRESSION CYCLE (Fig. 4).—The heat H_c absorbed by cooling water used in the condenser (and liquid cooler, if used) must equal heat absorbed by the evaporator H plus heat equivalent of the work of compression $W/778$ neglecting any gain or loss of heat by radiation or convection to or from the apparatus. $H_c = H + (W/778)$ per lb. of refrigerant circulated. W = work of compression, ft.-lb. Heat absorbed by evaporator per lb. of refrigerant circulated equals difference

between the heat content (enthalpy) of liquid leaving condenser (or liquid cooler, if used) and heat content of vapor at beginning of compression, h_1. If the liquid is not subcooled, q equals the heat content of the liquid q_c corresponding to condenser pressure p_c for saturated vapor. If the liquid is subcooled, q equals heat content corresponding to final temperature of liquid leaving the liquid cooler. For machine rating conditions, the liquid is assumed to be subcooled 9° F.

In the Rankine cycle, vapor at beginning of compression is assumed saturated, or $h_1 = h_s$. In standard rating of refrigerating machines, vapor at beginning of compression is assumed with 9° superheat or $h_1 = h_s + C_p\ (t_s + 9)$; C_p = mean specific heat of vapor corresponding to the temperature range. $H = (h_s - q_c)$ for the theoretical Rankine cycle, $= (h_1 - q)$ for machine rating conditions.

The weight of refrigerant to be circulated per min. per ton of refrigeration is: $M_r = 200/(h_s - q_c)$ for the theoretical Rankine cycle; and $M_m = 200/(h_1 - q)$ for machine rating conditions. Subcooling reduces the weight of refrigerant to be circulated and the power requirement for compression.

The heat equivalent of the work of compression is $W/778 = (h - h_s)$ for the theoretical Rankine cycle, and $W/778 = (h - h_1)$ for machine rating conditions with superheat for the vapor entering compressor from the evaporator. For the theoretical Rankine cycle compression horsepower per ton is Hp. $= M\ (h_c - h_s)/42.5$ $(42.5 = 33{,}000/778)$. The complete refrigerating cycle is best illustrated by indicating it on the heat content (enthalpy)-entropy diagram. See Figs. 4 to 8.

LOSSES WITH VAPOR REFRIGERATING CYCLE.—One inherent loss is due to heat of the liquid. It equals the difference between heat of liquid q_c leaving condenser and heat of liquid q_e corresponding to evaporator temperature. The refrigerating effect of a small portion of the evaporating gas cools, from condenser to evaporator temperature, the liquid passing through the expansion valve.

Another loss is due to heat added (cylinder heating) by compression, which superheats the gas to a temperature well above saturation temperature corresponding to condenser pressure. If it were possible to remove this heat as rapidly as formed, the compression would be isothermal instead of adiabatic as assumed.

The sum of these losses, *i.e.*, liquid expansion plus superheat, frequently is used as the criterion in comparing the percentage of power losses for various refrigerating media.

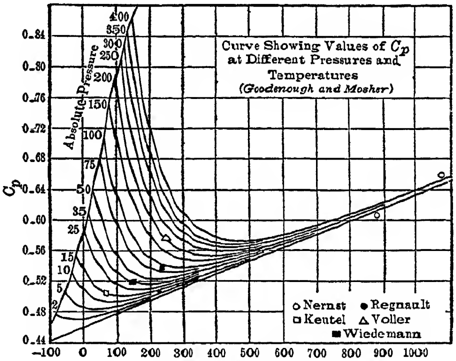

Fig. 12. Mean Specific Heat of Superheated Ammonia

COMPOUND OR STAGE VAPOR COMPRESSORS in refrigerating machines are analogous to stage air compressors with intercoolers. In refrigerating machines the intercooler between stages must be cooled by the refrigerant, due to the comparatively low temperature of the vapor entering the cylinder on the suction stroke. Some saving in power input may result in plants using more than one suction pressure and temperature.

COMBINED OR BINARY VAPOR REFRIGERATION SYSTEMS.—Ammonia is not well adapted as a refrigerant for the low temperatures used in oil refineries, quick food freezing, etc. (−50° to −75° F.), as the suction side of the system must work below atmosphere. CO_2 is well adapted to low temperatures. The power required per ton of refrigeration is somewhat greater with CO_2 than with NH_3. A combination of a CO_2 and an NH_3 system is satisfactory and economical of power input. The low temperature evaporating coil is part of the CO_2 system, the condenser being cooled by the evaporating coil of the NH_3 system. The NH_3 condenser is cooled by condensing water.

VOLUME CONTROL FOR MOTOR-DRIVEN COMPRESSORS.—A varying refrigerating load requires pumping a varying weight and volume of gas. Steam-driven compressors do this by varying engine speed. With compressors driven by constant-speed motors, another means of varying the weight of vapor pumped is required. Throttling the suction decreases capacity, but at the expense of increased power.

One method varies and reduces compressor capacity by clearance pockets around the

compressor cylinder, which communicate through auxiliary valves with the clearance space. The pockets increase the clearance volume by fixed percentages of cylinder volume, and vary the weight of vapor in the clearance space, and consequently the piston displacement volume available for drawing in vapor from the evaporator on the suction stroke. Some machines obtain 100%, 50% and zero capacity. The clearance pockets provide means of varying compressor capacity without increasing power requirement.

TURBO OR CENTRIFUGAL VAPOR COMPRESSORS.—Refrigerating media such as Dielene, Carrene and water vapor, are well adapted to turbo-compressors, the relative volume of the first two media to be handled being approximately 8 times that of ammonia for corresponding evaporator temperatures.

With standard ton conditions (5° F. evaporator and 86° F. condenser temperature), absolute pressures with Dielene are 1.7 in. Hg and 14 in. Hg; for Carrene, 2.39 in. Hg and 20.5 in. Hg; the complete system always operates below atmospheric pressure. The compressor is motor-driven at about 3300 r.p.m. A 5-stage machine operating at this speed is used in a number of plants for an evaporator temperature of approximately 39° F., with corresponding evaporator pressure of 24.8 in. Hg. The construction of the machines is similar to standard makes of multi-stage turbo air compressors. Calculations involved in design are similar, bearing in mind the different value of ratio n for the compression curve.

VOLUMETRIC EFFICIENCY OF RECIPROCATING COMPRESSORS is here defined as ratio of actual weight of vapor handled by a compressor in unit time, to weight of vapor computed from piston displacement, based on temperature and pressure conditions in suction line at compressor. The actual weight of vapor handled will be somewhat less than the theoretical, due to re-expansion of vapor in clearance space of the compressor, and superheating of vapor in passing the warmer intake valves and cylinder walls. Also the higher the discharge pressure, the greater is the re-expansion of vapor in the clearance from the previous stroke, with lower volumetric efficiency.

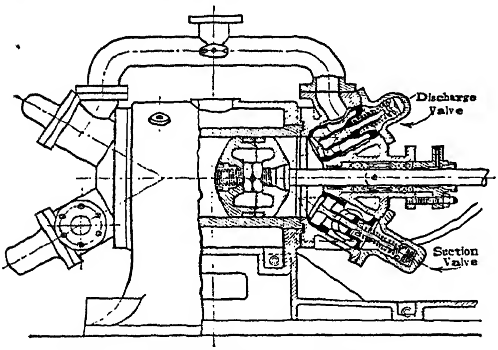

Fig. 13. Double-acting Compressor Cylinder

Clearance volume varies somewhat with different ratios of stroke to cylinder diameter; the actual condition or state of vapor at the end of the suction stroke and beginning of the compression is impossible to determine accurately in tests. This precludes giving very accurate data. Table 20 gives test results obtained by Reed and Ambrosius in 1931 at the Univ. of Ill. on a single-acting ammonia compressor with a clearance volume of 5.56% of the piston displacement volume.

SIZE OF COMPRESSOR CYLINDER.—To compensate for reduced compressor capacity, due to re-expansion of vapor on the suction stroke, and an increase in volume of saturated vapor, due to superheating while passing through hot suction ports and passages, volume G of saturated gas, as previously calculated, is taken as $G/0.75$ to $G/0.80$, the result being compressor displacement D, cu. ft. required per min. per ton of refrigeration per 24 hr. For purposes of calculation, assume $D = G/0.77$. Let N = number of working strokes per min. = 2 × r.p.m. for 1 single-, double-acting compressor or 2 single-

Table 20.—Volumetric Efficiency of Single-acting Ammonia Compressor

Suction Pressure, lb. per sq. in., abs.	Discharge Pressure, lb. per sq. in., abs.

30	.925	.875	.823	.776
40	.970	.910	.865	.817
50	.990	.945	.892	.848

acting compressors; l = length of stroke, in.; d = diameter of compressor cylinder, in.; M.E.P. = mean effective pressure in compressor cylinder, lb. per sq. in.

Approximate piston displacement, cu. in. per stroke $= {}^1/_4\, \pi d^2 l = 1728D/N$.

$$\text{M.E.P.} = p_s\{n/(n-1)\}\{(p_c/p_s)^{(n-1)/n} - 1\}, \quad . \quad . \quad . \quad . \quad . \quad [17]$$

where n = 1.31 for NH_3; = 1.25 for SO_2; = 1.31 for CO_2.

$$\text{I. Hp.} = \text{M.E.P.} \times M \times v_s/33{,}000. \quad . \quad . \quad . \quad . \quad . \quad . \quad [18]$$

Table 21 gives approximate mean effective pressures for various suction and condenser pressures. The brake Hp. of the compressor will be 1.5 × theoretical I.Hp. (approx.) for large compressors, and 2 × theoretical Hp. for small ones.

The heat-content (enthalpy)-entropy diagram generally is used to determine heat equivalent of work of compression per lb., $(h_c - h_s)$ B.t.u. See Figs. 4–8. Theoretical Hp. per ton of refrigeration $= 778\,(h - h_s)M/33{,}000 = (h_c - h_s)M/42.5$........ [19]

Example.—Required the size of NH_3 compressor cylinders for a 2-cylinder, single-acting machine and compressor, and also the I.Hp. to produce 40 tons of refrigeration per 24 hr., operating dry compression. Condensing pressure, 181.1 lb. per sq. in., gage, corresponding to a temperature of 95° F. for liquid entering the evaporating coil; suction pressure, 15.7 lb. per sq. in., gage, corresponding to a temperature of 0° F. for saturated gas leaving the evaporator coils. No subcooling of liquid, or superheat in suction vapor. Assumed volumetric efficiency of compressor = 80%.

Solution.—Refrigerating effect of 1 lb. of $NH_3 = R_1 = (h_s - q_c)$ = (611.8 − 149.4) = 462.4 B.t.u. per lb. NH_3 to be circulated per min. per ton of refrigeration = 200/462.4 = 0.43 lb.

Compressor Displacement Required.—Specific volume of NH_3 leaving the evaporator coils = 9.12 cu. ft. Volume of saturated vapor to be pumped per min. per ton of refrigeration per 24 hr. = 0.43 × 9.12 = 3.93 cu. ft. Piston displacement required per ton = 3.93/0.80 = 4.9 cu. ft. = 196 cu. ft. per min. for 40 tons. With an assumed stroke of 18 in. and a speed of 76 r.p.m., the area of each compression cylinder will be (196 × 144) ÷ (2 × 76 × 1.5) = 123.8 sq. in. or 12.55 in. diam. From Table 23, the nearest standard single-acting compressor is 12 1/2 × 18 in.

Compressor I.Hp.—The work to be performed per lb. of $NH_3 = (h - h_s)$ or, from Fig. 4, (733 − 611). Expected I.Hp. will be approximately 20% more than theoretical. Theoretical I.Hp. per ton = {0.43 (733 − 611)} ÷ 42.5 = 1.23. The expected I.Hp. per ton is 1.22 × 1.2 = 1.48. Expected I.Hp. of compressor = 40 × 1.23 × 1.20 = 59.0. Combined mechanical efficiency of engine and compressor averaging about 85%, the engine I.Hp. required is 58.6/0.85 = 69.4 Hp. Compare the piston displacement and the compressor I.Hp. with the data of Table 25.

BACK PRESSURES.—Table 22 gives the average temperature and corresponding back pressures of the expanding ammonia in the evaporating coils to maintain given room temperatures or brine tank temperatures. It is assumed that the room or tank has sufficient coil surface.

COMPARISON OF SINGLE- AND DOUBLE-ACTING AMMONIA MACHINES OPERATING DRY COMPRESSION.—Table 25 compares results obtained in tests by the York Mfg. Co. of single- and double-acting machines with a compressor cylinder 12 1/2 × 18 in. The better results (I.Hp. per ton of refrigeration) obtained with a single-acting machine were ascribed to the different design of suction valve in the two machines. In the double-acting machine it was small and had a more contracted area as compared with the large valve in the piston of the single-acting machine, giving an increased superheating effect of the gas during the suction stroke of the double-acting machine. The

NOTE.—The above efficiencies and displacements apply when the piston clearance does not exceed 1/32 in. Unless clearance is excessive no addition to the horsepower will be necessary. Where liquid is cooled lower than temperature corresponding to condensing pressure, there will be a reduction in horsepower and displacement proportional to the increase of work done by each pound of liquid handled.

initial volume to be compressed thus was increased, resulting in increased power consumption. For engine horsepower add 17% to the compressor horsepower up to 20 tons capacity, and 15% for larger machines.

WET COMPRESSION.—In the wet compression system, sufficient liquid is by-passed from the liquid line to the suction line of the compressor, so that as the end of compression the vapor will be dry and saturated ($x = 1$). Let x_2 = vaporized portion of 1 lb. of the mixture at the beginning of compression, r_s = latent heat at temperature t_s. Then

$$W = 778 \times \{H_c - (q_s + x_2 r_s)\}, \quad \ldots \quad [20]$$

where W = ft.-lb. of work per lb. of medium circulated. The I.Hp. per ton of refrigeration per 24 hr. = $MW/33{,}000$. Entropy being constant for an adiabatic change, the value of x_2 may be obtained from the entropy tables for the vapor under consideration. Weight per pound of vapor circulated that reaches evaporator coils and produces useful refrigeration is $(1 - x_2)$. Let n_s = entropy of the liquid corresponding to t_s; R_s/T_s = entropy of vaporization corresponding to t_s; N_c = entropy of the vapor corresponding to t_c. Then

$$n_s + (x_2 r_s/T_s) = N_c, \quad \text{and} \quad x_2 = (T_s/r_s)(N_c - n_s) \quad \ldots \quad [21]$$

Table 26 compares the results of tests made by the York Mfg. Co. obtained when operating with wet and dry compression. The tests were made on a double-acting machine at a compression pressure of 185 lb. per sq. in., gage, and 15.67 lb. per sq. in., gage, suction pressure. The figures in the table are the average results of 6 wet and 6 dry compression runs of 6 hr. duration each, wet and dry runs alternating.

Allowable Velocities in Vapor and Liquid Piping.—Table 27 gives suitable velocities in piping for liquid and vapor refrigerating media.

Steam-jet-Vacuum Refrigeration

The refrigerating effect in steam-jet-vacuum refrigeration is produced by evaporating part of the liquid circulated, in this case water, in a partial vacuum. Final temperature of the water corresponds to temperature of evaporation for the partial vacuum. See Fig. 14. The relatively large volumes of water vapor to be removed and compressed, for refrigerating effect, have made reciprocating vapor compressors in this connection impracticable. Water is sprayed into the evaporator to present a surface from which evaporation may occur in a reasonable space. The unit is compact, simple and has few parts; it is used to cool water for industrial purposes, and with air conditioning apparatus when steam is available. Usual final temperature t_e of the chilled water is 40° to 60° F. Considerably more condensing water is required than for electrically-driven NH_3, CO_2,

SO_2, etc. machines, as the evaporated vapor producing refrigerating effect must be condensed along with steam supplied to the jet.

Fig. 15 is a diagram of the apparatus. Steam expands in a single or multiple set of steam nozzles to a pressure corresponding to temperature t_e maintained in the evaporator. The velocity, ft. per sec., of steam leaving nozzle exit, for adiabatic expansion is $w = 223.7\sqrt{h_1 - h_e}$, where h_1 and h_e = heat content of steam supplied to nozzle, and after expansion to evaporator pressure, respectively. For an initial pressure p_1 = 125 lb. per sq. in., abs., w = 4000 ft. per sec. (approx.) for usual chilled water temperatures.

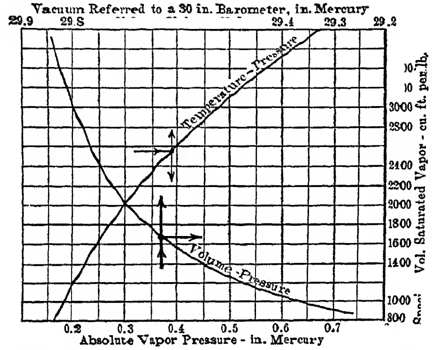

FIG. 14. Pressure-Temperature-Volume Curve of Water Vapor

The high velocity steam mixes in the injector chamber with saturated vapor from the evaporator, and passes through the converging portion of the machine. Mixture is compressed adiabatically to pressure corresponding to the partial vacuum in condenser.

Part of the kinetic energy of the nozzle steam S lb. is used to accelerate the evaporated vapor W lb. to the velocity at which the mixture enters the compressor section. Part of the kinetic energy of mixture $(S + W)$ is used to compress the mixture from evaporator pressure p_e to condenser pressure p_c. Condenser temperature t_c is approximately 5 to 10°F. higher than initial temperature of condensing water. The usual partial vacuum for the condenser is 27.5 to 28.5 in. Hg. The vapor mixture enters the diverging portion of the unit, where it is compressed and its velocity reduced to approximately 500 ft. per sec., at which velocity it passes into the condenser. The compression is from p_e to p_c.

Let M = water to be cooled, lb. per hr.; t, t_e = initial and final temperature of water to be cooled, deg. F.; 12,000 = heat to be extracted from water per hr. per ton of refrigeration, B.t.u.; W = lb. of water to be evaporated at evaporator temperature t_e, deg. F. per hr. per ton of refrigeration. Then $M\,(t - t_e)/12{,}000$ = tons of refrigeration required.

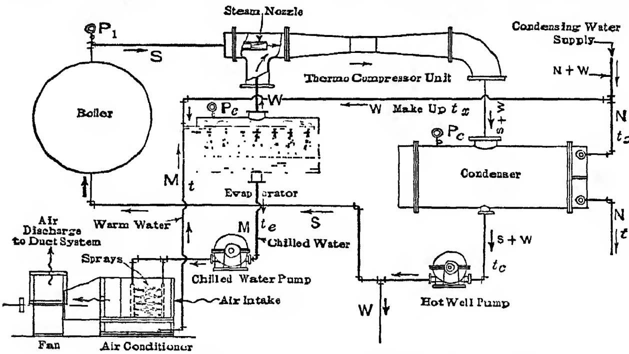

FIG. 15. Diagram of Steam-jet Refrigerating Apparatus

WEIGHT OF WATER, W, lb., to be evaporated per hr. per ton of refrigeration is, $W = 12{,}000/(h_e - q_x)$, (approx. 12 lb.). It may be assumed for approximation that the quality of the vapor leaving the evaporator is 90% at pressure p_e. h_e = total heat of vapor leaving evaporator, B.t.u. per lb.; q_x = heat of liquid make-up water, B.t.u. per lb.

WEIGHT OF STEAM S, lb. per hr. per ton of refrigeration, to be supplied unit may be approximated as follows, using the total-heat-entropy diagram or chart, page 5–19: Let h_1 = total heat of steam supplied to nozzles, B.t.u. per lb.; h_e = total heat of steam

expanded adiabatically to pressure p_e, B.t.u. per lb.; E = combined efficiency of expanding nozzles, entrainment and compression (approximately 0.40).

Assume the vapor entering condenser to be dry and saturated, with total heat h_c at pressure p_e (actually it will contain some moisture). Compression is assumed to be adiabatic. From the chart determine the total heat h per lb. of the mixture $(S + W)$ at beginning of compression. The heat available for work of compression is $S\,E\,(h_1 - h_e)$, and the heat equivalent to the work of compression is $(S + W)\,(h_c - h)$ B.t.u. per hr. per ton of refrigeration. Then

$$0.42\,S\,(h_1 - h_e) = (S + 12)\,(h_c - h) \quad . \; . \; . \; . \; . \; . \; . \; [22]$$

from which the value of S is obtained. The steam used by the steam-jet condenser air pumps is not included in the value of S.

Example.—Assume chilled water temperature required to be 40° F.; condenser vacuum, 28 in.; initial steam pressure 125 lb., gage, dry and saturated.

Referring to heat-content-entropy chart, $h_1 = 1193$; $h_e = 792$; $h_c = 1105$; $h = 990$.

$0.42\,S \times 401 = (S + 12)\,115$. $\therefore S = 30.6$ lb. of steam per hr. per ton of refrigeration.

The overall thermal efficiency of the complete system sometimes is stated as the ratio of heat extracted from the evaporator to heat input to boiler, including the steam used by steam-jet condenser air pumps, as well as the heat equivalent of the work of boiler-feed pump. A detailed analysis and discussion of the steam ejector cycle by P. Kalusian, will be found in *Trans.* A.S.R.E., 1934.

Fig. 16 gives results obtained with a steam-jet refrigerating unit for various operating conditions with an initial steam pressure of 125 lb., gage, dry and saturated. The condensing water REQUIRED is approximately

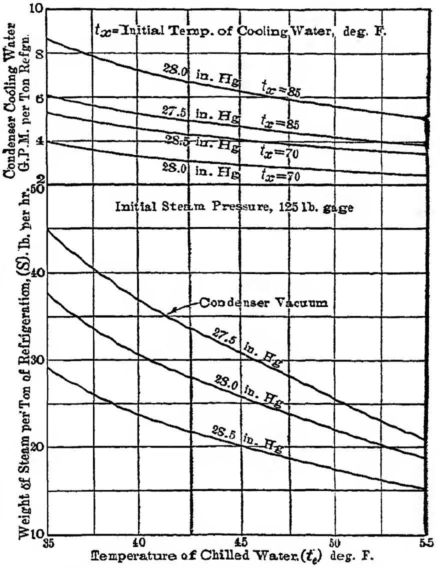

Fig. 16. Performance Curve, Steam-jet Refrigerating Apparatus

$$N = (S + W)\,r_c/(t_y - t_x) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; [23]$$

where N = lb. per ton per hr.; t_y may be assumed 5 to 10° F. below t_c; t_x = initial temperature of condensing water, deg. F.; r_c = latent heat corresponding to t_c, B.t.u. per lb. When a cooling tower is used assume t_x = 80° F. for preliminary estimates.

A number of American manufacturers build steam jet refrigerating machines; the majority use multiple nozzles in the ejector chamber. A surface condenser ordinarily is used, although barometric condensers may be employed, either type equipped with a two-stage steam-jet air eliminator having inter- and after-condensers. Maximum efficiency is obtained only when the machine operates at the designed rate of flow of steam nozzles and other portions of the apparatus. It is customary to provide two or more separate steam-jet units to obtain the best overall efficiency under variable loads. The units all are connected to the same evaporator and condenser.

5. THE AMMONIA ABSORPTION MACHINE

Fig. 17 is a diagram of the ammonia absorption machine. Superheated ammonia, gas and steam are driven off from a solution of ammonia and water in the generator, heated by steam coils. The total pressure existing in the generator consists of the partial vapor pressures of ammonia, gas and water. Vapors leaving the generator are condensed in the rectifier (dehydrator) in which the temperature is maintained at a sufficiently low point to condense practically all water vapor but not the ammonia. The condensed water re-absorbs a portion of the ammonia and is returned to the generator as rich liquor. The practically dry ammonia gas then is liquefied in the ammonia condenser and ex-

panded in evaporating coils, producing a refrigerating effect as in the compression system. The expanded ammonia gas from the evaporating coil is re-absorbed in the absorber by weak liquor drawn from the bottom of the generator. The rich liquor produced by absorption is returned to the generator, flowing over a series of trays in the analyzer where it reduces the superheat in the gases given off by the generator. This reduces the amount of heat to be removed in the rectifier and condenser. The analyzer sometimes is omitted to reduce first cost of the apparatus, but this saving is effected at the expense of operating economy. Pressure existing in generator and rectifier depends on temperature maintained in the condenser, which, in turn, is governed by quantity and temperature of cooling water available.

Calculations for the design of an absorption machine involve: 1. Dalton's law of partial vapor pressure, modified. 2. Properties of saturated and superheated steam and saturated and superheated ammonia vapor. 3. Boiling point of ammonia solutions of various strengths corresponding to various pressures. 4. Weight of ammonia absorbed by water. 5. Heat developed by chemical reaction occurring when ammonia is absorbed by water.

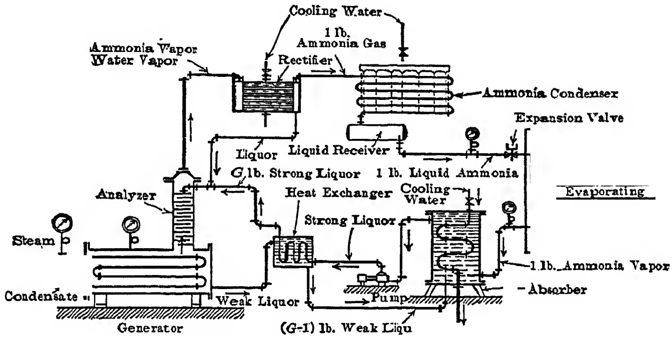

Fig. 17. Arrangement of Ammonia Absorption Plant

BOILING POINT OF AMMONIA SOLUTIONS.—Table 29 gives boiling points at various pressures of solutions of water and ammonia. It is condensed from a table calculated by H. J. MacIntire, based on the experiments of Mollier, using a formula $T_s = T_a/(0.00466x + 0.656)$, where T_α = absolute temperature of saturated ammonia corresponding to the observed pressure; T_s = absolute temperature of the solution; x = percent of ammonia in solution, by weight. Between concentrations of 15% and 35% this formula checks with the experimental work of both Starr and Mollier.

HEAT OF ABSORPTION.—Let x = mean concentration or weight of ammonia in 1 lb. of solution; x_1 = weight of ammonia in 1 lb. of weak solution; x_2 = weight of am-

monia in 1 lb. of strong solution; n = pounds of water to 1 lb. of ammonia in solution; m = pounds of ammonia gas added to the solution; then

$$x = \tfrac{1}{2}(x_1 + x_2);\ x_1 = 1/(1+n);\ x_2 = (1+m)/(1+n+m).$$

The heat h, in B.t.u., developed when 1 lb. of ammonia gas is added to a solution of ammonia of concentration x_1 may be determined by Mollier formula $h = 887 - 350x - 400x^2$. See Table 30. The formula is good for values of x up to about 0.60 at which value and over h is constant at 540 B.t.u. The heat in B.t.u. developed when 1 lb. of ammonia is added to water so that the final concentration is x, is $h = 893x - \{142.5x^2/(1-x)\}$.

AMOUNT OF LIQUOR TO BE CIRCULATED.—For each pound of anhydrous ammonia passing through the condenser and evaporating coils, G lb. of strong solution must be circulated, and $(G - 1)$ lb. of weak liquor enters the absorber. Weight G depends on the degree of concentration of the strong and weak solution. Using the notation of the preceding paragraph $G = (1 - x_1)/(x_2 - x_1)$. Table 30 gives values of G for various concentrations of weak and strong solutions.

RELATIVE WEIGHTS OF SUPERHEATED AMMONIA AND WATER VAPOR.—Dalton's law for mixtures of perfect gases is only approximately true for mixtures of superheated ammonia and water vapor. *Jour.* Am. Chem. Soc., vol. 83, shows that for low pressures and low percentages of ammonia solutions, the partial water-vapor pressure is directly proportional to the number of molecules in solution. Assuming this to be true for higher pressures, vapor pressure existing in the analyzer may be approximated by Spangler's formula

$$p_3 = p_1\{(1700 - 17x)/(1700 + x)\};\ p_2 = p - p_3 \quad . \quad . \quad . \quad . \quad . \quad [24]$$

where p = total pressure in generator, rectifier and condenser (gage pressure + 14.7), being fixed by the ammonia condenser temperature and pressure; p_1 = pressure of saturated water-vapor corresponding to its temperature; p_2 = pressure of ammonia gas; p_3 = partial water-vapor pressure; all pressures are in lb. per sq. in., absolute; x = percent of ammonia by weight in 1 lb. of solution. One cu. ft. of mixture leaving the analyzer and entering the rectifier consists of 1 cu. ft. of superheated ammonia gas and 1 cu. ft. of steam. If d_2 = lb. per cu. ft. of ammonia gas at pressure p_2, and d_3 = lb. per cu. ft. of steam at pressure p_3, each cu. ft. of vapor contains d_2 lb. of ammonia gas and d_3 lb. of water vapor. For each pound of ammonia gas entering rectifier there will be d_3/d_2 lb. of water vapor. If v_2 = specific volume of 1 cu. ft. of ammonia gas at pressure p_2, and v_3 = specific volume of 1 cu. ft. of vapor at pressure p_3, $d_2 = 1/v_2$ and $d_3 = 1/v_3$.

HEAT SUPPLIED TO GENERATOR.—The amount of ammonia to be circulated per ton of refrigeration depends on the condensing pressure and temperature desired in the evaporating coil. Total heat taken into the system must equal that removed, radiation being neglected. Calculations can be made most conveniently on the basis of 1 lb. of active ammonia passing through the evaporating coil. Let h_g = B.t.u. supplied to generator per lb. of active ammonia passing through evaporating coils; h_r = B.t.u. to be removed from rectifier; h_c = B.t.u. to be removed by condenser; h_e = B.t.u. taken in by evaporator coils; h_a = B.t.u. removed from absorber; h_i = B.t.u. lost in heat exchanger. Then

$$h_g + h_e = h_a + h_c + h_r + h_i, \quad \text{and} \quad h_g = h_a + h_c + h_r - h_e + h_i.$$

The weight of saturated steam required in the generator coils per lb. of active ammonia is $W = (h_g/L) + 15\%$ to 20% for radiation losses. L is the latent heat of steam corresponding to pressure in the coil. Steam temperature in coil should not be less than boiling temperature of the weak solution. All quantities are per lb. of ammonia.

Heat to be supplied the generator may be approximated by the following method: Heat developed when 1 lb. ammonia liquid is absorbed in a solution of strength x_1, thereby raising the strength to x_2, is given by the Mollier formula $h = 345 - 345x - 400x^2$, where $x = (x_1 + x_2)/2$. This is practically the same as the previous equation for heat developed when ammonia gas is absorbed by a solution, if 542 be added. It is equivalent to assuming that 542 B.t.u. must be removed in every case to change gas to a liquid. Heat to be supplied to generator per lb. of NH_3 is sum of items $a + b + c$, below:

a. Heat required to change concentration of solution from x_1 to x_2, per lb. of NH_3 driven off; $h = 345 - 345\,x - 400\,x^2$.

b. Difference between heat content of 1 lb. superheated NH_3 gas (at pressure carried by generator and temperature of strong solution returned to generator) and heat content of 1 lb. liquid NH_3 at temperature of weak solution leaving generator.

c. Weight of weak solution circulated per lb. of NH_3, $(G - 1)$ × temperature difference between strong and weak solution entering and leaving generator × specific heat of solution (approx. 1.05).

The small amount of heat required to evaporate and superheat the water vapor driven off with the ammonia here is neglected. Temperature in generator must be sufficient to boil the weak solution.

HEAT TO BE REMOVED FROM THE RECTIFIER.—Temperature t_3 of gas leaving the rectifier need be only approximately 10° higher than condenser temperature t_c, to condense approximately 95% of the water vapor, leaving the ammonia gas practically dry and uncondensed. The condensing temperature of the water vapor corresponding to its pressure p_3 is higher than the condensing temperature of the ammonia corresponding to its pressure p_2. In practice it is sufficiently accurate to assume all water vapor to be condensed from the mixture of gas and vapor in the rectifier. As shown above, each pound of ammonia gas entering rectifier is mixed with d_3/d_2 lb. of water vapor. To determine the amount of ammonia which this amount of vapor will re-absorb, the maximum concentration x_m possible for the absolute temperature of the solution T_s, and the absolute temperature T_a corresponding to the partial pressure p_2 must be determined.

$$T_s = T_a \div (0.00466x_m + 0.656) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [25]$$

whence the value of x_m may be found. If the initial concentration of the water vapor be that of the strong solution $= x_2$, the weight of ammonia absorbed by d_3/d_2 lb. of water condensed is $w = (d_3/d_2) \times (x_m/x_2)$ per lb. of ammonia entering rectifier. Then for 1 lb. of active ammonia passed to condenser and evaporator coils, $w_2 = 1 + \{(d_3/d_2) \times (x_m/x_2)\}$ lb. of ammonia vapor, and $w_3 = (d_3/d_2)\ \{1 + (d_3/d_2) \times (x_m/x_2)\}$ lb. of water vapor entering rectifier.

Let t_x = temperature of vapors entering rectifier (approximately 30° to 40° lower than boiling temperature of the strong solution of concentration x_1); t_3 = temperature leaving rectifier (approximately 10° higher than the ammonia condensing temperature t_c corresponding to pressure p_3); C_{ps} = mean specific heat of water vapor = 0.44 (approx.); C_{pa} = mean specific heat of ammonia vapor for pressure p_3 and temperature range t_3 to t_x = 0.66 (approx.) for usual conditions of operations; L_3 = latent heat of water vapor for temperature t_3; x = mean concentration of final solution of ammonia gas absorbed by the water vapor condensed $= {}^1/_2\,(x_m + x_2)$; A = heat in B.t.u. removed from rectifier to lower temperature of the vapors from t_x to t_3; B = heat, B.t.u., removed from rectifier to condense the water vapor; h = heat, B.t.u., developed by the absorption of w lb. of ammonia in the water condensed; h_r = total heat, B.t.u., removed by cooling water. Then

$$A = (C_{pa}w_2 + C_{ps}\,w_3)\,(t_x - t_3);\ B = r_3\,w_3. \quad . \quad . \quad . \quad . \quad . \quad . \quad [26]$$

$$h = 893\,x - \{142.5\,x_2/(1 - x)\};\ h_r = A + B + h. \quad . \quad . \quad . \quad . \quad [27]$$

HEAT REMOVED BY CONDENSER.—If the water vapor has been removed by the rectifier, the heat, B.t.u., to be removed by the condenser is $h_c = r_c + C_{pa}\,(t_3 - t_c)$, where t_3 = temperature of superheated gas arriving at the condenser (approximately $t_c + 10$); t_c = temperature of saturated ammonia gas corresponding to condenser pressure; r_c = latent heat of condenser pressure, and C_{pa} = mean specific heat at constant pressure of superheated ammonia vapor for condensing pressure p_3. See Fig. 12.

HEAT TAKEN INTO THE SYSTEM BY THE EVAPORATING COILS is $h_e = (h_s - hq_c)$, as in the compression system, where h_s = heat content of saturated vapor corresponding to evaporator temperature t_s, and q_c = heat of the liquid at temperature t_c.

HEAT TO BE ABSTRACTED FROM THE ABSORBER AND THE WEAK LIQUOR COOLER.—The temperature of the strong liquor leaving absorber ordinarily should be below 125° F., and 110° F. often is specified. With low steam and suction pressures, the temperature must be still further reduced. The temperature limit of absorber is fixed by the pressure in the evaporating coil, which is approximately the pressure in the absorber. Maximum absolute temperature of solution is determined by

$$T_s = T_a/(0.00466x_2 + 0.656) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [28]$$

where T_a = absolute temperature of saturated ammonia gas in evaporating coil and x_2 = concentration of strong solution.

The cool strong liquor from the absorber at temperature t_a absorbs heat in the heat exchanger from the hot weak liquor and enters the analyzer at a temperature t_g approximately 35° less than that of the outgoing weak liquor. For approximate calculations, temperature of the weak solution may be assumed as $(t_a + 10)$, being cooled to absorber temperature in an auxiliary cooler.

The heat, B.t.u., developed by the addition of ammonia gas to a weak solution of ammonia is

$$h = 887 - 350x - 400x^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [29]$$

The total heat h_a to be abstracted from the weak liquor cooler and absorber by the cooling water per pound of active ammonia passing through evaporating coil, comprises: *a*. Heat developed by absorption = h_1. *b*. Difference between heat contained in the weak liquor at the temperature of the generator t_g, and temperature t_a carried in the absorber, $= (G - 1) \times (t_g - t_a)$, where G = lb. of strong solution circulated per lb. of anhydrous ammonia passing through evaporating coil. Specific heat of solution is taken as 1. *c*. The negative quantity of heat introduced by the ammonia in raising its tem-

perature from the evaporating temperature t_s, to the temperature of the absorber t_a, or $\{-C'_{pa}(t_a - t_s)\}$, where C'_{pa} = specific heat of ammonia gas for the pressure existing in the evaporator coils. Then

$$h_a = h_1 + (G - 1)(t_g - t_a) - C'_{pa}(t_a - t_s) \quad . \quad . \quad . \quad . \quad . \quad [30]$$

LIQUOR PUMP.—The power required for the pump depends on the quantity of liquor to be pumped, cu. ft. per min., and the effective pressure per sq. in. on the plunger. The effective pressure is the difference between the pressure existing in the generator and evaporator coils plus the friction pressure loss. A non-condensing, fly-wheel type pump with cut-off requires approximately 35 to 40 lb. of steam per I.Hp.-hr. A direct-acting pump requires 100 to 150 lb. per I.Hp.-hr.

NOTES ON THE DESIGN OF ABSORPTION MACHINERY.—The concentration of weak liquor in high-pressure plants may be assumed as approximately 20% ammonia, and of strong liquor as 28%, by weight, for ordinary conditions. Corresponding figures for low-pressure plants are 30% and 38% respectively. Temperature of steam in the generator coils should not be less than that required to boil the weak solution.

Temperature t_x of vapors entering the rectifier may be assumed as 30° to 40° lower than temperature t_g of the weak hot liquor. Temperature of ammonia gas leaving the rectifier may be assumed as approximately 5° to 10° higher than its condensing temperature corresponding to condensing pressure p_3 and temperature t_c. Temperature of the strong liquor leaving the absorber may be assumed as 110° to 130° F. A heat exchanger of sufficient surface will increase the temperature of the strong liquor approximately 73% of the number of degrees temperature drop of the weak liquor. Absorption plants are usually operated with exhaust steam at 5 to 10 lb. per sq. in. back pressure.

STEAM REQUIRED PER HOUR PER TON OF REFRIGERATION.—Table 31 gives test data based on various condensing gage pressures and evaporator pressures of 15.67 lb. gage, on actual steam consumption per ton of refrigeration. The steam consumptions given are without analyzer. If an analyzer is used, deduct 3 lb. per ton of refrigeration as an approximation. Actual difference depends on amount of aqua ammonia circulated.

PERFORMANCE OF ABSORPTION MACHINES.—From an elaborate review by Gardner T. Voorhees of the action of an absorption machine under certain stated conditions, showing the quantity of ammonia circulated per hour per ton of refrigeration, its temperature, etc., at the several stages of the operation, and its course through the several parts of the apparatus, the following condensed statement is obtained:

Generator.—30.9 lb. dry steam, 38 lb. gage pressure, condensed, evaporates 32.2% strong liquor to 22.3% weak liquor.

Exchanger.—3.01 lb. weak liquor at 264° F. cools to 111° F.

Absorber.—Adds 0.43 lb. vapor from the brine cooler, making 3.44 lb. strong liquor at 111° F. to go to the pump.

Exchanger.—3.44 lb. heated to 224° F.; some of it is now gas, and the rest liquor of a little less than 32% NH_3.

Analyzer.—Delivers strong liquor to the generator, while the vapor, 91% NH_3, 0.4982 lb., goes to the rectifier.

Rectifier.—Cools the gas to 110° F., separating water vapor as 0.0682 lb. drip liquor which returns through a trap to the generator.

Condenser.—0.43 lb. NH_3 gas at 110° F. cooled and condensed to liquid at 90° F. by 2 gal. of water per min. heated from 73° F. to 86° F.

Table 31.—Steam Consumption, Lb. per Ton of Refrigeration for Various Condensing Pressures

(Evaporator pressure = 15.67 lb. per sq. in., gage)

40	30.0	31.2	32.5	33.9	35.1	36.8	37.9
45	29.5	30.7	32.0	33.4	34.6	36.2	37.4
50	29.0	30.1	31.4	32.8	34.0	35.7	36.8

Expansion Valve and Cooler.—Reduces liquid to 0° F. and boils it at 0° F., cooling 3 gal. of brine per min. from 12° F. to 3° F. Gas passes to absorber and cycle repeats.

Of the 2 gal. per min. of cooling water flowing from the condenser, 0.2 gal. goes to the rectifier, where it is heated to 142° F., and 1.8 gal. through the absorber, where it is heated to 110° F.

Heat Balance.—Absorbed in the generator, 496 B.t.u.; in the brine cooler, 200 B.t.u.; total, 696 B.t.u. Rejected: condenser, 220 B.t.u.; absorber, 383 B.t.u.; rectifier, 93 B.t.u.; total, 696 B.t.u.

Table 32 shows the strength of liquors and quantity of steam required per hour per ton of refrigeration under the conditions stated.

Table 33 gives steam consumption, lb. per hour per ton of refrigeration, for engine-driven compressors and for absorption machines with liquor pump not exhausting into the generator at suction and condenser pressures (gage) given.

The economy of the absorption machine is much better for all conditions than that of a simple non-condensing engine-driven compressor. At suction gage pressures above 8 to 10 lb. the economy of the compound condensing engine-driven compressor exceeds that of the absorption machine, the absorption machine giving the superior economy at suction pressures below 8 to 10 lb.

Relative Performance of Ammonia Compression and Absorption Machines, Assuming No Water to be Entrained with the Ammonia-gas in the Condenser. (Denton and Jacobus, *Trans.* A.S.M.E., xiii.)—See Table 34. It is assumed in the calculation for both machines that 1 lb. of coal imparts 10,000 B.t.u. to the boiler. The condensed steam from the generator of the absorption machine is assumed to be returned to the boiler at temperature of steam entering the generator. The engine of the compression machine is assumed to exhaust through a feedwater heater that heats the feedwater to 212° F. and to consume 26 1/4 lb. of water per Hp.-hr. Figures for the compression machine include the effect of friction, which is taken at 15% of the net work of compression.

For discussion of the efficiency of the absorption system, see Ledoux's work; paper by Prof. Linde, and discussion on the same by Dr. Jacobus, *Trans.* A.S.M.E., xiv, 1416, 1436; and papers by Denton and Jacobus, *Trans.* A.S.M.E., x, 792, xiii, 507.

SILICA-GEL SYSTEM.—The following was abstracted from A.S.R.E. Data Book: Silicon dioxide SiO_2, or silica gel, is a hard glassy material resembling quartz sand. It is chemically inert toward most substances, and particularly those used as refrigerating media except ammonia. It is obtained as a gelatinous mass, and after drying becomes a sponge which is granulated to from 8–20 mesh. It has the property of absorbing large quantities of vapors or liquids, SO_2 being used with it as a refrigerant. The internal volume of silica gel is about 50% of its total volume. In refrigeration 1 lb. SiO_2 will absorb 0.25 to 0.35 of SO_2. During adsorption, the latent heat of adsorption, about equal to the heat of vaporization, is liberated and must be removed. The adsorbed SO_2 is given up by activating the silica by heat, heat of desorption being about twice the latent heat. Silica gel is used also to dry air in air conditioning. Here, heat of desorption is more favor-

able, being about equal to latent heat. In practice, about 1.5 × latent heat is required to drive off adsorbed water.

NH_3-$CaCl_2$ ABSORPTION SYSTEM uses as a solid absorbent a calcium chloride sponge, specially treated to increase its absorbing capacity (set in cement). The general method of operation is similar to that of the silica-gel system.

6. VAPOR CONDENSERS

HEAT ABSTRACTED.—Let h = heat content of gas leaving the compressor and arriving at the condenser; q_c = heat content of liquid leaving condenser; p_c = condenser pressure. Heat abstracted in the condenser is

$$(h - q_c) = h_c + C_p\,(t - t_c) - q_c = r_c + C_p\,(t - t_c) \quad . \quad . \quad . \quad . \quad [31]$$

C_p = mean specific heat between temperatures t_c and t; t = final compression temperature; t_c = condenser temperature; h_c = heat content of saturated vapor for pressure p_c; r_c = latent heat for temperature t_c. Values of h may be obtained from Figs. 4, 5 and 7 for NH_3, CO_2, and SO_2, and values of q_c from the saturated vapor tables.

AMOUNT OF CONDENSING WATER REQUIRED.—Let t_x and t_y = initial and final temperatures, respectively, of condensing water; C = lb. of condensing water required per lb. of ammonia circulated. Then, with $(h - q_c)$ as given above,

$$C = (h - q_c)/(t_y - t_x) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [32]$$

The temperature of condensing water for the warmer summer months should be ascertained in advance for each individual case. Usual assumed initial temperatures are 68° to 70° F. if the source is a reservoir, river or lake, or 55° if the source is an artesian well. The final temperature of condensing water determines the final temperature of the condensed liquid and, therefore, should be as low as practicable. It will be approximately 80° to 85° F. with an initial temperature of 70°, and the final temperature of the condensed liquid then will be about 95°, which gives a final compression pressure of 182.6 lb. per sq. in., gage, when ammonia is used as the refrigerating medium.

The most economical compression pressure depends upon the cost of producing 1 I.Hp. in a compressor cylinder for various pressures. This, in turn, depends upon the cost of water per gallon, either by purchase or by pumping.

Example.—Required the cooling water per ton of refrigeration for an ammonia condenser operating under a condensing pressure and temperature of 182.6 lb. gage and 95° F. respectively, with suction pressure and temperature of 15.25 lb. gage and 0° F., respectively. Initial temperature of circulating water is 70° F., and its final temperature 85° F.

Solution.—Weight of refrigerating medium circulated per minute per ton of refrigeration = $M = 200/(h_s - q_c) = 200/(538.5 - 71.3) = 0.428$ lb. of ammonia circulated per ton per minute.

* 5% of water entrained in the ammonia will lower the economy of the absorption machine about 15% to 20% below the figures given in the table.

Heat rejected to the condenser per ton per minute $= M(h - q_c) = 0.428 \times (663 - 71)$
$= 253$ B.t.u. lb. of water per ton per minute $= 253/(85 - 70) = 16.8$,
or $16.8/8.33 = 2$ gal. $= 2 \times 1.75 = 3.5$ gal. per minute per ton of ice manufactured per 24 hr.

Condensing Surface Area

TYPES OF CONDENSERS.—The types of vapor condensers in common use are: The atmospheric, the double pipe and the shell and tube type.

The atmospheric type is recommended when its location on the roof or in the open room is unobjectionable. It is economical of water and easy of access for repairs or cleaning. See Table 35 for dimensions, and Table 36 for amount of pipe per ton of refrigeration usually allowed in atmospheric condensers.

The double-pipe type is recommended where condensing water is used for other purposes. The water is under pressure and the absence of drip and dampness makes this type suitable for all locations. It is essential that the water be soft, with no tendency to form scale. Condensers for ammonia usually are made 12 pipes high, the three upper pipes being 2 1/2 in. diam., and the balance 2 in. diam. The water pipe is 1 1/4 or 1 1/2 in. diam. throughout. The larger pipes at the top provide a wider annular space around the water pipe for gas when it reaches the condenser in a rarefied condition. See Table 37.

The shell and tube type is similar to the surface type of steam condensers. It is the

Shell thickness, in.	1/4	5/16	3/8	1/2	5/8	5/8	3/4

most widely used type for ammonia, and is available in both horizontal and vertical designs. Tube sizes range from 1 1/4 to 2 1/2 in., and generally are No. 10 gage.

RATING OF ATMOSPHERIC CONDENSERS.—The water required per min. per ton of refrigeration in atmospheric condensers is, according to J. Levey, as follows:

Temperature, deg. F.	50	55	60	65	70	75	80	85
Gal. per min........	1/2	5/8	3/4	7/8	1	1 1/5	1 1/2	2

These quantities are based on water leaving the condenser at 95° F. and are the smallest quantities that should be allowed.

RATING OF DOUBLE-PIPE AMMONIA CONDENSERS.—Table 38 gives data on double-pipe condensers. The capacities and horsepower per ton of refrigeration are based on one section of a counter-current double-pipe condenser of 1 1/4 and 2 in. pipe, 12 pipes high, 19 ft. outside of water bends, and on water velocities of from 100 to 400 ft. per min., with an initial temperature of condensing water of 70° F. The horsepower per ton is for a single-acting compressor, and 15.67 lb. suction pressure. The friction in the water pump and connections should be added to water horsepower and to total horsepower.

THE FLOODED CONDENSER.—In the flooded condenser sufficient liquid ammonia is injected into a mixing chamber in direct contact with the ammonia gas to absorb the superheat and insure full saturation. Condensation is effected by cooling water applied externally. The advantages of the flooded type of condenser are lower first cost, reduced space and reduced upkeep. The flooded condenser is built in the atmospheric, double-pipe and shell-and-tube types. One section of a flooded atmospheric condenser, 12 pipes high, 20 ft. long, made of 2-in. pipe, or a total of 150 sq. ft. of pipe surface is rated as follows when operating at a condensing pressure of 185 lb. and various temperatures of water:

Temperature of water, deg. F....	55	60	65	70	75	80	85	90
Tonnage per coil................	54.6	49.9	44.4	39.3	33.5	26.5	17.1	11.8
Water per min. per ton of refrigeration, gal....................	1.1	1.19	1.36	1.53	1.79	2.26	3.86	5.68

Similar data for a double-pipe coil, 8 pipes high, 18 ft. 2 in. long, made of 2- and 3-in. pipe are:

Temperature of water, deg. F....	55	60	65	70	75	80	85	90
Tonnage per coil................	62.5	55.9	49.3	42.5	35.8	28.8	21.3	13.0
Water per min. per ton of refrigeration, gal....................	1.44	1.61	1.83	2.12	2.51	3.13	4.22	6.9

COOLING TOWERS IN REFRIGERATING PRACTICE.—Natural draft water-cooling towers are rated on a basis of a wind velocity of 5 mi. per hr., with major axis of tower at right angles to prevailing wind movement of the locality.

Table 39 gives data for guarantees of final water temperatures, based on 5 mi. per hr. wind velocity; towers 17 to 32 ft. high; water circulation, 1.5 to 3.0 gal. per min. per sq. ft. of distributing deck; decks 4 to 12 ft. wide. Wet bulb temperature is that of entering outside air to tower.

In mechanical towers, air is circulated by fan or blower and is independent of outside wind movement. The two types are forced and induced draft. Table 40 gives the prac-

7. BRINE CIRCULATING SYSTEM

In the brine circulating system, Fig. 18, brine circulates through coils in the storage room. The evaporating coils of the refrigerating system are located in the brine tank, and the brine acts simply as a heat transfer medium. The principal advantage of this system is that the refrigeration can be stored and the refrigerating machine shut down for part of the time. The length of refrigerant piping and number of joints also are reduced to a minimum.

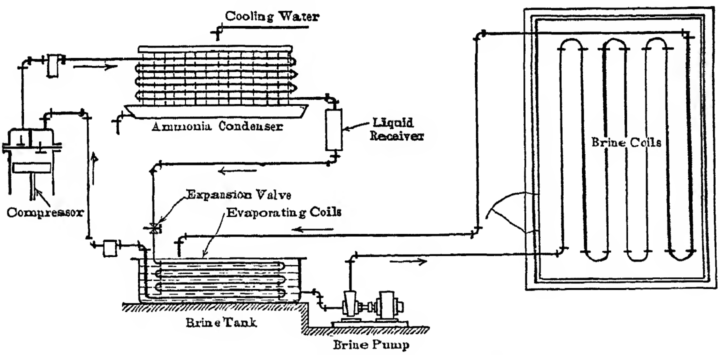

Fig. 18. Arrangement of Brine Circulating System

The brine system is more expensive to operate, as a lower back-pressure must be carried by the machine at all times, due to the fact that at least 10° difference in temperature must be maintained between outgoing brine from the tank and the evaporating coils, in order to obtain the necessary heat transfer from brine to the refrigerant. The brine tank sometimes is placed in the room to be cooled.

SIZE OF BRINE TANK.—For continuous operation about 60 cu. ft. of brine per ton of refrigeration is required. For non-continuous operation weight of brine required is

$$W = 12{,}000\, R(24 - h) \div \{S_b(t_1 - t_2)\} \quad . \quad . \quad . \quad . \quad . \quad . \quad [33]$$

where R = refrigeration, tons per 24 hr.; h = number of hours per 24 that machine operates; S_b = specific heat of brine solution (Table 41); t_1 = initial temperature of brine when machine is starting; t_2 = final temperature of brine when machine is shut down.

The specific gravity of the brine solution to be used depends on the lowest tempera-

ture t_2 to be carried, which fixes the percentage of salt in making up the solution. If x = specific gravity of solution at 60° F. the weight d, lb. per cu. ft. = $62.5x$, approximately, and the contents of the brine tank = W/d cu.ft. The size of the brine circulating pump is calculated in the same manner as that of a water pump. If a reciprocating pump is used, allowance for slip must be made.

RATING OF MACHINE.—The refrigerating machine and condensing apparatus must produce R tons of refrigeration in h hr., and also dispose of the heat absorbed by the brine tank. If the brine tank be located in one of the rooms to be refrigerated, the heat transmission of the tank produces useful refrigeration and is not an extra tax on the machine. The rating of the machine (tons per 24 hr.) required will be: $C = (R/h) \times 24$. Rating is based on a suction temperature in evaporator coils approximately 10° lower than lowest brine temperature required. A shell-and-tube, shell-and-coil or double-pipe brine cooler is used in preference to a submerged coil. The shell-and-tube type brings a larger body of ammonia in contact with the cooling surface than the others.

The three-pipe balanced system is used in larger installations, especially where brine is to be pumped against a great head. The balancing brine tank is placed slightly higher than the top coils in the building; pump and brine cooler are located in the basement. The pump discharges brine from the bottom of the balancing tank through the cooler to the room coils, whence it returns to the balancing tank.

BRINE SOLUTIONS.—Common Salt (NaCl) corrodes pipes so freely that leakage, repairs, etc., offset the lower first cost of salt. Refrigerated brines must circulate so close to 0° F., the freezing point of common salt brine, that crystals of salt separate out, clog pipes, increase friction and tend to insulate pipes, thus requiring that more brine be circulated than would be necessary with clean pipes. See Table 41 for properties.

Calcium Chloride ($CaCl_2$) brine has no action on the pipe and may be used at temperatures below 0° F. A somewhat greater cost of calcium chloride, compared to common salt, is offset by the fact that 25% less in weight is required. See Table 42 for properties.

BRINE PIPING.—Factors entering into design of brine piping are: 1. Heat absorbed by each coil, basing calculations upon refrigeration required for the various rooms or refrigerators. 2. Amount of brine to be circulated to absorb the calculated amount of heat with a temperature rise of from 2° to 5° F. 3. Pipe friction of the system.

Quantity of Brine to be Circulated per deg. F. rise of temperature per ton of refrigeration, when the specific heat of brine is 0.829, is 242.4 lb. or 25.2 gal. per min. If the number and character of fittings is not definitely known, an estimated friction loss in fittings, etc., of from 20% to 40% usually will be sufficiently accurate, using the latter figure for small jobs and the former for, say, large drinking-water systems.

Regulation of flow is facilitated if the system is so arranged that it always will be full of brine while in operation and also if it is kept under pressure. To insure this latter, it may be advisable to place a reducing valve on the discharge.

Direct Expansion versus Brine Circulating System with Ammonia

DIRECT EXPANSION.—Assume a temperature of 20° F. in a refrigerating room piped with direct expansion coils. The ammonia temperature then must be approximately 10° F., corresponding to a suction pressure of 23.3 lb., gage. If the condensing pressure is 182.6 lb., gage, corresponding to a temperature of 95° F., then $200/(541.2 - 71.3) = 0.425$ lb. of ammonia must be pumped per min. per ton of refrigeration. The specific volume of

Table 41.—Properties of Common Salt Brine at 60° F.

Degrees Baumé	Degrees Salinometer	Specific Gravity	Percent Salt	Wt. of 1 gal., lb.	Wt. of 1 cu. ft., lb.	Freezing Point, deg. F.	Specific Heat
5	20	1.037	5	8.7	64.7	25.4	0.96
10	40	1.073	10	9.0	67.0	18.6	.892
15	60	1.115	15	9.3	69.6	12.2	.855
19	80	1.150	20	9.6	71.8	6.9	.829
23	100	1.191	25	9.9	74.3	1.0	.783

Table 42.—Properties of Calcium Chloride Brine

Specific Gravity at 68° F.	Lb. 75% Solvay $CaCl_2$ per gal.	Lb. 75% Solvay $CaCl_2$ per cu. ft.	Freezing Point, deg. F.	Specific Heat
1.100	1.46	10.9	18.0	0.88
1.125	1.83	13.7	12.5	.87
1.150	2.20	16.5	+ 6.5	.85
1.175	2.59	19.4	− 2.0	.835
1.200	2.99	22.4	−12.5	.81
1.225	3.38	25.3	−23.5	.80
1.250	3.75	28.3	−36.5	.77

the gas is 7.34 cu. ft., and 0.425 × 7.34 = 3.12 cu. ft. of saturated vapor to be handled by the compressor per ton per min. requiring 1.22 compressor I.Hp. per ton per 24 hr.

BRINE CIRCULATING SYSTEM—CONTINUOUS OPERATION.—Brine temperature in room coils must approximate that of the ammonia in the direct expansion system; *i.e.*, 10° F. Temperature of ammonia in the evaporating coils in the brine tank will be approximately 0° F. in which case 0.427 lb. of ammonia must be circulated per min. per ton of refrigeration per 24 hr. The specific volume of saturated ammonia at 0° F. is 9.19 cu. ft. per lb. The compressor must handle 0.427 × 9.19 = 3.92 cu. ft. per min. per ton of refrigeration per 24 hr., the compressor I.Hp. being 1.46. Under the conditions, assumed, therefore, with the brine circulating system continuously operated the compressor capacity is 25.6% larger, and the power consumption 20% greater than with the direct expansion system, no allowance being made for the power required to operate brine circulating pump.

ICE MANUFACTURE

Two systems of ice manufacturing in general use are: 1. Can system. 2. Plate system. The former may be subdivided into *a*. Distilled water system; *b*. Raw water system. Ammonia is the commonly used refrigerant in ice plants.

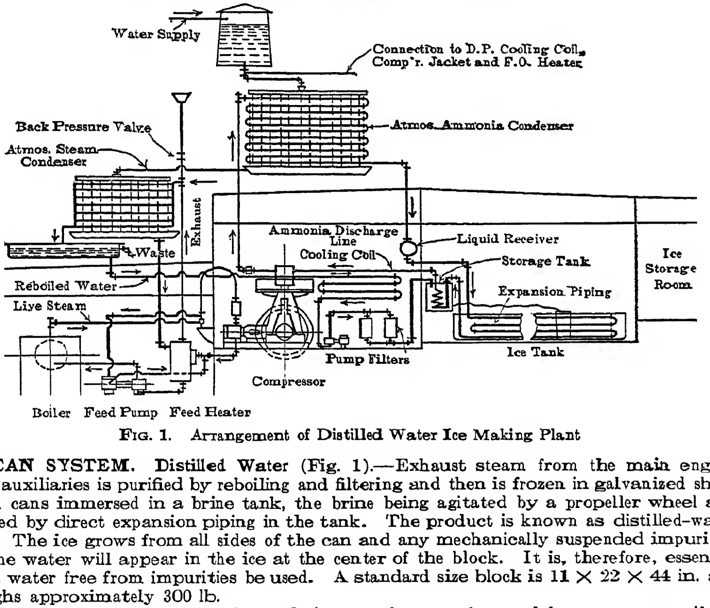

Fig. 1. Arrangement of Distilled Water Ice Making Plant

CAN SYSTEM. Distilled Water (Fig. 1).—Exhaust steam from the main engine and auxiliaries is purified by reboiling and filtering and then is frozen in galvanized sheet steel cans immersed in a brine tank, the brine being agitated by a propeller wheel and cooled by direct expansion piping in the tank. The product is known as distilled-water ice. The ice grows from all sides of the can and any mechanically suspended impurities in the water will appear in the ice at the center of the block. It is, therefore, essential that water free from impurities be used. A standard size block is 11 × 22 × 44 in. and weighs approximately 300 lb.

Raw Water.—A clear merchantable ice may be manufactured from raw water if the water in the cans is agitated during the entire freezing period by air discharged under a pressure of 3 to 6 lb. per sq. in. at or near the bottom of the cans through a $^1/_{16}$-in. opening. The unfrozen water, heavily charged with impurities, is pumped out of the center of the block before this part is entirely closed and frozen, and the space is filled with raw water containing only the initial amount of impurities. As this system does not require distilling apparatus, the most economical form of drive may be used, the majority of plants being motor-driven. The size of the motor should be ample to provide for a higher terminal pressure than ordinarily is considered for 70° F. condensing water, to prevent possible overloading of motor. See Fig. 2 for capacities of can system.

PLATE SYSTEM.—A tank approximately 10 ft. deep by 12 ft. wide, divided by $^1/_2$-in. plates, bolted to direct expansion piping, into compartments 30 in. wide is used. The plates form the freezing surface. Ice grows from the plates outwards and mechani-

Brake horsepower at machine means the effective Hp. actually delivered at the belt-wheel of the machine or at the shaft for direct-connected machines. For belt-driven machines, 5% should be added to the brake Hp. for friction and slippage of belt.

Table is based on 70° F. water to storage tank. For different temperatures of water multiply these figures by percentages in table below.

Tons of Refrigeration Required to Produce One Ton of Ice, When the Water To Be Frozen Is Delivered to the Apparatus Operated by the Machine, at the Temperatures Given:

Temperature of water, degrees F.	50	60	70	80	90
Tons of refrigeration per ton of ice	1.46	1.53	1.60	1.67	1.74
Refrigeration work, percent, based on 70° F. water = 100 percent	91 1/4	95 5/8	100	104 3/8	108 3/4

cally suspended impurities in the water are separated and fall to the bottom of the tank. The ice cake usually is thawed from the plate by passing hot gas through the coils. Distilled water is not required for the manufacture of clear ice, and electric drive may, therefore, be used. The ice gradually forms in from 8 to 10 days to a thickness of 12 to 14 in.

The freezing tank area required by the plate system is about 12 times that required by the can system and the cubical contents are about 4 times as great. The advantage of the plate system that clear ice is produced without special apparatus is offset by the fact that the building up of the ice is slow and expensive; also, for continual operation several tanks are required, so that one or more may be frozen while the others are being emptied. The cost of the plate system is about $^1/_3$ more than that of the can system. In the can system, ice is drawn throughout the 24 hours while in the plate system the entire product is harvested, cut and stored in a few hours.

THE DISTILLING SYSTEM.—Exhaust steam from the main engine and auxiliaries, after passing through an oil separator, is condensed at atmospheric pressure in a steam condenser. About 10% is diverted to the feedwater heaters. The feedwater first is used as cooling water in the ammonia and steam condensers and distilled water cooler. The condensed steam flows to the reboiler and skimmer, where a live-steam coil boils the water at atmospheric pressure, driving out air and absorbed gases. Oil and other impurities that rise to the surface are skimmed off. The steam coil either may be perforated or closed. If perforated, the high-pressure steam is reduced to atmospheric pressure and mixes with the distilled water. If closed, condensation returns to the feedwater heater.

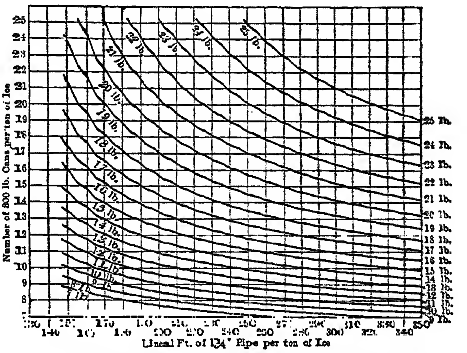

FIG. 2. Number of Cans per Ton of Ice for Various Suction Pressures and Areas of Evaporated Surface

The reboiled distilled water is reduced to a temperature of approximately 90° F. in the distilled water cooler, usually of the double-pipe type. After filtering through quartz, sand or maple charcoal filters, it is stored and further cooled in the storage tank or fore-cooler, containing a coil through which gas from the evaporating coils passes on its way to the compressor. When reduced to a temperature of approximately 40° F., it is used to fill the cans. A regulating device automatically controls the flow of water from the reboiler to the storage tank and also controls the pump circulating distilled water through coolers and filters.

ICE-MAKING CAPACITY.—The ice-making capacity of a refrigerating machine is approximately 61% of its refrigerating capacity, as given under Rating of Refrigerating Machine, p. 10-03. Table 1 gives data from which ice-making capacity may be determined.

SIZE OF FREEZING TANK.—Let W = weight of ice, lb., to be pulled every 24 hr. = tons rating × 2000; H = freezing time, hr., N = number of cans required; C = weight of 1 block of ice, lb. Then $N = WH/(C \times 24)$. For 300-lb. blocks, $H = 50$ and $N = W/144$, and the number of 300-lb. cans per ton capacity rating of plant is 14. Some manufacturers recommend 16 cans per ton of capacity. Dimensions of the freezing tank may be approximated from data given in Table 3.

Table 2.—Suction Pressures Required for Various Brine Temperatures

Table 5.—Lineal Feet of Pipe per Ton of Ice

Pipe size, in.........		1 1/4	/2	2
15° brine, ft. of pipe.	400	320	270	210
18° brine, ft. of pipe.	450	360	310	240

Table 6.—Water Consumption per Ton of Ice in Compression Plants (O. Gueth)

Initial temp. water over ammonia condenser, deg. F.....	55	60	70	80
Water temp. entering steam condenser, deg. F..........	80	85	90	95
Water temp. leaving steam condenser, deg. F...........	125	125	125	125
Gallons per minute	4	4.5	5.15	6

FUEL CONSUMPTION IN ICE PLANTS operating on the compression system may be computed as follows: Assuming an average steam consumption for the main engine (Corliss type) of 27 lb. per I.Hp.-hr. and an additional 4% to operate the feed pump, total steam required is 28 lb. per I.Hp.-hr. The agitator engine and distilled water pump will use an additional 8 lb. of steam per hr. per ton of ice-making capacity. Then, since each ton of ice made requires 1.75 tons of refrigeration, and each ton of refrigeration requires 1.5 compressor I.Hp., the steam required per ton of ice-making capacity for main engine and feed pump will be $(1.75 \times 1.5 \times 28)/0.85 = 87$ lb. of steam, when the mechanical efficiency of the engine and compressor is taken at 85%. Exhaust steam available is $87 + 8 = 95$ lb. Adding approximately 10% for waste in the reboiler and in filling the cans, 105 lb. of water must be evaporated per hour, equivalent to approximately 3 1/2 boiler Hp. per ton of ice-making capacity.

HEATING, VENTILATING AND AIR CONDITIONING

By Louis A. Harding

TABLE OF CONTENTS

HEATING, VENTILATING AND AIR CONDITIONING

By Louis A. Harding

HEATING

1. ESTIMATING HEATING REQUIREMENTS OF BUILDINGS*

HEAT REQUIRED TO BE SUPPLIED.—The amount of heat, in B.t.u., to be supplied by the heating apparatus to a building to maintain the inside temperature above that of the outside, commonly termed heat losses, is: (*a*) The heat required to offset the heat transmission of the walls, ceiling or roof, and floor. This loss of heat depends upon the type and materials of construction used and the temperature difference to be maintained between the inside and the outside of the building. (*b*) The heat required to warm the air entering the building from the outside, either by infiltration or purposely introduced for ventilation. (*c*) The heat supplied by persons, lights, machinery and motors, which may be deducted from the sum of Items (*a*) and (*b*) to obtain net amount of heat to be supplied by the heating system. [Item (*c*) usually is not considered.] In the design of heating installations it is customary to estimate the amount of heat per hour to be supplied by the apparatus. The total heat to be supplied, B.t.u. per hour, is $H = [(\text{Item } a) + (\text{Item } b) - (\text{Item } c)]$.

This is the assumed amount of heat that must be supplied by the heat emitting apparatus, *i.e.*, radiators, unit heaters, etc., after a condition of heat equilibrium has been established for the assumed temperature differential. The amount of heat to be supplied by the boiler or furnace during the "starting up" period with cold rooms and apparatus will be considerably greater. See Rating of Heating Boilers, p. 11–11.

TEMPERATURES.—The inside temperatures to be maintained for various classes of work are given in Table 1. The outside temperature for which the heating installation should be designed is fixed by the lowest outside temperature that is liable to continue for several days during the heating season.

HEAT TRANSMISSION OF BUILDING CONSTRUCTION.—Heat is transferred to and from a surface by *radiation* and *convection*. The transfer of heat through a material is by *conduction*.

As it is difficult to measure separately the heat transfer by radiation and convection, they ordinarily are combined. Let t and t_1 = temperature of the inside air and wall surfaces respectively; t_0 and t_2 = temperature of the outside air and outside wall surface respectively. K_1 and K_2 = the combined coefficient of radiation and convection for the inside and outside wall surfaces respectively. (B.t.u. transferred per sq. ft. per hour per

Table 1.—Usual Inside Temperature Specified

Kind of Building	Degrees F.	Kind of Building	Degrees F.
Public buildings	68–72	Bath-rooms	85
Factories	65	School-rooms	68–70
Machine-shops	60–65	Hospitals	72–75
Foundries, boiler-shops, etc.	50–60	Paint-shops	80
Residences	70		

Table 2.—Values of K in Still Air Tests

Brickwork	1.40	Glass window	1.50
Concrete	1.30	Sheet asbestos	1.40
Corkboard	1.25	Magnesia board	1.45
Cement plaster	0.93	Wood (finished)	1.40

The average of the above values of K is 1.34.

* Largely condensed from Heating, Ventilating and Air Conditioning, by L. A. Harding and A. C. Willard. John Wiley & Sons, Inc.

degree difference in temperature, between the surface and air in contact with the surface.) Then $K_1(t - t_1) = K_2(t_2 - t_0)$. Table 2 gives values of K determined in a series of conductivity, absorption and emissivity tests by Harding and Willard at Univ. of Ill. in 1915.

A wind velocity of 15 miles per hour over the surface increases the values of K approximately 3 times the tabular values. Hence, it is recommended that for inside wall surfaces the tabular values of K be used, and for outside surfaces (tabular values $\times$ 3).

CONDUCTION.—Let C = coefficient of conductivity, or B.t.u. transferred through a material per sq. ft. per hr. per deg. F. difference in temperature of the two surfaces, per in. of thickness; x = thickness of material, in. Then $(C/x)(t_1 - t_2)$ = heat transmitted by conduction per sq. ft. per hour. Tables 4, 5 and 6 give conductivities for various materials for the thickness stated. See *The Guide*, published by A.S.H.V.E., each year for a complete report of conductivity tests covering building and insulation materials. Tables 4, 5 and 6 were abstracted from the 1932 *Guide*.

* Oct. 1 to May 1. † In Dec., Jan., :

CALCULATION FOR THE HEAT TRANSMISSION OF WALLS.—The amount of heat absorbed by the inside wall surface, the amount conducted through the wall and the amount emitted by the outside wall surface is evidently the same. Let u = heat transmission of the actual wall per sq. ft. per hour per degree F. difference in temperature of the air on the two sides. Then

$$u = 1 \div \{(1/K_1) + (1/K_2) + (x/C) + (x_1/C_1) + (x_2/C_2) + \text{etc.}\} \quad . \quad . \quad [1]$$

The value of (x/C) for thin plates, glass or roofing material is so small that it safely may be neglected in ordinary calculations. For example, the unit heat transmission u for a window is assumed as $(1/1.5) + (1/4.5) = 1.12$.

EXAMPLE.—Determine the heat transmission of an 8-in. brick wall, furred with 1 1/2-in. split furring tile laid up in plaster, and finished with 1/2-in. plaster. $K_1 = 1.34$; $K_2 = 3 \times 1.34 = 4.02$; C, for brick, $= 5$; C, for split tile, $= 1.25$; C, for plaster, $= 2.32$ (see Table 4).

$$u = 1 \div \left(\frac{1}{1.34} + \frac{1}{4.02} + \frac{8}{5} + \frac{1}{1.25} + \frac{0.50}{2.32}\right) = 0.28 \text{ B.t.u. per sq. ft. per hr. per deg. F. difference in temperature of air inside and outside.}$$

Heat is transmitted through air space construction from one surface to another by radiation and convection. The conduction of one air space, as shown by the experiments of Prof. F. B. Rowley, is approximately $C = 1.0$ for the usual temperatures encountered in heating practice.

EXPOSURE FACTOR.—Some engineers increase the calculated heat transmission loss of wall and glass surfaces when they are exposed to high winds, to compensate for the increased convection and the leakage of cold air through the wall. The following are commonly used arbitrary factors by which heat transmission losses are multiplied: North, northeast and northwest exposure, if winds are an important factor, 1.15 to 1.30; east or west walls, moderately exposed, 1.10 to 1.20; south walls, 1.0. If the data from Tables 4, 5 and 6 are used, *it is not necessary* to use an exposure factor.

The heat transmission of stone walls is approximately 50% greater than that of brick

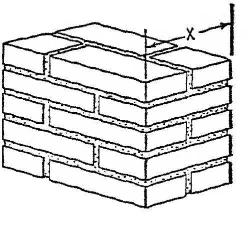
Table 4.—Coefficients of Transmission (C) of Solid Brick Walls

NOTE.—These coefficients are expressed in B.t.u. per hr. per sq. ft. per 1° F. temperature difference between the air on the two sides, and are based on an outside wind exposure of 15 mi. per hr.

Values of C are based on the following internal conductivities or conductances, B.t.u. per hr. per sq. ft. per 1° F.

Brick	5.00 per 1 in.
Cement mortar or concrete	8.00 per 1 in.
Plasterboard	3.73 per 3/8 in.
Plaster (gypsum)	2.32 per 1 in.
Wood lath and plaster	2.00 as applied
Corkboard	0.30 per 1 in.
Rigid insulation (board form)	0.33 per 1 in.
Cellular gypsum (18 lb.)	0.59 per 1 in.
Flaked gypsum, dry (24 lb.)	0.48 per 1 in.

Split furring tile: 1 1/2-in. = 1.40; 2-in. = 1.25
Hollow tile: 6-in. = 0.54; 8-in. = 0.49; 10-in. = 0.46; 12-in. = 0.33
Y = thickness of insulation, in., where specified



No.	Interior Construction	Y	Thickness of Brick, X 8 in.	12 in.	16 in.
	Plain walls—no interior finish		0.385	0.295	0.238

of equal thickness. The B.t.u. loss per foot of sash perimeter (Table 8), is based on the leakage determinations by Voorhees and Meyer, *Trans.* A.S.H.V.E., 1916.

HEAT TRANSMISSION OF ROOFS AND FLOORS.—The temperature of the air in contact with the under side of a ceiling or roof is higher than the temperature at the breathing line, where the temperature usually is measured. This is due to the natural tendency of the warmer or less dense air to rise. It is recommended that an increase of approximately 20% be made to the specified inside temperature for the temperature at the ceiling for ceiling or wall heights exceeding 15 ft. Thus, if 65° F. is the specified inside temperature to be maintained in a room the height of which is 25 ft., the temperature of the air in contact with the under side of the roof may be assumed to be 65° + 20%, or 78° F. The loss of heat through the ceiling of a room over which a large air space exists, through partitions between a heated and a cold room, or through the first floor to the cellar, may be estimated on the assumption that the warmed rooms give off sufficient heat to maintain the temperature of these colder spaces according to the following schedule:

Closed attics under metal or slate roofs.................. 14° F.
Closed attics under tile, cement, tar, or gravel roofs....... 23° F.
Cellars and rooms kept closed......................... 35° F.

The heat transmission of floors that are laid directly upon the ground may be estimated on the assumption that the ground in contact with the under side of the floor has an approximate temperature of 55° F. Thus the estimated heat loss through a 6-in. concrete floor, laid directly on the ground, assuming an inside temperature of 65° F., is

$$u = 1 \div \{(1/1.34) + (6/8)\} = 0.66;\ 0.66\ (65 - 55) = 6.6 \text{ B.t.u. per sq. ft. per hr.}$$

HEAT LOSS BY INFILTRATION.—The heat required to warm the outside air which may enter by leakage through the cracks or clearances around windows and doors is that required to raise the temperature of the weight of incoming air per hour from the outside to the inside temperature.

Table 5.—Coefficients of Transmission (*C*) of Wood Siding on Clapboard Frame Walls

* Pre-cast cement tile. For heat-treated clay aggregate cement tile covered with roofing, C = 0.55 (1 5/8-in. slab) and C = 0.62 (1-in. slab), based on a conductivity of 3.00 per 1 in.

† Nominal thicknesses specified; actual thicknesses used in computations.

‡ No built-up roofing. The value for corrugated iron is obtained by assuming that the surface area is increased 50%.

Let b = B.t.u. required per hour to heat the incoming air; t = inside room temperature, deg. F.; t_0 = outside temperature; C_p = specific heat of air at constant pressure = 0.24; d = density of the air at temperature t, = 0.075 for 70° inside temperature, = 0.076 for 60° inside temperature; Q = cubic feet of air per hour entering building by infiltration, measured at temperature t; W = weight of air per hour entering building by infiltration = $d \times Q$. Then

$$b = C_p(t - t_0)Q \times d = 0.24 \times W \times (t - t_0)$$
$$= 1.26\,Q \text{ for } 70° \text{ inside temperature and } t_0 = 0.$$
$$= 1.08\,Q \text{ for } 60° \text{ inside temperature and } t_0 = 0.$$

Two assumptions are made by engineers in practice for obtaining the value of Q. The common method is to assume a certain number of air changes, n, per hour in the cubical contents of the room. Table 7 may be used as guide when this method is employed.

Table 7.—Air Changes per Hour

	n		n
Halls	3	Offices and stores, 2d floor	1 1/2 to 2
Rooms on 1st floor	2	Churches, public assembly-rooms	3/4 to 2
Rooms on 2d floor	1	Large rooms with small exposure	1/2 to 1
Offices and stores, 1st floor	2 to 3	Factory buildings	1/2 to 1

Table 8.—Air Infiltration Around Window Sashes

Plain wooden sash	114 cu. ft. air per hr. per ft. perimeter
Plain wooden sash, weather-stripped	24 cu. ft. air per hr. per ft. perimeter
Hollow metal sash	216 to 268 cu. ft. air per hr. per ft. perimeter
Hollow metal sash, weather-stripped	72 to 150 cu. ft. air per hr. per ft. perimeter
Copper-covered sash	132 cu. ft. air per hr. per ft. perimeter

Example.—Required the heat loss, by infiltration, from a room containing 20,000 cu. ft., the temperature of which is maintained at 70° F. in zero weather, the estimated number of air changes n being two per hour.

Solution.—$Q = 2 \times 20{,}000 = 40{,}000$ cu. ft. of air entering per hour at 70° F., $b = 1.26 \times 40{,}000 = 50{,}400$ B.t.u. per hour.

The second method is to use the estimated amount of air leaking in the building through the cracks around the sash perimeter and meeting rail. Table 8 may be used in this connection. The data are based on a wind movement of approximately 20 miles per hour (Voorhees and Meyer tests).

For a room with more than one outside wall use only the sum of the perimeters of the windows, in the side having the greater number.

Example.—An office, 14 by 16 ft. with a 10-ft. ceiling, has two 3 × 7-ft. wooden sash windows. The maintained inside temperature is 70°, and the outside temperature 0° F. Required the heat loss by infiltration.

Solution.—By the first method, assuming two air changes per hour, the loss is

$$b = 1.26 \times 2 \times (14 \times 16 \times 10) = 5645 \text{ B.t.u. per hr.}$$

By the second method this loss is:

$$b = 1.26 \times 2(3 + 3 + 3 + 7 + 7 \text{ perimeter}) \times 114 = 6607 \text{ B.t.u. per hr.}$$

HEAT SUPPLIED BY PERSONS, LIGHTS, MOTORS, MACHINERY, ETC.—See Air Conditioning, p. 11–54.

CALCULATING THE HEAT LOSSES FROM A BUILDING.—It is evident from the foregoing data that the heat transmission calculations for each wall, each roof or ceiling and floor for every room must be performed separately and tabulated for future reference as required for the proper selection of the amount of radiation to be installed, or the amount of warmed air to be introduced into the various rooms.

2. HEATING SYSTEMS

HEATING SYSTEM is generally understood to mean the kind of heating medium and the type of apparatus used to release or transfer heat from the medium to the enclosure to be warmed.

All heating systems comprise at least two principal parts or necessary apparatus to effect the desired result: *a*. **Heat generator** where the heat released from burning fuel is transferred to the heating medium. This apparatus is termed the boiler in steam and hot water systems, or simply a furnace in warm air furnace systems. *b*. **Distribution system** used to convey the medium from the generator to the heat emitting apparatus; for example, steam or hot water piping and air ducts. *c*. **Heat emitting or releasing apparatus**

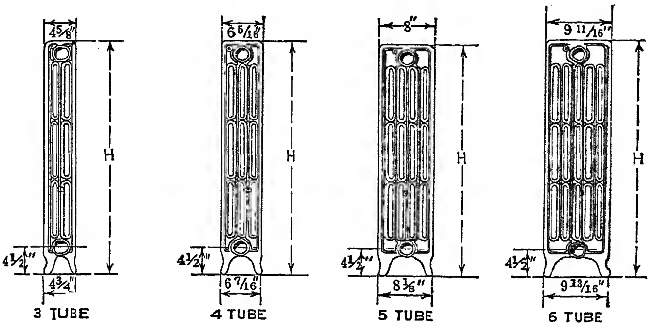

Fig. 1. Cast-Iron Radiators, Tubular Type

to which the distributing system is connected, termed the radiator. In a simple warm air furnace system, only *a* and *b* are required, whereas in a steam or hot water system all three parts are essential.

Radiator commonly means a heat emitting unit located within the enclosure to be warmed. If no provision is made for introducing outside air for ventilation, to be circulated over the radiator, it is termed a direct radiator. Radiators often are installed in recesses in the walls of the building.

The most common type of direct radiator is made of hollow cast-iron sections joined by malleable-iron nipples. Practically only two types of direct cast-iron radiators are now (1935) manufactured: *a.* Tubular type; *b.* Wall type. See Figs. 1 and 2. Several special types of tubular radiators are not illustrated. A variety of direct radiators is built of brass or copper pipe coils, with extended surface in the form of thin metal fins or spiral wound ribbons. Direct radiators are built of steel or iron pipe and standard fittings still are employed to some extent for industrial work. See Fig. 3.

Iron pipe coils, through which hot water is circulated, buried in the wall and ceiling construction of buildings and termed panel heating, are used to some extent in England in place of direct radiators.

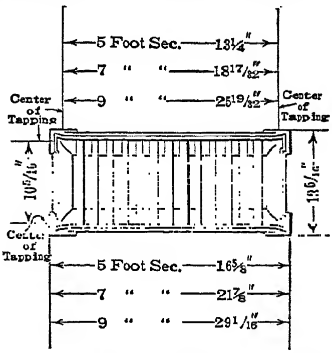

Fig. 2. Cast-iron Radiators, Wall Type

A **UNIT HEATER** is a combination of a radiator and fan located within a common enclosure or casing and placed within or adjacent to the space to be warmed. The unit heater largely used for industrial heating is made in two general types: *a.* Floor type; *b.* Ceiling or hung type. The air passed through the casing is warmed by convection. Comparatively little heat is emitted by radiation. See p. 11–44.

Air for industrial installations almost invariably is recirculated, with no provision for

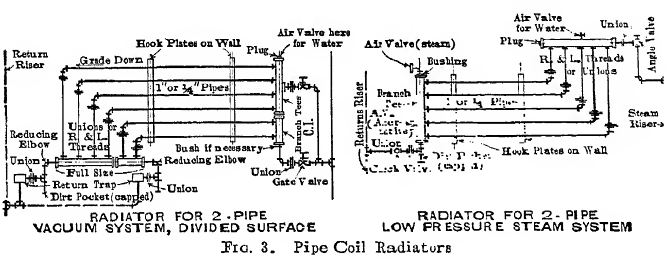

Fig. 3. Pipe Coil Radiators

introduction of outside air to be passed through the unit. Ordinarily, sufficient air for adequate ventilation is provided by infiltration in single-story industrial buildings having monitors or saw tooth roofs. Unit type heaters are now (1935) practically standard heating equipment for industrial establishments. Steam ordinarily is used as the heating medium, although hot water occasionally is used. The circulation of air at a velocity of 1000 ft. per min. or more over a heating surface greatly increases the convection coefficient of the heat emitting surface. This results in a large reduction in installed heating surface, as compared with direct radiation, to obtain the same heating results. The ratio is often as low as 1 to 5.

UNIT VENTILATOR is defined as a floor-type unit heater, designed to circulate all or part outdoor air, with or without recirculation. It is designed primarily for school and office building use where a positive ventilation is required. See Fig. 31. Provision often is made to introduce moisture into the air circulated through the ventilator, and thermostatic control ordinarily is provided. These units may supply both heating and ventilating requirements or ventilation alone in conjunction with direct radiation.

FAN OR BLAST HEATING is understood to mean a combination of heat emitting surfaces, enclosed by a casing through which air is blown or drawn by a fan. As usually installed, the blast heater is located on the suction side and the duct system is connected to the fan outlet. See Figs. 25 to 27 inclusive and Figs. 29 and 30.

RATING OF RADIATORS. EQUIVALENT DIRECT RADIATION.—All types of direct radiators are tested to determine the heat emission, in B.t.u. per hr., of the assembled radiator in still air at 70° F., using dry steam at a temperature of 215° F., corresponding to a pressure of 0.50 lb. per sq. in. gage at the radiator inlet. Manufacturers publish the rating in terms of square feet of *equivalent direct radiation* (e.d.r.) 1 sq. ft. of equivalent direct steam radiation being assumed equal to a heat emission of 240 B.t.u. per hour. No fixed relation exists between the actual measured external heating surface of the many and varied types of radiators, particularly when they are of the extended surface type, and their heat emission; hence the necessity of either publishing radiator ratings in B.t.u. or in terms of e.d.r.

Cast-iron direct radiators, being constructed of sections, the e.d.r. per section is stated. See Tables 9 and 10. When a number of these sections are assembled more or less heat actually may be emitted, depending on height and number of sections. If the same radiator is to be used in conjunction with a hot-water system, based on supplying the radiator with water at 180° F. in still air at 70° F. with a 20° drop in temperature passing through the radiator, the heat emission is assumed to be 150 B.t.u. per sq. ft. of e.d.r. per hour. The temperatures stated for the steam or water and air surrounding the radiator are known as *standard conditions*. Thus, if the published rating of any type of direct radiator, unit heater or blast heater is stated as R sq. ft. of e.d.r., the expected heat emission, when the heat emitting unit is supplied with steam at a temperature of 215° F., will be $R \times 240$ B.t.u. per hour. The latent heat at this pressure is 967 B.t.u. per lb. The weight of steam condensed per sq. ft. of e.d.r. per hr. is, therefore, 240/967, or approximately 0.25 lb. per hr.

AMOUNT OF E.D.R. TO BE INSTALLED.—If H is the calculated heat loss, B.t.u. per hr., the sq. ft. R of e.d.r. to be installed is $R = H/240$ sq. ft. for steam at 0.50 lb. per sq. in. gage in 70° F. air. For a hot-water installation, $R = H/150$ sq. ft. with initial temperature of water of 180° F., and a 20° drop through the radiator.

DIRECT RADIATION FOR CONDITIONS OTHER THAN STANDARD.—Cases arise where both steam temperature and temperature of the room air are other than 215° and 70°, as for example in drying rooms, etc. The coefficient of heat emission of direct radiators, when the steam or room temperature is other than standard, increases with the temperature difference between the radiator and the air. In order to correct for changed conditions, the following formula safely may be applied within the limits of the usual variations met in practice. Let t = temperature of steam or water, deg. F.; t_a = room temperature, deg. F.; R = equivalent direct radiation (e.d.r.) as calculated for standard conditions, sq. ft.; r = equivalent direct radiation (e.d.r.) to be installed, sq. ft. The variation in heat emission from a direct radiator is approximately 0.2% per deg. F. above or below a temperature difference of 145° F. between the radiator and room temperature. Then

$$r = \frac{R}{\{(t - t_a)/145\} + 0.002\,(t - t_a - 145)} \quad . \; . \; . \; . \; . \; . \; . \; [2]$$

RADIATOR DIMENSIONS.—Table 9, with example following, gives the necessary data to determine a tubular type cast-iron radiator, Fig. 1. Table 10 gives corresponding data for wall type radiators, Fig. 2. Manufacturers' catalogs must be consulted for the dimensions of the many and varied types of iron, copper or brass tube extended surface type radiators.

Table 9.—Corto Cast-iron Radiators. (Fig. 1)
(Tubular Type Radiation—Am. Radiator Corp.)

5–A	16 5/8	13 5/16	2 7/8	3 1/2	5
7–A, 7–B	21 7/8	13 5/16	2 7/8	3 1/2	7
9–A, 9–B	29 1/16	13 5/16	2 7/8	3 1/2	9

E.—Required the dimensions of a 5-tube, 32-in. high, tubular type, cast-iron direct radiator to supply 14,400 B.t.u. per hr. Standard conditions: steam 0.50 lb. per sq. in., gage; room temperature, 70° F. The e.d.r. rating required is 14,400/240 = 60 sq. ft. The e.d.r. surface for a 5-tube, 32-in. high section is 4 1/3 ft. (Table 9.) The number of sections required is therefore 60/4 1/3, or (approx.) 14. The length of the assembled radiator will be 14 × 2 1/2, or 35 in., and the width will be 8 in. The actual installed e.d.r. is 14 × 4 1/2 = 63 sq. ft. The expected weight of steam to be supplied (or resulting condensate) per hour will be 63 × 0.25 or 15 3/4 lb.

HEAT EMISSION OF DIRECT CAST-IRON RADIATORS.—The coefficient of heat emission K of direct radiation in still air, or the B.t.u. emitted per hour by the radiator per measured square foot of external surface per degree difference in temperature between the heating medium and the surrounding air, is found by tests to be a variable. Its value depends on the length, width, number of sections in the radiator, and the temperature difference. The value of K varies from 1.45 to 1.95, the average value being 1.70. The values may be applied to either steam or hot water.

The coefficient K is increased or decreased at the approximate rate of 0.2% per degree of temperature difference above or below the standard temperature difference of 145° F.

Effect on Heat Emission of Location of Direct Radiators.—The maximum heat emission is obtained when the radiator is placed in the center of the room. The Committee "Report on Best Position for a Radiator in Room," *Trans.* A.S.H.V.E., 1916, states that the following values of K were obtained by test: 1.76 with radiator placed in center of room and 1.588 with radiator placed under a window in the outside wall.

The heat emission of direct radiation should be reduced by the following percentages when inclosures are provided. (See report by Prof. K. Brabbee, Royal Tech. Inst. of Berlin; translated by Geo. Stumpf, Jr., *Heat. & Vent. Mag.*, May, 1914):

Radiator set in recess of wall without front grill, 8%; radiator with shelf over top, 10%; radiator with shelf over top and front grille, 20%.

Effect of Painting on Heat Emission.—Tests by J. R. Allen indicate that the effect of painting the surface of radiators is to influence the loss of heat from the surface only, and depends largely on the radiation factor for the surface in question. The following are the relative transmissions of various surfaces: Bare iron, 1.00; aluminum and copper-bronze, 0.75; snow-white enamel, 1.01; white-lead paint, 0.987; white-zinc paint, 1.01.

3. RATING OF HEATING BOILERS

HEATING BOILER LOAD.—In order to make a satisfactory selection of a heating boiler a number of factors must be considered. As a result, manufacturers have fixed certain standard conditions under which the ratings of their boilers are established.

The *Code of Minimum Requirements for the Heating and Ventilation of Buildings* of the A.S.H.V.E., in discussing the Minimum Capacity and Installation Requirements for Low-Pressure Steam and Hot-water Heating Boilers summarizes the more important factors or conditions as follows:

Estimated Heating Boiler Load.—For the purposes of the Code, the estimated connected load to the boiler or boilers using solid fuels, shall be taken as $B = (a + b + c) \times F$, where $B =$ esti-

mated load connected to the boiler, B.t.u. per hr.; a = estimated heat emission, B.t.u. per hr., of the connected radiation, direct, indirect or both, to be installed as determined by computation from data given for normal operation. (Heat transmission calculations, see p. 11–03); b = estimated maximum heat, B.t.u. per hr., required to supply water heaters or other apparatus to be connected to the boiler or boilers; c = the estimated heat loss, B.t.u. per hr., of the piping connecting radiation and other apparatus with the boiler or boilers (see below); F = estimated increase in the normal load, B.t.u. per hr., due to starting with cold radiation, if boilers are to be in service intermittently. This increase is to be based on $a + b + c$, and assumed to be not less than the following:

Sum of a, b and c in B.t.u. per Hour	Multiplying Factor, F
Up to 100,000	1.65
100,000 to 200,000	1.60
200,000 to 600,000	1.55
600,000 to 1,200,000	1.50
1,200,000 to 1,800,000	1.45
Above 1,800,000	1.40

The values of F are based on heating 1 sq. ft. of cast-iron radiation weighing 7 lb. (specific heat = 0.12) from 35° F. to 220° F. during the first hour of operation, or $7 \times 0.12 \times (220 - 35) = 156$ B.t.u., which is $(156/240) \times 100 = 65\%$ of the heat emission of the radiator.

Heat losses from the piping system, which comprises all connections not considered as direct radiation, and including all mains, branches and risers, may be estimated as follows: Let H = heat loss, B.t.u. per hr. per sq. ft. of external surface of uncovered piping; t_1 = temperature of surrounding air; t = temperature of steam or hot water; $t_2 = (t - t_1)$; K = a constant = 2.0 for steam, and 1.8 for hot water. Then $H = t_2 \times K$. Based on steam and hot-water temperatures of 219.4° F. and 180° F., respectively, the following are values of H for various values of t_1.

t_1	40	45	50	55	60	65	70	75
H (steam)	358.8	348.8	338.8	328.8	318.8	308.8	298.8	288.8
H (hot water)	252	243	234	225	216	207	198	189

If pipe covering $^3/_4$ in., or more, thick is used, the above figures may be reduced 75%. If the covering is less than $^3/_4$ in. thick, the piping should be considered as bare.

Boiler Capacity to be Installed.—The boiler capacity installed should be able to supply, at the boiler outlets, the total B.t.u. per hour as computed by the method outlined in the preceding paragraph, under the conditions of operation which are stated in the specifications covering the installation for which the boilers are intended.

STANDARD CONDITIONS.—American manufacturers of heating-boilers rate the boilers in terms of B.t.u. per hr. or sq. ft. of direct cast-iron radiating surface (e.d.r.) that the boiler is capable of supplying, for the firing period stated (fuel available in hours), under the following conditions: 1. *Steam boilers,* steam pressure, 2.3 lb. gage at the boiler; 2. *Hot-water boilers,* water temperatures, 180° F. leaving and 160° F. entering the boiler; 3. *Fuel,* stove size anthracite, of a heating value of at least 12,000 B.t.u. per lb. of dry coal.

The rate of combustion, or coal required per hour for the boiler to develop this rating, has, until recently, seldom been given. The method of determining rating has varied with different makers and often is not stated. Also, it is possible for a boiler to be placed on the market and given a certain rating, although such rating never actually has been checked by tests. It is, therefore, important to establish standard conditions for rating tests, and the manufacturer should be in a position to produce certified test sheets of such tests. The standard conditions under which a boiler should be tested to develop its rating are generally understood by manufacturers to be as follows:

1. Pressures, temperature and fuel as stated above. 2. Fuel capacity sufficient to carry the boiler for the period stated, and leave 20% reserve for igniting a fresh charge. 3. Draft of sufficient intensity to burn the fuel at the required rate to produce the rating stated. 4. Each square foot of equivalent direct radiation (e.d.r.) is assumed to transmit 240 B.t.u. per hr. for steam, and 150 B.t.u. per hr. for hot-water radiators, respectively. 5. The condensation from steam radiators returns to the boilers at the same temperature as the steam, so that the boiler simply supplies the latent heat of evaporation at 2.3 lb. gage pressure, or 965.4 B.t.u. per lb. of water evaporated. 6. The water from hot-water radiators returns to the boiler at 160° F., allowing a 20° drop in the radiators. No loss of temperature is allowed in the return main.

EQUIVALENT BOILER HORSEPOWER RATING OF HEATING BOILERS.—The capacities of heating-boilers may be stated in boiler horsepower, and its equivalent in square feet of radiation may be determined as follows: 1 boiler Hp. = 34.5 lb. water evaporated from and at 212° F. = 34.5×970.2 (latent heat at 212° F.) = 33,472 B.t.u. per hr. 1 sq. ft. of standard cast-iron steam radiation is assumed to transmit 240 B.t.u. per hr., and 1 boiler Hp. = $33{,}472 \div 240 = 139.5$ sq. ft. of equivalent direct radiation.

The equivalent boiler Hp. rating of a hot-water boiler is $33{,}472 \div 150 = 223.1$ sq. ft. of direct cast-iron hot-water radiation.

GRATE-SURFACE.—It is advisable to check the grate-area required for heating-boilers. The total heat loss must include not only the calculated loss, due to transmission through walls and glass for which the radiation is proportioned, but also about 50% additional for heat losses from the piping system, boiler, etc. If B is the B.t.u. to be supplied by the boiler, $G = B \div (C \times F \times E)$, where G = grate-area, sq. ft.; C = rate of combustion of dry coal, lb. per hr.; F = calorific value of fuel, B.t.u. per lb.; E = combined efficiency of boiler and grate (usual assumption, 65%). The boiler selected should not have a smaller grate-area than that given by the above formula. Special attention is called to the distinction between grate-area and firebox or fuel-pot area. (See Depth of Fuel-pot, below.) The rate of combustion C varies from approximately 5 lb. for small boilers up to approximately 10 lb. for the largest sizes. Table 11 gives the maximum rate of combustion during the starting up period, and the rate for the normal load as ordinarily found in practice.

Table 11.—Rates of Combustion for Heating Boilers

Based on 13,000 B.t.u. Anthracite, and on Boiler and Grate Efficiency of 65%

Estimated Normal Boiler Load, Sum of Items, $a+b+c$ (see p. 11-03)		Maximum rate of Combustion for Starting Up Load, C_m lb. per sq. ft. of grate per hr.†	Rate of Combustion of Normal Load, C, lb. per sq. ft. of grate per hr.‡	Factor for Starting Up Load, $F=C_m/C$
B.t.u. per hr.	Equivalent Direct Steam Radiation, sq. ft.*			
Up to 100,000	Up to 420	8	4.85	1.65
100,000 to 200,000	420 to 840	8	5.00	1.60
200,000 to 600,000	840 to 2,500	9	5.80	1.55
600,000 to 1,200,000	2,500 to 5,000	10	6.70	1.50
1,200,000 to 1,800,000	5,000 to 7,500	11	7.50	1.45
1,800,000 to 2,880,000	7,500 to 12,000	12	8.60	1.40
2,880,000 to 3,840,000	12,000 to 16,000	14	10.00	1.40

*B.t.u. per hour/240. † $C_m = (a \times F \div (G \times 0.65 \times 13{,}000)$.
‡ $C = (a+b+c) \div (G \times 0.65 \times 13{,}000)$.

EXAMPLE.—The estimated boiler load (sum of items $a + b + c$) is 150,000 B.t.u. per hr. The maximum starting load is assumed as $150{,}000 \times 1.6 = 240{,}000$ B.t.u. per hr., or 1000 sq. ft. of e.d.r. *Required*: The grate area with 13,000 B.t.u. anthracite, and an assumed boiler efficiency of 65%. From Table 11, assume a combustion rate of 8 lb. per sq. ft. of grate per hr. for the maximum starting up load. Then $G = 240{,}000/(8 \times 0.65 \times 13{,}000) = 3.55$ sq. ft. The rate of combustion at normal load will be about 5 lb. per sq. ft. of grate per hr.

DEPTH OF FUEL-POT.—The average area of the firebox is usually somewhat larger than the grate-area in sectional boilers. It may be less than the grate-area in certain types of round boilers. In any event, the capacity of the firebox or fuel-pot, measured from grate to middle of firedoor, should be sufficient to hold all the coal required for an 8-hr. firing period, plus at least 20% reserve for igniting the new charge.

To determine the depth of pot or firing period, as the case may be, let G = grate-area, sq. ft.; C = rate of combustion, lb. per hr.; A = average area of fire-pot, sq. ft.; h = firing period, hr.; W = weight of fuel per cu. ft. (50 lb. for anthracite, 40 lb. for bituminous); D = depth of fuel bed from grate to center of firedoor, ft. Then $(G \times C \times h) + 20\%$ or $A \times W \times D$ = total weight of one charge. Hence, $D = 1.2\, GCh/AW$, or $h = AWD/1.2\, GC$. This formula allows for the greater bulk of soft coal.

EXAMPLE.—In a boiler with a grate-area of 8 sq. ft., average firepot area, 9 sq. ft., height to center of firedoor, 18 in., and a rate of combustion of 6 lb. per sq. ft. of grate for anthracite, $h = (9 \times 50 \times 1.5) \div (1.2 \times 8 \times 6) = 11.7$ hr.

MANUFACTURERS' RATING OF STEEL HEATING BOILERS.—The Steel Heating Boiler Institute adopted (1929) a rating code for steel heating boilers based on grate-area as follows: For boilers with ratings of 300 sq. ft. to 4000 sq. ft. of e.d.r. for steam, grate area, sq. ft. = $\sqrt{(\text{catalog rating, sq. ft. steam radiation} - 200) \div 25.5}$. For boilers with ratings of 4000 sq. ft. of steam radiation and larger, grate-area, sq. ft. = $\sqrt{(\text{catalog rating, sq. ft.} - 1500) \div 16.8}$. The code further states that the boiler heating surface must not be less than $^1/_{14}$ of the e.d.r. rating in square feet. Catalogs of steel boilers give both grate area and boiler heating surface. The heating surface ratio is based on 10 sq. ft. per nominal boiler Hp. One boiler Hp., as previously shown, will supply 139.5 sq. ft. of e.d.r. Therefore, $10/139.5 = {}^1/_{14}$ (approx.).

EFFECT OF FUELS ON RATINGS.—All ratings are based on anthracite, unless otherwise stated. If bituminous coal is used and the boiler is selected by catalog rating, one with a fire-pot of at least 25% greater capacity should be selected. With soft coal, additional heating-surface also is required, as soot accumulations render the heating-

surfaces less effective. Boilers for pea coal should have a larger fire-pot than those for stove or furnace coal. As the small sizes of anthracite contain more ash than the larger sizes, they have greater bulk for the same heating effect and so require larger fuel-pots for the same capacity. Firing periods differing from that on which the boiler is rated, also affect the fuel-holding capacity. For example, if boilers designed for an 8-hr. period are operated on a 12-hr. basis, at least 50% greater fuel-holding capacity will be necessary and larger boilers must be selected.

FUEL CONSUMPTION.—The estimated fuel consumption of heating-boilers per heating season may be based on grate-area, square feet of radiation installed, or cubic contents of the building to be heated. The U. S. Treasury Dept. allows for government buildings 5 tons of coal per sq. ft. of grate-area per season of 240 days, or 1 lb. of coal per cu. ft. of building content. District steam-heating companies estimate 500 lb. of steam per sq. ft. of direct radiation per season or about 70 lb. of good coal. This is approximately equivalent to assuming that $^1/_3$ of the radiation installed is operated continuously for 240 days. The amount of coal for maximum conditions is determined as follows:

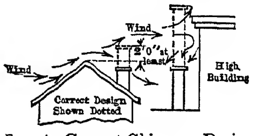

Fig. 4. Correct Chimney Design

Assume 1 sq. ft. of direct steam radiation to emit 240 B.t.u. per hr., 70° air surrounding the radiator, and assume the piping on the average job to be 25% of the direct radiation. Assume 8000 B.t.u. per lb. of anthracite burned. If R = direct radiation, sq. ft., and C = coal burned per hr., lb., $C = (1.25 \times R \times 240) \div 8000$. In a heating season from Oct. 1 to May 1, 210 days of 24 hr. each, there would be burned under maximum conditions, a total of

$$(1.25 \times R \times 240 \times 210 \times 24) \div (8000 \times 2000) = 0.0945\,R \text{ tons of coal,}$$

and for hot-water heating, 0.0197 R tons.

The estimated seasonal consumption is the product of the preceding figure and the "demand factor," or $(70 - T_a)/T_d$, where T_a = average outside temperature (Table 1), and T_d = temperature for which the system was designed, usually 70° F.

Table 12.—Average Steam Consumption of Various Type Buildings, per Year
(Indianapolis, Ind.)

Buildings	No.	Pound Steam per sq. ft. Radiation	Buildings	No.	Pound Steam per sq. ft. Radiation
Hotels	11	482	Public garages	3	280
Apartments	13	562	Manufacturing	4	447
Department stores	6	315	Public buildings	4	292
Theaters	5	364	Clubs, lodges	3	500
Office buildings	20	354	Printing	5	655
Auto sales	8	498	Warehouses	2	590

Average of above is 400 lb. per sq. ft. per year.

TYPES OF HEATING BOILERS.—Cast-iron steam-heating boilers are designed to operate at a maximum pressure of 15 lb. per sq. in. The sections are tested in manufacture to about 100 lb. per sq. in. hydrostatic pressure. The maximum size of round-type boilers manufactured is rated at about 1400 sq. ft. Sectional boilers are built up to 10,000 sq. ft. rating (see manufacturers' catalogs for dimensions, capacities, etc.).

SELECTION OF CAST-IRON BOILERS.—The selection of cast-iron boilers should not be influenced too largely by price and the ease of carrying them into a building, where structural conditions interfere with the introduction of a steel boiler. The character of the service or attendance, especially in government or other public buildings, often is such that steel equipment, capable of standing more abuse, should be used, particularly if the returns are handled by a pump.

STEEL HEATING BOILERS.—The two general types of all-steel boilers used for heating are the firebox type and the return tubular type. In the firebox type, the grate and combustion chamber are surrounded by a water-jacketed extension of the shell. The products of combustion pass directly through the tubes to the smoke flue at the rear. The return tubular type is similar to the ordinary horizontal tubular boiler used for power plants (see Steam Boilers).

Capacities of the usual firebox type boilers range from 500 to 13,000 sq. ft. of direct radiation. Detailed information as to capacities, dimensions, etc., are available in makers' catalogs. The return tubular boiler commonly is used in heating systems of 10,000 sq. ft. or more of direct radiation, and is rated at 10 sq. ft. of boiler heating-surface per boiler Hp. A special design of setting is required for smokeless combustion when bituminous

coal is used. The so-called standard setting should not be used in this connection. (See Steam Boilers.)

CHIMNEYS FOR HEATING BOILERS.—The minimum height of chimneys for low-pressure heating boilers, hot-water boilers, and hot-air furnaces is 35 ft. measured from the grate. No flue should be less than 8 × 8 in. Many heating installation failures may be traced to insufficient draft to burn the fuel at the rate required for the rated capacity of boiler or furnace. Flue-gas temperatures should range between 400° and 500° F. when the apparatus is worked at its rated capacity. The chimneys should be so located with reference to nearby higher buildings that wind currents will not form eddies and force air downward in the shaft. (See Fig. 4.) The flue should be as straight as possible from

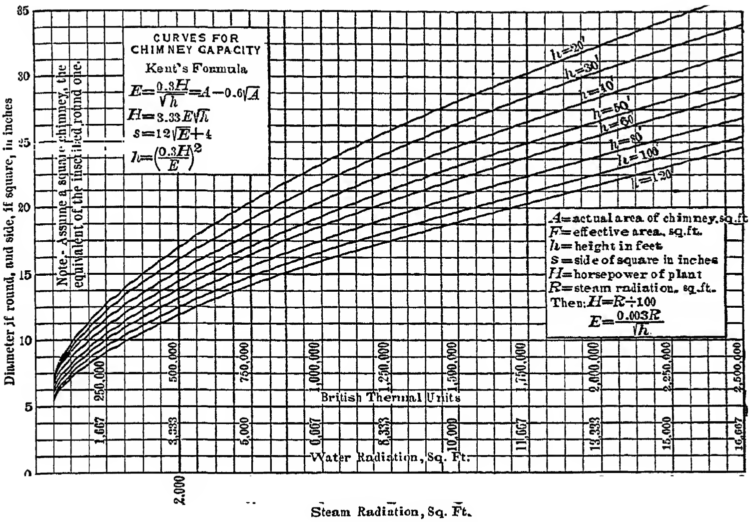

Fig. 5. Capacity of Chimneys

base to top outlet and should have no opening except the boiler smoke pipe. The outlet must not be so capped that its area is less than the flue area. Sharp bends and off-sets in the flue may reduce the area and choke the draft. The flue must have no feature which reduces the full area. In tile flues, joints must be well cemented and all space between tile and brickwork tightly filled in. If crevices open into the flue where tile sections meet, the draft will be checked. With brick flues, the stacks should have outside walls at least 8 in. thick. Exposed bricks at the top should be laid in cement mortar to prevent acid

18 × 18	18 × 18	15 1/2 × 15 1/2	30	35

fumes and rains from cutting out the joints, as will occur with lime mortar. The best location for a chimney is near the center of the building, as all walls then are kept warm. If there is a soot pocket in the flue below the smoke-pipe opening, the clean-out door always should be tightly closed. Other openings into it, from fire-places, etc., check the draft and prevent best results. The smoke-pipe should not extend into the flue beyond the inside surface of the latter, as its end cuts down the area of the flue. Joints where the smoke-pipe fits the smoke-hood of the boiler, or where the pipe enters the chimney, should be made tight with boiler putty or asbestos cement. The best practice uses fire-clay linings for small and medium-sized flues. Rectangular flue linings are rated by outside dimensions and round linings by inside dimensions.

Reference.—An Ordinance for Construction of Chimneys, recommended by Nat. Board of Fire Underwriters, *Jour.* A. S. H. V. E., Dec. 1921.

Table 14, giving dimensions and heights of chimneys, has been used with success in many heating installations. For large installations and for power boilers, draft losses should be estimated and a height of chimney chosen to give sufficient intensity of draft to balance the sum of the losses. See William Kent's Chimney Formula, p. 6–104 and Fig. 5.

The loss of draft through a cast-iron sectional boiler, normal rating, is approximately 0.15 in. water column, and 0.07 in. for loss through fuel bed, with a combustion rate of 8.6 lb. of egg coal per hr.

Stacks for Tall Buildings are special cases and should be designed by the methods used in the design of chimneys for power boilers. See Chimneys and Draft, p. 6–102.

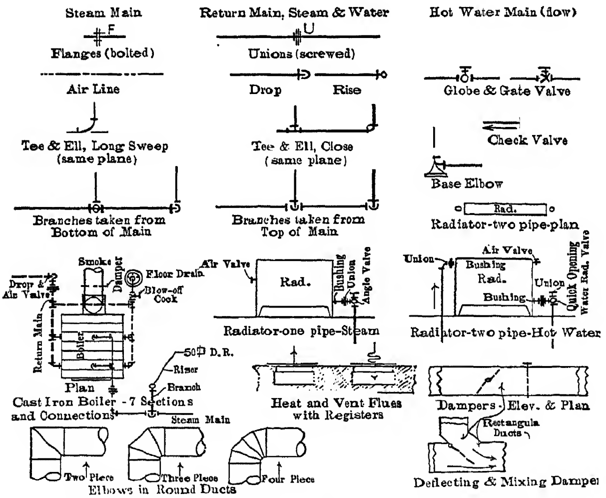

FIG. 6. Symbols Used for Heating and Ventilating Apparatus

4. DIRECT STEAM HEATING

Systems using direct steam radiators are: 1. Gravity circulating. 2. Mechanical circulating. The distinguishing characteristic is the manner in which the condensate from the radiators returns to the boiler. In Type 1 the condensate returns by gravity, due to the static head existing in the returns, and the system is a closed circuit. The steam pressure is the same in boiler, mains and radiator, except for friction-pressure losses due to the flow of steam. In Type 2, the condensate returns to a receiver or feedwater heater, and then is forced into the boiler by a pump or return traps, or both. The system is not closed, and boiler-pressure may be higher than that in mains and radiators. The receiver usually is vented to atmosphere, and in vacuum systems an additional pump, attached directly to the returns, discharges the condensate into the receiver or heater. Gravity circulating systems are also divided into 1-pipe and 2-pipe systems, with basement mains supplying

* Dimensions below are larger than those in which rectangular fire-clay flue linings are commercially available, and hence are for unlined rectangular flues—requiring thicker walls than when lined.

risers to the various floors, or with overhead mains supplying drop risers to the floors below. In the latter arrangement, steam and the water of condensation in the risers flow in the same direction. As there are no counter-currents, less friction is produced, and somewhat smaller pipes may be used. The overhead system commonly is known as the Mills system. See p. 11–18.

The following types of steam heating systems are in common use: One-pipe circuit systems, Fig. 7; One-pipe Relief systems, Figs. 8 and 9; Two-pipe systems, Fig. 10; Air-line systems, Fig. 11; Vapor or Air Return systems (2-pipe), Fig. 12; Vacuum systems, Fig. 13. In all systems provision must be made to maintain the water in the boiler at the normal water-line level. A most prolific cause of cracking of sections in a cast-iron boiler is the lowering of the water line, thereby uncovering heating surface which is practically in contact with the fire. Due to loss of pressure in a gravity return system caused by frictional resistance in piping, valves, etc., a static head of water must exist in the return piping, above the boiler water line, equivalent to this pressure loss (30 in. per lb. loss in pressure). When the system is started with cold radiation, a greater volume of steam is moved through the piping. Consequently, greater loss in pressure results, and more water is drawn from the boiler than is necessary during the normal heating period to create the necessary static head in the return piping. It is during this starting period that cracking of cast-iron boiler sections sometimes occurs.

ONE-PIPE GRAVITY SYSTEM.—The 1-pipe *circuit system* (Fig. 7) with basement mains commonly is used for small residence heating. The main rises close to the basement ceiling, just above the boiler, grading down from this high point with a fall of 3/4 or 1 in. per 10 ft. to the last radiator riser. The main then drops below the boiler water-line, and now being required to carry only condensation, is reduced in size. This construction is called *wet return,* and is the most satisfactory arrangement whenever its use is possible. If the return main is above the boiler water line, it is a *dry return.* Return mains slope to the boiler 1 in. per 30 ft. An automatic air valve should be placed on the main, at the drop, to remove air from the pipe system.

In mains of unusual length the height of the end of the main above the boiler water line must be carefully determined to prevent water backing up from the boiler and flooding the main, air valve and branches. For steam mains up to 80 ft. long, there should be

at least 20 in. between the under side of the steam main at the low point and the normal water level in the boiler. This height should be increased 2 in. for every 10 ft. of run above 80 ft. in all types of gravity systems. In operation, steam and water flow in the same direction in the steam main, and in opposite directions in basement branches, risers and radiator branches. This necessitates larger piping and valves than in any other steam system. The main, especially, must be full size from boiler to drop, unless dripped at intervals.

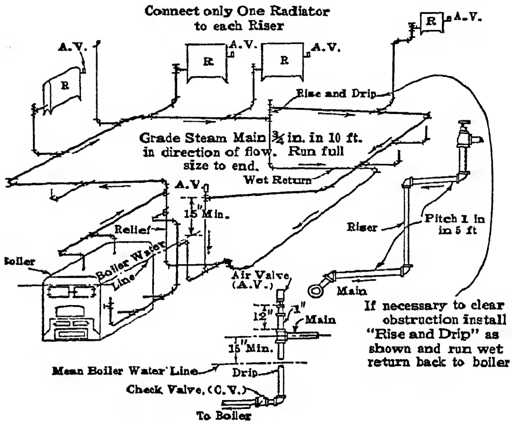

FIG. 7. One-pipe Circuit System

THE ONE-PIPE RELIEF SYSTEM, Fig. 8, resembles the 1-pipe circuit system, except that the individual risers drip to the return main, which may be either wet or dry. A wet return is preferred. The steam main carries no condensate, and also drips at intervals to the return. A *rise and drip*, as shown, is used when the head room under the steam main would be too much reduced. In this system it is possible to reduce the size of the main at each branch, and to run the main closer to the basement ceiling, which is important where basement space is valuable. This is the system most commonly used in large installations. For tall buildings, the 1-pipe system with basement mains and gravity circulation frequently is used. It is satisfactory if the piping is properly designed for the circulation of steam and return of condensate. In long, narrow buildings, using a gravity system, a deep boiler pit is necessary, otherwise the elevation of water in the return connections may flood the far end of the steam lines.

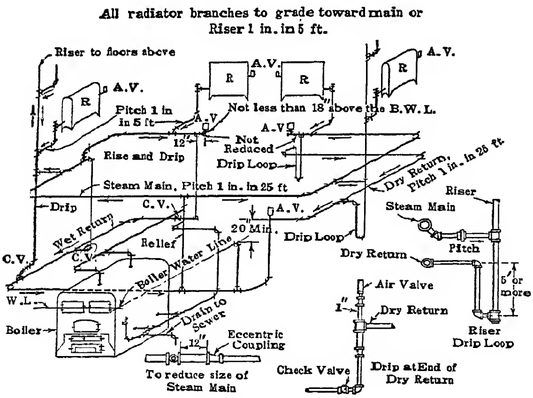

FIG. 8. One-pipe Relief System

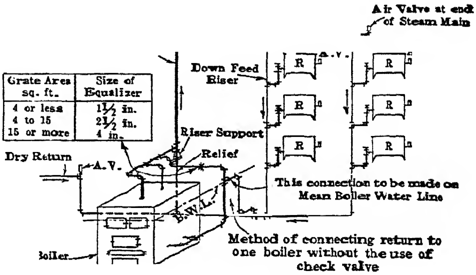
MILLS SYSTEM.—A more satisfactory arrangement, Fig. 9, for tall buildings and factories is to run the steam main near the ceiling of the top floor or the roof and install down-feed risers to the radiation. This arrangement of the piping is known as the Mills System. In it, the steam and condensate flow in the risers in the same direction and with higher velocities. Consequently smaller pipe may be used than with an up-feed system. The risers drip at the bottom to the return as previously indicated. These systems ordinarily operate at 2 to 5 lb. boiler pressure at normal load. The steam piping usually is designed for a loss in pressure of approximately 1 oz. per 100 ft. of run, including allowances for ells and other fittings.

THE TWO-PIPE GRAVITY SYSTEM, Fig. 10, with basement mains often is used in large buildings, and *always* with indirect radiation. A thermostatic valve on each radiator will adapt it to vapor and mechanical vacuum systems. When used as a gravity

system, the return from each radiator is separately sealed either by dropping below the boiler water line to a wet return or by using drip loops, before connection to a dry return. Even in 1-pipe systems, all drips or reliefs should be sealed as in Fig. 8. If this is not done, steam may enter a drip or return from the outlet and cause water-hammer, due to counter-currents of steam and condensate. All drips, reliefs, return-risers and connections from the steam to the return side of the system must be sealed, either by connection below the water line or by using a running or return-trap on the connecting line. Failure so to seal will result in unsatisfactory operation.



Grate Area sq. ft.	Size of Equalizer
4 or less	$1\frac{1}{2}$ in.
4 to 15	$2\frac{1}{2}$ in.
15 or more	4 in.

FIG. 9. Mills System

SPECIAL GRAVITY SYSTEMS.—Many special steam-heating systems, known as air-line and vapor systems, also operate with gravity return of the condensate. The air-line system may be applied to any 1- or 2-pipe gravity system, by connecting the automatic air valve of each radiator, by small size piping, to an exhauster maintaining a slight vacuum in the air piping and removing accumulated air from the radiators. The application of this scheme to the ordinary 1-pipe or 2-pipe gravity system, will improve its operation. The exhauster for less than 2500 sq. ft. of radiation is a water-driven vacuum-pump with a pressure of at least 20 lb. per sq. in. Larger systems use a high-pressure steam jet, or if steam is not available, a motor-driven vacuum pump of about $^1/_4$ Hp.; 1-in. air mains in the basement are used, with a gate valve on each riser. See Fig. 11. The steam used varies from 1 to 5% of the total condensation.

The Vapor Systems, so-called, Fig. 12, are 2-pipe gravity systems in which the accumulated air in the radiators is removed through the return, the air valve on the radiator being omitted. The return on each radiator has a check valve or thermostatic trap, and the dry main return in the basement terminates in a small receiver, having an automatic air valve of sufficient capacity to remove all accumulated air. Each radiator ordinarily is fitted with a graduated fractional valve on the steam connection, permitting partial heating of the radiator when desired.

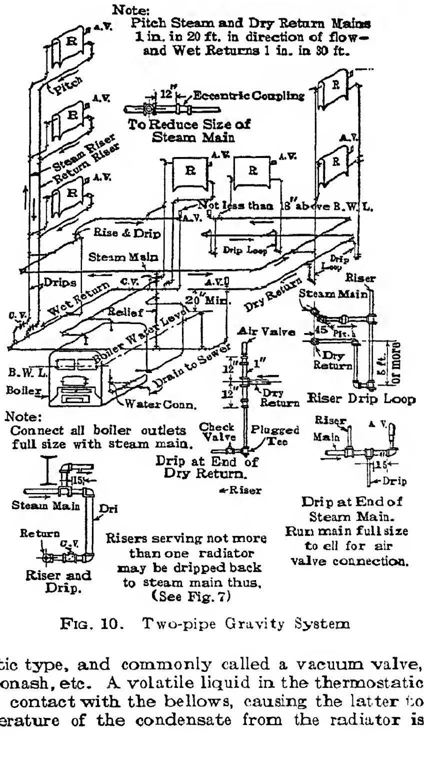


FIG. 10. Two-pipe Gravity System

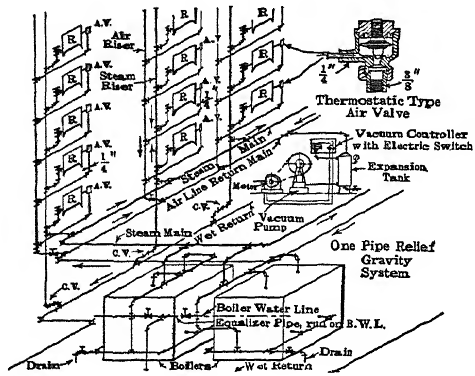
MECHANICAL VACUUM SYSTEMS are of the 2-pipe type and have a vacuum pump attached directly to the returns. See Fig. 13. This pump must be capable of handling both air and water, as no air valves can be used on the radiators in this system. The return end of each radiator has a radiator trap, usually of the thermostatic type, and commonly called a vacuum valve, such as the Dunham, Webster, Illinois, Monash, etc. A volatile liquid in the thermostatic bellows vaporizes when steam comes in contact with the bellows, causing the latter to expand and close the valve. The temperature of the condensate from the radiator is



Note:
All Connections to radiator air Valves $\frac{1}{4}$ in.
Air risers are $\frac{1}{2}$ in., up to 8 stories high.
Air mains in basement are: 1 in. for $\frac{1}{2}$ in. Risers and $1\frac{1}{4}$ - $1\frac{1}{2}$ in. for $\frac{3}{4}$ -in. Risers.
Air Valves are of the thermostatic type.
This illustration shows the recommended method of connecting piping for a two-boiler installation without the use of check valves.

Fig. 11. Air-line Vacuum System

Note: Pitch Steam and Dry Return Mains 1 in. in 20 ft. in direction of flow. All Radiator Branches to grade toward Main or Riser 1 in. in 5 ft.

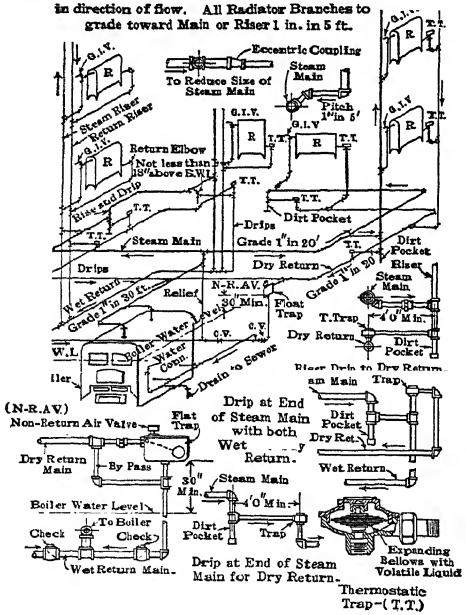


Fig. 12. Vapor System

not sufficiently high to vaporize the liquid, and the valve, therefore, remains open to pass condensate and air until the steam starts to flow. The valves are very sensitive, and when in proper adjustment and repair will not blow steam. It is good practice to connect a $^1/_2$-in. cold water line to the main return at the pump, to condense steam that may leak past the vacuum valves, due to dirt getting under the seat.

Figs. 14*A* and 14*B* show the application of vacuum traps to the 2-pipe system. The vacuum valve or trap is placed 4 ft. from the riser or main which it drains. Otherwise, conduction of heat through the connection to the trap will keep the valve open. Return connections for a vacuum system are smaller than for the ordinary 2-pipe system.

Vacuum systems are used with exhaust steam heating, where the back pressure from engines or turbines ordinarily should not exceed 5 lb. per sq. in. A by-pass with a reducing valve cross connects the live-steam main with the heating system, allowing live steam at reduced pressure (usually 2 to 5 lb.) automatically to enter the heating system whenever the demand is greater than the supply from the engines, or when they are not operating (see Fig. 18). The pump on the main return-line ordinarily maintains a vacuum of about 10 in. of mercury. It is under automatic control, the negative pressure in the return line operating the controller.

RADIATOR VALVES.—Table 15, giving radiator valve ratings, is based on average cast-iron radiation for a 20-minute heating-up period. If the 20-min. quick heating-up feature is disregarded and ratings are desired for normal requirements after the radiator is fully heated, multiply values in Table 15 by 2. The capacity and rating of various types of fractional valves as manufactured by various concerns will naturally vary somewhat.

PRESSURE LOSSES IN PIPING.—The pressure loss due to friction in steam mains, valves and traps in low-pressure gravity systems, ordinarily should not exceed, approximately, 1 oz. or 0.062 lb. per sq. in. per 100 ft. of run. Fig. 15 shows the reason for limiting the pressure loss. As the steam flowing through the main loses pressure, the pressure at the last riser will be lower than in the boiler. The difference in pressure, or pressure loss, p, causes the water line in the return main to be higher than in the boiler. The added height of water in the return is that of a column of water which pressure p will support. Thus, if boiler-pressure is 2 lb. per sq. in., and the pressure at the far end of the main is $1\,^1/_2$ lb., with water weighing 61 lb. per cu. ft. (0.035 lb. per cu. in.), the water in the return will stand $(2 - 1.50) \div 0.035$ or 14 in. above the water-line of the boiler. In this instance, unless the water-line of the boiler is 18 in. or more below the last riser or radiator-connection, water is liable to flood the steam-main and cause hammering and poor circulation in the radiators near the end of the run.

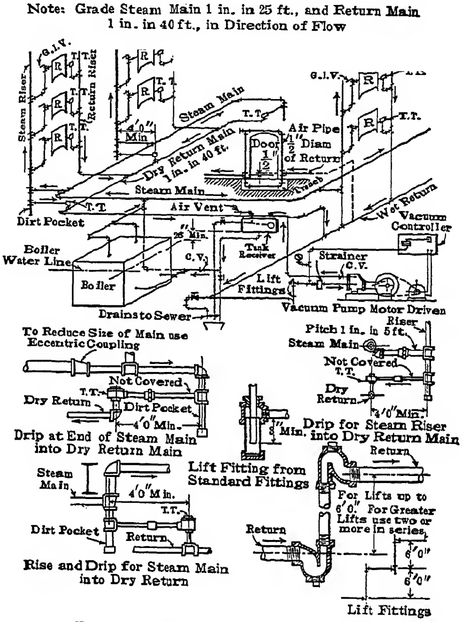

FIG. 13. Mechanical Vacuum System

Fig. 15, showing the various pressure losses existing in a vapor system, illustrates the method of approximately estimating pressure losses in any low-pressure heating system. The height of the water line in the return piping above the boiler water line then may be determined. The example is based on normal or designed load conditions of operation. The pressure losses are calculated as follows:

Let P_1 = pressure loss, or effective pressure, required to impart initial velocity in the steam main and overcome friction at entrance to main, lb. per sq. in.; H = head of water column, ft., $= P/0.415$; then $P_1 = 1.65 \times$ velocity pressure $= 1.65\, v^2d/9262$; v = velocity of steam, ft. per sec.; d = density of steam. (See Steam Tables, p. 5–04.) The velocity of the steam in the main at

* Fractional or graduated inlet type. Use 2-oz. rating for vapor and 8-oz. rating for vacuum systems.

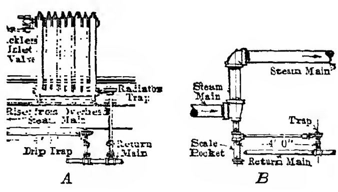

FIG. 14. Application of Vacuum Traps to 2-Pipe System. A. Riser Drip. B. Riser and Drip Connection

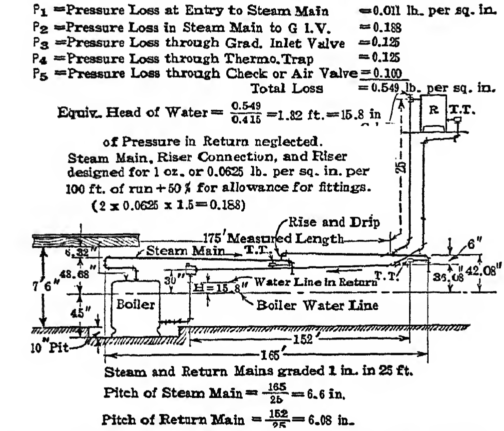
the boiler, as ordinarily designed, usually does not exceed 40 to 50 ft. per sec. at rated load. Assuming 1 lb. gage pressure at the boiler, d = 0.04, and

$$P_1 = 1.65\,d(40^2 \times 0.04/9262) = 0.011 \text{ lb. per sq. in.}$$

P_2 = pressure loss due to friction in steam main, horizontal connection to riser and riser to inlet valve of radiator farthest from the boiler, lb. per sq. in., taken as 1 oz. or 0.0625 lb. per sq. in. per 100 ft. of run, including all allowances for loss through ells and tees. (See Figs. 16 and 17.) If no actual estimate for ells or tees is made, 1.5 L is usually sufficiently accurate, L being the measured length, ft., from boiler outlet to last radiator valve.



Note: In the case of Long Steam Mains it sometimes becomes necessary to install "Rise and Drip", as indicated, to keep end of Steam Main high enough to Drip into the Dry Return Main at end of run.

Fig. 15. Pressure Losses in Piping

Then P_2 (approx.)

$$= 0.0625 \times (1.5L/100)$$
$$= 0.094\,L/100 \text{ lb. per sq. in.}$$

P_3 = pressure differential required to overcome pressure loss through a graduated inlet valve wide open. With proper valve size, P_3 should not exceed 0.125 lb. per sq. in. at normal rated operation. Exact data should be obtained from the maker of valve used.

P_4 = pressure differential required to overcome pressure loss through the radiator return valve as applied to a vapor system. In thermostatic return valves for vapor systems in normal operation, P_4 (approx.) = 0.125 lb. per sq. in. With thermostatic valves for pressure systems (1 to 2 lb.), P_4 = (approx.) 0.25 lb.

P_x = pressure loss in radiator and return lines; it is negligible if returns are properly graded.

P_5 = effective pressure causing air-vent check valve to open at end of return line, or the effective pressure to operate check valve on return line at boiler, whichever is greater. Air-vent check valves usually are rated on a basis of completely venting the system of air in 40 min. at starting, with a pressure differential of 0.0625 lb. per sq. in. In normal operation perhaps 0.05 lb. or less is required. A horizontal swing check may require approximately 0.10 lb. per sq. in. in normal operation. A swing check in the return main adjacent to the boiler, or on a drip line, requires an effective head of approximately 3 in. to 4 in. of water, $\approx$ 0.103 to 0.138 lb. per sq. in. The cubic content of the radiation and connecting piping is approximately 3 cu. ft. per 100 sq. ft. of installed direct radiation.

The sum of the losses P as above indicated is

$$P = P_1 + P_2 + P_3 + P_4 + P_5 = 0.011 + (0.094\,L/100) + 0.125 + 0.125 + 0.10$$
$$= 0.361 + (0.094\,L/100).$$

Assuming L = 200 ft., P = 0.361 + 0.188 = 0.549 lb. per sq. in.; then $H = P/0.415$ = 1.32 ft. = 15.8 in.

During the starting period (cold radiation and maximum pressure condition) the condensation rate, and consequently, the weight of steam flow and pressure loss in the main, inlet valve, and radiator trap may approximate twice the amounts stated. For the example given, H then approximately equals 30 in. Vapor systems using thermostatic traps place the air trap on the return main 24 to 30 in. above normal water line of boiler to prevent flooding of the dry return main.

PRESSURE LOSS IN STEAM MAINS.—The pressure loss in a pipe full of flowing steam may be approximated by the Unwin or Babcock formula

$$\sqrt{\frac{y\,p\,d^5}{L \times (1 + 3.6/d)}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

where W = weight of steam flow, lb. per min.; L = length of pipe, ft.; d = diam. of pipe, in.; y = density of steam, lb. per cu. ft.; p = loss of pressure, lb. per sq. in. Figs. 16 and 17 are based on this formula. Under normal conditions of operation, 1 sq. ft. of direct radiation will condense 0.25 to 0.30 lb. per hour. The density of steam, y, is 0.04 lb. for 2.3 lb. per sq. in. pressure. The capacities of steam mains in Table 19 were

calculated by the above formula, the pressure loss p being limited to 1 oz. or 0.062 lb. per sq. in. per 100 ft. of straight pipe. To allow for fittings, use the data in Table 16. The steam main should not be smaller than the riser connected to it.

ALLOWABLE PRESSURE DROP IN LOW-PRESSURE, VAPOR AND VACUUM STEAM-HEATING MAINS.—Usual practice has been to design steam-heating mains in buildings on a basis of 1 oz. pressure drop per 100 ft. of run regardless of length. Good practice (1935) limits the total drop in pressure from boiler to the farthest radiator to approximately the values given in Table 17.

The allowable pressure loss per 100 ft. of run is $p_l = \{p_t \div (L/100)\}$, where p_t = total allowable pressure drop, and L = length of run, ft. See Table 18. The length of run includes allowances for elbows, side outlet tees and valves.

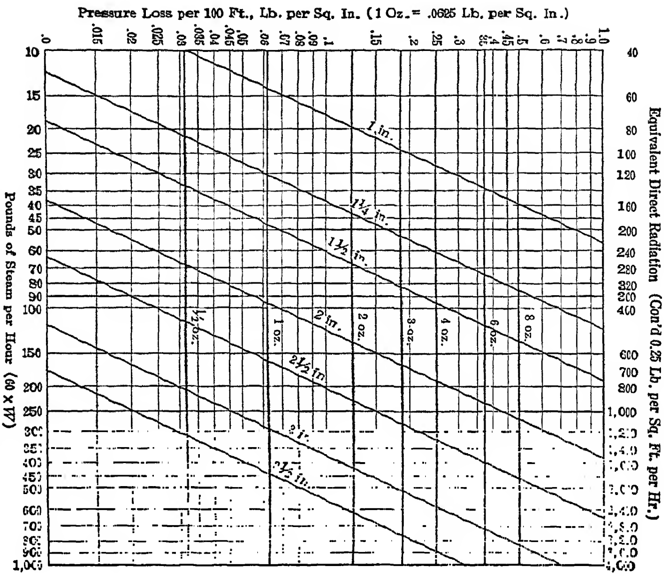

Fig. 16. Pressure Losses in Steam Mains, 40 to 4000 sq. ft. E.D.R.

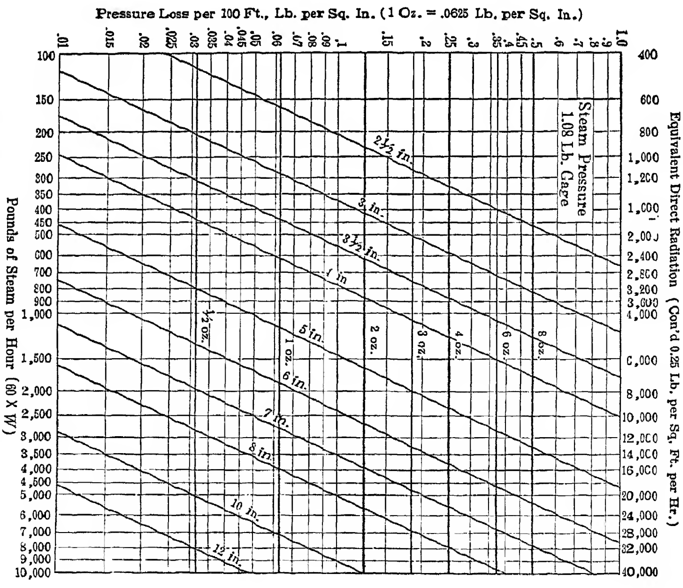

Fig. 17. Pressure Losses in Steam Mains, 400 to 40,000 sq. ft. E.D.R.

EXAMPLE.—In a vapor system the measured distance from the boiler to the farthest radiator, including allowances for ells, is 350 ft. Total allowable drop is 2 oz. Allowable drop per 100 ft., 2 ÷ (350/100) = 0.57 oz. = 0.0356 lb. per sq. in. A horizontal line through this pressure loss per 100 ft. in Figs. 16 and 17, intersects the diagonal pipe size lines. The equivalent direct radiation for a 2-in. pipe is read at the top of the chart as 285 sq. ft.

PIPE SIZES FOR LOW-PRESSURE STEAM, VAPOR AND VACUUM SYSTEMS.—Tables 19 and 20 may be used to determine pipe sizes in buildings for all types of low-pressure steam and vapor systems. They represent present (1935) practice. The rating of the steam mains is based on pressure losses of 1 oz., 2 oz., and 3 oz. per 100 ft. of run. To design the steam main for a fixed total pressure loss, P, for a length, L, determine the pressure loss per 100 ft. of run, equal to $P \div L/100$; locate this pressure loss on the chart; from the intersection of the horizontal pressure loss line with the vertical line corresponding to the weight of steam to be carried by the pipe per hour or the equivalent direct radiation, determine the nearest size of pipe required. It is advisable in any large gravity steam system to check the total pressure loss in the system.

5. EXHAUST STEAM HEATING

The economy of using exhaust steam for heating is apparent, since approximately only 7% of the heat above 32° F. supplied to the average non-condensing engine appears as work in the steam cylinder. Approximately 80% of the exhaust may be utilized for heating, drying, etc. The steam consumption of *non-condensing* automatic high-speed engines and turbines in first class condition with atmospheric exhaust is given in Table 22, when operating at normal load. The arrangement of piping for an exhaust steam heating system is shown in Fig. 18.

Direct-acting feed pumps consume approximately 4% of the total steam generated by boilers; forced draft equipment approximately 2% to 3%. A feedwater heater will condense approximately 17% of the total weight of exhaust steam when heating feedwater from 50° to 210° F., and 6% when heating the water from 150° to 210° F. The latter assumption may be used when all of the exhaust is utilized and the heating returns are piped back to the feedwater heater. Allow 20% loss by radiation in piping and heater in determining the net direct radiation which the power equipment will supply.

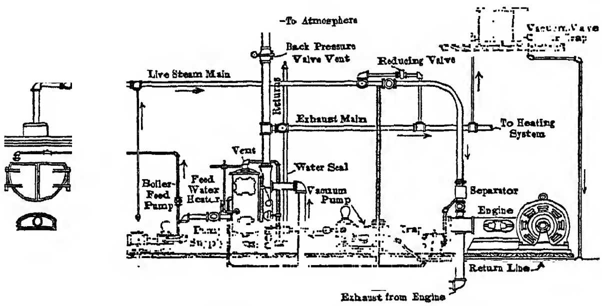

Fig. 18. Piping for Exhaust Steam Heating System

Example.—Required the amount of direct radiation (0.25 lb. condensation per sq. ft. per hour) which a 200-kw. non-condensing engine-driven unit will supply; hand-fired natural-draft boiler plant and 5 lb. back-pressure on the engine.

Solution.—Boilers must evaporate: $200 \times 48 = 9600$ lb. of water per hour for engine; $(9600 \times 0.04)/(1.00 - 0.04) = 400$ lb. per hour for feed pump, or a total of 10,000 lb. per hour. The feedwater heater will condense approximately 6% of this amount or 600 lb., leaving $(10{,}000 - 600) = 9400$ lb. of steam per hour for heating. Deducting 20% from this amount for unavoidable losses, 7520 lb. of steam per hour is available for the radiation. Maximum amount of radiation which plant will supply is: $7520 \div 0.25 = 30{,}000$ sq. ft.

A vacuum system should be used in conjunction with exhaust steam heating in order to obtain good steam circulation with a minimum of back pressure on the engine. For additional information, see L. A. Harding, Power from Process and Space Heating Steam, *Trans.* A. S. H. V. E., 1930.

Table 22.—Approximate Steam Consumption of High-speed Engines and Turbines

Size of Unit		Steam Consumption per Hour	
I.Hp.	kw.	Per I.Hp.	Per kw.
Engines 100 lb. Gage Initial Pressure			
10–25	....	45	....
50	30	33	51
100	65	29	55
300	200	28	43
Turbines 150 lb. Gage Initial Pressure			
...	50	...	56
...	100	...	47
...	200	...	41
...	500	...	36
...	1000	...	34

1 kw. = 1.34 electrical Hp. Allowing for efficiency of engine and generator, 1 kw. at the generator terminals requires approximately 1.55 I.Hp. The above water rates will be increased approximately 3% for 2 lb. back-pressure and 10.5% for 5 lb. back-pressure.

6. DIRECT HOT-WATER HEATING

SYSTEMS IN USE.—Direct hot-water radiator heating systems may be divided into two general classes: 1. All systems operating by gravity only, depending on the difference in density of the water columns in the flow- and return-lines to cause circulation; 2. Systems in which a forced circulation is maintained by a pump placed just in front of the boiler or heater on the return-line. Class 2 systems usually are employed only in large installations, or in district heating service.

GRAVITY HOT-WATER HEATING SYSTEM.—The gravity systems are: *a.* Up-feed systems, using basement mains; *b.* Down-feed systems, using overhead or attic mains. Up-feed systems may have either a 1-pipe or 2-pipe basement main; and the latter type may have either a direct or a reversed return main. (See Fig. 20, for reversed return.) The down-feed systems may have either single or double risers. Either system may operate with an open or a closed expansion tank, as shown in Fig. 19. In general, the down-feed or overhead systems are more positive, permit the use of smaller mains and risers, and provide for the automatic removal of air from radiators and piping. For proper installation of overhead mains and branches, the headroom in the attic must be at least 4 ft. If the overhead mains can be run at the ceiling of the top floor, this restriction does not apply. Mains in attics must be well insulated to prevent freezing.

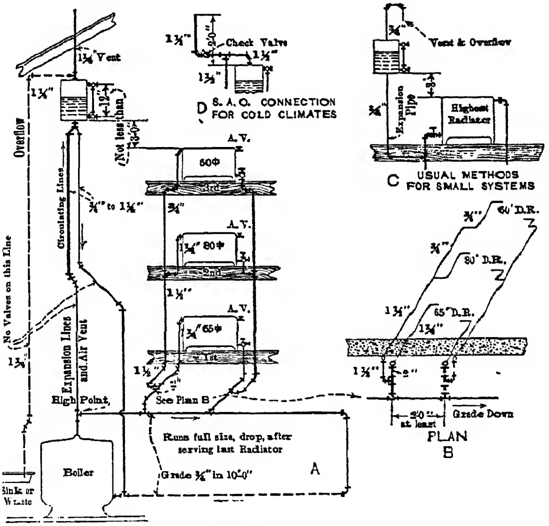

Fig. 19. Expansion Tank Connections

Under-feed systems are used where basement space of little or no value is available, and the radiation is located on two or more floors; or where attic space is so limited that overhead mains and branches cannot be installed. Under-feed systems are liable to be unsatisfactory in buildings less than two stories high, as the motive head, with radiators on the first floor only, is so slight, that faulty or deficient circulation is probable.

The only rational method for designing gravity flow hot-water piping is to balance the friction head against the head available. The head available is calculated from the difference in weight of the water in the flow and return lines. The friction head formulas for pipe of American manufacture, valves and fittings, was determined by Dr. F. E. Giesecke, in 1924. Space limitations do not permit of the reproduction of the method or tables required to use the rational basis for determining pipe sizes.

See The Friction of Water in Pipes and Fittings, F. E. Giesecke, Univ. of Texas *Bull.* No. 1759; The Art of Heating Buildings by Gravity-flow Hot Water Heating Systems, F. E. Giesecke, a thesis for the doctor's degree conferred by the Univ. of Illinois, June, 1924. See also *Heating* and *Vent. Mag.*, for The Friction of Water in Elbows, F. E. Giesecke, C. P. Reming, and J. W. Knudson, Jr., Bureau of Engineering Research, Univ. of Texas *Bull.* 2712, March 22, 1927.

Up-feed, One-pipe Systems.—The up-feed, 1-pipe system consists of a supply main in the basement, sloping down $^3/_4$ in. per 10 ft., from a point close to the ceiling above the boiler to beyond the last supply branch, after which it drops and returns to the boiler, together with flow-risers and radiator branches taken off at the top, and return-branches entering at the side or bottom of the main. The main is of the same diameter throughout the circuit. In the case of branches near the boiler, or branches supplying only upper-floor radiators, flow connections may be made to the supply main at 45° instead of at the

top. Radiators on upper floors will assist the circulation in radiators on the first floor, if the upper-floor risers are taken from the side of the branches supplying the first floor radiators. See Fig. 19*A* and *B*. First-floor branches usually are all full size.

Radiators should be connected at the top to the supply by a union-elbow, and at the bottom to the return, by a quick-opening hot-water radiator valve. Only one valve is required to control a radiator. The area of the last radiators on a main should be increased from 5% to 10%, as the temperature of the water is gradually decreased in passing through the preceding radiators; it is advisable to increase the size of branch and riser connections at the end of a main by one pipe size.

Tables 23 and 24 (J. J. Hogan) give data for proportioning piping. In using the tables, all mains must be measured back to the boiler. For mains over 100 ft. long, reduce the capacity in the ratio of $\sqrt{100 \div L}$. Risers to a given floor must be made large enough to supply not only the radiators on that floor, but also on all the floors above it.

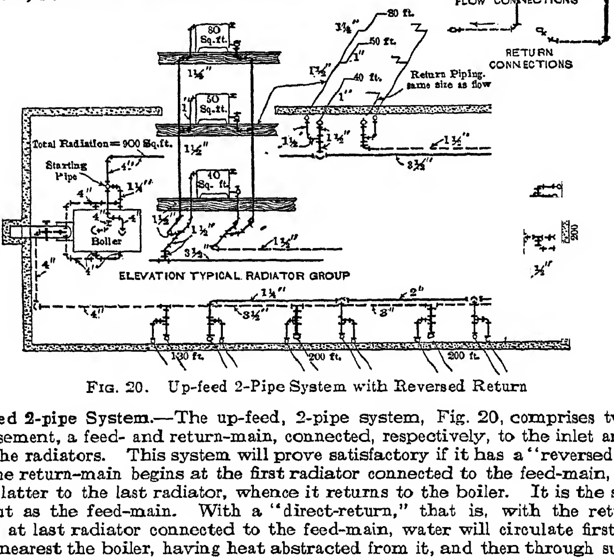

Fig. 20. Up-feed 2-Pipe System with Reversed Return

Up-feed 2-pipe System.—The up-feed, 2-pipe system, Fig. 20, comprises two mains in the basement, a feed- and return-main, connected, respectively, to the inlet and return risers of the radiators. This system will prove satisfactory if it has a "reversed return," that is, the return-main begins at the first radiator connected to the feed-main, and parallels the latter to the last radiator, whence it returns to the boiler. It is the same size throughout as the feed-main. With a "direct-return," that is, with the return-main beginning at last radiator connected to the feed-main, water will circulate first through radiators nearest the boiler, having heat abstracted from it, and then through succeeding

Table 24.—Sizes of Branches and Risers for Hot-water, Up-feed, Open Tank Heating Systems with Basement Mains

Pipe Size, in.	Direct Radiation, sq. ft.				Pipe Size, in.	Direct Radiation, sq. ft.			
	1st Floor	2d Floor	3d Floor	4th Floor		1st Floor	2d Floor	3d Floor	4th Floor
3/4	30	45	55	70	2 1/2	400	490	525	550
1	60	75	85	95	3	620	650	690	730
1 1/4	110	120	135	150	3 1/2	820	870	920	970
1 1/2	180	195	210	230	4	1050	1120	1185	1250
2	290	320	350	370	4 1/2	1325	1400	1485	1560

radiators in turn. The last radiators thus will be slow in warming up and the system may prove unsatisfactory. With the reversed return each radiator offers the same resistance to the flow of water and all become warm at the same time. With the reversed return, the flow is in the same direction as in the flow main. The return increases progressively in size while the flow main decreases. Flow mains should slope up from, and return mains down to, the boiler 3/4 in. per 10 ft. Pipe sizes in Tables 23 and 24 will apply to 2-pipe systems, and the size of main should be reduced or increased as rapidly as the change in radiation supply will permit. A "starting pipe" of from 1 1/4 to 2 1/2 in. diam. is, in government work, installed between the flow main and the return at the boiler in under-feed systems, to assist establishing initial circulation between flow and return headers.

EQUALIZATION OF PIPES.—The relative capacities of different sizes of pipe for the same friction loss per 1000 ft. of run are as follows:

Pipe Size, in.	1/2	3/4	1	1 1/4	1 1/2	2	2 1/2	3	3 1/2	4	5	6	7	8
Relative Capacity.	2	5	10	20	30	60	110	175	260	380	650	1050	1600	2250

The equivalent numbers are proportional to the 5/2 powers of the diameters and the quantity of water W flowing equals $Kd^{5/2}$, where K = a constant and d = pipe diameter, in.

Example.—Find a pipe of equivalent capacity to a 1 1/4-, 1 1/2- and 2-in. pipe.

Solution.—The equivalent capacity numbers are 1 1/4 = 20; 1 1/2 = 30; 2-in. = 60. 20 + 30 + 60 = 110, which is the number equivalent to a 2 1/2-in. pipe.

DETAILS OF PIPING SYSTEMS FOR GRAVITY HOT-WATER HEATING.—**Mains and Branches** must be uniformly graded with provision for expansion and contraction by means of flexible double elbow joints or otherwise. Air traps and pockets must be avoided and automatic air outlets provided at the top of all points where such pockets may occur. Eccentric fittings must be used wherever the mains are reduced in size to keep the tops of the pipe in the same plane and avoid air pockets. The piping must be so arranged that the system will completely drain of water when the blow-off cock at the boiler is open. Branch mains from a header at the boiler must all rise to the same elevation; the tops of all branches must lie in the same plane as they start away from the boiler.

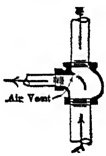

Fig. 21. O. S. Fitting

Long Sweep Fittings must be used on all main piping and branches. Risers supplying radiators on two or more floors should be connected through special tees, known as O. S. fittings, to the branches. See Fig. 21. The deflector to divert the current of flow into the outlet of the tee will favor the radiators on the intermediate or lower floors. The maximum length of branch employed above the floor for connecting either steam or water radiators is 9 in. The branch must run in the floor or under the ceiling if longer than 9 in. Risers to upper floors should not be over 2 in. from finished walls.

Radiators should be connected to the flow at the top and to the return at the bottom. A single valve on the return thus will control the radiator. With both connections made at the bottom, two valves are necessary.

Air Removal.—Small air cocks or automatic air relief valves should be attached to the high point of each radiator on all up-feed systems and opened periodically to relieve air accumulations. Automatic air valves heretofore have been liable to derangement and to passing water as well as air. Unless air accumulations are removed, faulty circulation and failure to heat the radiator will result.

EXPANSION TANKS.—A suitable tank to take care of the expansion and contraction of water in the system must be provided on all low-pressure hot-water heating systems. This tank should be opened and connected to the nearest return riser or to a separate expansion line at an elevation at least 3 ft. above the highest radiator. The capacity of the tank depends on the amount of water in the system and on its temperature range. Water heated from 32° to 212° F. increases in volume approximately 4.33%. Hence, for every 23 gal. of water in the system at 32° F., a tank capacity of 1 gal. must be provided, when water is heated to 212° F. Cast-iron radiators have an internal volume of about 1 1/2 pint per sq. ft.; steel radiators and 1-in. pipe contain about 1 pint per sq. ft. of surface. It generally is assumed that the internal volume of radiators is 50% of the volume of the entire system and the capacity C of the tanks on this basis, therefore, would be, $C = (R \times 2) \div 0.125$, where C = capacity, gal. and R = sq. ft. of radiation in radiators.

Table 25 shows the sizes and capacities of commercial expansion tanks. These are slightly smaller in the larger sizes than given by the above formula, but will prove satisfactory with all systems employing up to 6000 sq. ft. of radiation. For larger systems, the size of the tank should be determined separately.

Expansion tanks on 1-pipe systems preferably are connected through an expansion line from the high point of the main, just above the boiler connection, to a return bend just below the tank, with a return circulating line connected through the side of the bend

with the return main at the boiler. See Fig. 19. A 1 1/4-in. vent from the top of the tank should lead through the roof with a 1 1/4-in. overflow connected in the vent line just above the tank. The vent should discharge into an open sink or a drain near the boiler. In small installations, the expansion line may be connected to a radiator return riser.

CLOSED TANK SYSTEMS.—In open-tank systems, the highest temperature practically possible is 212° F. At this temperature, the water, rising into the open tank, will boil and empty the system of water. The remedy is to raise the pressure on the system, which, by increasing the hydrostatic head, will raise the boiling point. The hydrostatic head may be increased by interposing a column of mercury in the expansion line. A device for this purpose is the Honeywell "heat generator," Fig. 22. Water entering the generator forces the mercury up in tube *A*, until a head of 20 in. or 10 lb. is established, and the entrance to the tube is uncovered. Water and air then may pass to the expansion tank. Any excess of mercury over that required to fill tube *A*, returns by tube *B* to the reservoir. When the system cools, water flows back in tube *A* as the mercury column drops, the small head of mercury at the outlet of the tube being overcome by the head of water in the expansion tank. The 10-lb. increase in static pressure makes possible a temperature of 240° F. in the system, and allows the use of smaller radiators. A greater difference in temperature will exist between flow and return risers than in open tank systems, giving a greater motive head, and permitting smaller mains and risers to be used. As the system will contain less water, it will be more sensitive both in heating up and in cooling off. The "generator" may be located any place in the expansion line, excepting close to the expansion tank. Other devices for the same purpose as described for the generator are available.

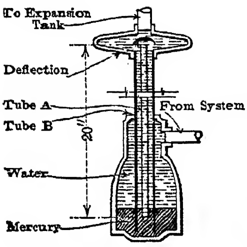

FIG. 22. Heat Generator

Table 25.—Sizes and Capacities of Expansion Tanks

Size, No.	Size, in.	Capacity, gal.	Sq. Ft. of Radiation	Size, No.	Size, in.	Capacity, gal.	Sq. Ft. of Radiation

4	16×30	26	950	9	22×60	100	6000

7. FURNACE HEATING

The term applied to warming or heating a building by a hot-air furnace is *furnace heating*. Furnaces for soft coal usually are designed with a secondary air supply or over-draft, to admit heated air at the surface of the fire to consume the volatile gases liberated immediately after firing. The over-draft should be so controlled that it may be checked or closed when the fuel has coked. Soft coal also may be burned efficiently in the under-feed type of furnace.

The furnace should be centrally located in the basement with reference to the rooms to be heated, and preferably toward the side or sides exposed to prevailing winds in winter. This arrangement favors the more exposed rooms by shortening the leaders to them and reduces the length of cold-air duct which should run from the exposed side of the building. In operation, some or all of the air circulated is cold air drawn from outdoors through the cold-air duct, passed through the space between the heater and its jacket, and warmed by contact with the surface of the combustion chamber and the radiator just above it.

LEADERS AND STACKS.—Leaders are the nearly horizontal round pipes in the basement, connecting the furnace to the vertical rectangular pipes or stacks leading to the register grilles. Leaders should pitch upward toward the base of the stack at least 1 in. per ft. For best results, they should not be over 12 to 15 ft. long. Stacks should run between the studding of interior walls or partitions. If placed in outside walls, the cooling effect reduces their efficiency, both in temperature of air and velocity of flow. Leaders and stacks usually are made of bright IX tin, although for leaders larger than 12 in., galvanized steel, No. 26 U. S. Std. gage, is used. Leaders, boots and stacks, and also the furnace, should be covered with first-class insulation. As stacks are usually in a 4-in. studding-space, with a net depth of about 3 3/4 in., they should be kept as deep as possible. Steel lath or expanded metal should be used in front of all such stacks which usually have but one layer of asbestos-paper covering. The double-wall stack, with space between

inside and outside pipes, and without asbestos covering, is more effective. Attention is called to the fact that where large second-floor rooms are heated by one register, 6-in. stud partitions usually are required on the first floor.

Design of Furnace Heating Systems

HEAT LOSS AND AIR REQUIRED.—The size of the furnace, and of the connecting leaders, stacks, etc., depends on: 1. The actual heat loss from each room in the building, including wall and glass transmission losses, as well as loss due to infiltration. 2. The amount of air to be circulated per hour, which, in turn, is based on this heat loss. A building is heated by hot-air by introducing the air into the rooms at a temperature above that maintained in the rooms at the breathing line (approximately 70° F.). The air, in cooling, gives up 0.24 B.t.u. per lb. for each degree drop in temperature, thus supplying the heat necessary to offset the heat transmission of the walls, etc. The maximum temperature of the air leaving the furnace cap is approximately 190° F.; it leaves the registers at 175°. These figures are maximum values, not to be exceeded. If all the air is drawn from outdoors, and the outdoor temperature is 0° F., then the air is heated, from 0 to 190° F., and cooled on entering the room from 175° to 70° F., or 105° F. That is, 0.24×105 or 25.2 B.t.u. apparently is thrown away for every pound of air circulated. If all the air for ventilation must be brought from outdoors, this is the price that must be paid for ventilation. It would be the same for equally good ventilation, irrespective of the system of heating. Usually, however, much, if not all, of the air may be recirculated. In this event, for equal ventilation, the furnace system requires no greater expenditure of fuel than a direct steam or hot-water system, and is just as economical when correctly designed, installed and operated. The head, producing the flow, is due to the difference in weight between the ascending column of heated air and the weight of an imaginary similar column of the colder intake air. The system generally is proportioned for recirculating all the air during extreme cold weather.

WEIGHT OF AIR TO BE CIRCULATED PER HOUR.—Let W = air to be circulated per hour, lb.; t = inside temperature to be maintained, deg. F.; T = temperature of air leaving registers deg. F. (assumed 15° lower than temperature leaving furnace cap); H = B.t.u. to be supplied to room per hr., as determined by heat loss calculations (see page 11–03). $0.24 \times (T - t)$ = B.t.u. given up per lb. of air circulated. Then,

$$W = H \div \{0.24(T - t)\} \qquad [4]$$

The maximum value for T is approximately 175° F. and t = 70° F. Then, $W = H/25.2$, and $Q = W/d = W/0.062 = H/1.6$, where Q = warm air entering the room, cu. ft. per hr., and d = density of entering air = 0.062 at 175° F.

HEAT REQUIRED FROM FURNACE, BASED ON RECIRCULATION.—The heat required per hour from the furnace depends on the temperature of the entering air. It will be a maximum if all air circulated is taken from outdoors, and a minimum if all the air is recirculated. Let h = B.t.u. required from heater per hr.; T_e = temperature of air entering heater = 65° F.; T_h = temperature of air leaving heater = 190°. Then

$$h = 0.24\,(T_h - T_e)\,W \qquad [5]$$

Substituting the values given above for T_h and T_e, $h = 1.2\,H$.

SIZE OF FURNACE.—The capacity of the furnace for heating air depends primarily on the amount of coal that may be burned per hour or (rate of combustion) × (grate area). With an assumed rate of combustion, capacity depends on grate area. Grate area, therefore, is the basis for rating and comparison of hot-air furnaces. The average rate of combustion in furnace heating ranges from 3 to 4 lb. per sq. ft. of grate per hr. In zero weather this rate may be as high as 6 lb., and readily is obtainable with the ordinary height of residence chimney, that is, at least 35 ft. A properly-designed furnace will have a combined furnace-and-grate efficiency of 55 to 60%.

FURNACE RATING BASED ON EFFICIENCY AND RATE OF COMBUSTION.—The B.t.u. per hr. that a furnace can impart to the air (not to the room) also may be estimated from the grate area by assuming that the average coal used has a heat value of 12,000 B.t.u. per lb. A combined furnace-and-grate efficiency of 55% and a maximum combustion rate of 6 lb. per sq. ft. of grate per hr. for coldest weather conditions also usually are assumed.

GRATE SURFACE REQUIRED BASED ON RECIRCULATION.—The area of the grate is readily calculated when the heat to be supplied per hr. has been determined. Let H = B.t.u. to be supplied per hr.; h = B.t.u. required from furnace per hr. for heating the air = $1.2\,H$; C = B.t.u. of coal per lb.; E = combined furnace-and-grate efficiency; R = rate of combustion, lb. of coal per sq. ft. of grate per hr.; G = grate area, sq. ft.

Table 26.—Air-heating Capacity of Warm-air Furnaces

Fire-pot		Casing *	Total Cross-sectional Area of Heat Pipes, sq. in.	Number and Size of Heat Pipes that May be Supplied
Diameter, in.	Area, sq. ft.	Diameter, in.

30	4.9	52–60	730	3–12″, 3–10″ and 3–8″ 5–10″, 5– 9″ and 1–8″

* The casing diameter should be such that the minimum cross-sectional area between casing and radiator will be at least 20% greater than the total cross-sectional area of all the heat-pipes.

Table 27.—Capacities and Dimensions of Warm-air Piping and Registers

Diameter of Round Cellar or Riser-pipe, in.*	Proper Size of Rectangular Riser-pipe, in.*	Area of Riser-pipe, sq. in.	Required Area of Register-face, sq. in.*	Diameter of Round Cellar or Riser-pipe, in.*	Proper Size of Rectangular Riser-pipe, in.*	Area of Riser-pipe, sq. in.	Required Area of Register-face, sq. in.*
6	3 × 9 1/2	28	52	13	6×22	132	242
6 1/2	3 1/2× 9 1/2	33	62	13 1/2	8×18	143	254
7	3 1/2×11	38	72	14	8×19	154	276
7 1/2	3 1/2×12 1/2	44	84	14 1/2	8×20 1/2	165	298
8	3 1/2×14	50	96	15	8×22	176	320
8 1/2	4 ×14	57	108	16	8×25	201	358
9	4 ×16	64	120	17	10×22 1/2	227	410
9 1/2	4 ×18	71	134	18	10×25 1/2	254	450
10	4 ×20	78	142	19	12×23 1/2	283	508
10 1/2	6 ×14 1/2	86	158	20	12×26	314	554
11	6 ×16	95	176	21	12×28 1/2	346	618
11 1/2	6 ×17 1/2	104	194	22	14×27	380	686
12	6 ×19	113	204	23	14×29 1/2	415	707
12 1/2	6 ×20 1/2	122	222	24	14×32	452	770

* When the required size of pipe falls on the odd half-inch (as 7 1/2, 8 1/2, etc.), the size may be increased to the even inch (as 8 for 7 1/2, 9 for 8 1/2, etc.), for the first-floor rooms and bath-rooms; provided that the pipes for upper-floor rooms, other than bath-rooms, be decreased by 1/2 in. when the required sizes fall on the odd half-inch. It is better, however, to use pipes of the sizes given above, with proper allowances for length of pipe, extra bends, etc., beyond straight runs 12 ft. long.

Then $h = G \times C \times E \times R \quad 1.2$; $H = G \times 12{,}000 \times 0.55 \times 5.5 = 36{,}300\,G$; $G = (1.2 \times H) \div 36{,}300$.

The usual assumptions with anthracite are: $C =$ 12,000 B.t.u. per lb., $R = 4$ lb., ordinary rate, and 5.5. lb., coldest weather conditions. $E = 0.55$. Then $G = h \div 36{,}300 = 1.2\,H \div 36{,}300 = H \div 30{,}250$.

SIZE OF LEADERS AND STACKS.—The area of the air pipes (leaders and stacks) required for a room depends on the quantity of air to be introduced per minute and the velocity with which the air will flow with natural circulation. The theoretical velocity of air in a duct depends on the difference in weight of the column of heated air and of an imaginary column of equal height of air at the temperature of air entering the heater.

$Q/60$ = warm air to be introduced per min., cu. ft.; V = attainable velocity of air, ft. per min.; H = heat loss, B.t.u.; A = area of pipe, sq. in. Then, $Q/60 = AV/144$, and substituting value of $Q = H/1.6$; $A = 1.5\,H/V$ sq. ft.

The theoretical velocity of air in a duct is expressed by the formula

$$V = \qquad \times$$

where V = velocity in the duct, ft. per sec.; t_1 = absolute temperature of air in the vent duct; t_2 = absolute temperature of external air; h = vertical height of duct, ft.; $2g = 64.4$. Actual velocities will be considerably lower due to loss by friction, which will vary with the form and cross-sectional area of the duct and its connections, and the degree of smoothness of its interior surface. The following approximate velocities are obtained in leaders and

stacks for the several floors given: First floor, 173 ft. per min.; second floor, 240 ft. per min.; third floor, 322 ft. per min. Then, substituting in the equation in the preceding paragraph, we have: $A_1 = H/115$ (first-floor pipes, leaders, etc.); $A_2 = H/160$ (second-floor pipes, etc.); $A_3 = H/215$ (third-floor pipes, etc.).

Fig. 23 shows graphically the results of tests made under the direction of Prof. A. C. Willard, and described in *Bull.* No. 112, Engg. Experiment Station, Univ. of Illinois, 1919. From the test data it was found that the temperature at the registers on the second floor is approximately 10° lower than on the first floor, so that if 175° is used for the register temperature on the first and third floors, 165° should be used for second-floor registers.

Actual leader and stack sizes are based on the above areas, using the nearest $^1/_2$ in. for leader diameter (Table 27), and keeping the stacks of such proportions that the cross-sectional dimensions are never in a greater ratio than 3 to 1. For example, a stack 4 × 20 in. is seldom effective over its full area, it being too narrow and the large rubbing surface causing excessive friction. The actual velocities obtained, however, will depend on the head causing the flow, and on the friction-head, and seldom will exceed 50% of the theoretical velocity. Table 27 gives sizes of round pipe for leaders and of wall pipe for stacks, and free areas of registers to connect with them. Leaders over 12 ft. long should be increased 1 in. diameter for each 5 ft. over 12 ft.

REGISTERS.—The free area through the ordinary register grille is approximately 55% of the gross area. Hence, the register must have double the gross area of the pipe connected to it to avoid contraction of the air passage and reduced capacity. Commercial register sizes are based on actual inside dimensions of grille opening.

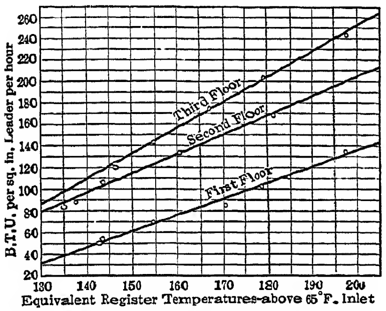

FIG. 23. Effect of Register Temperature on Leader Capacity

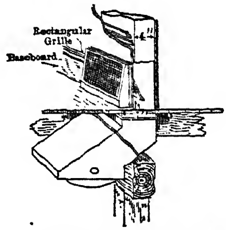

FIG. 24. Baseboard Register

Warm-air registers may be placed in the floor, but preferably in inside partitions for first-floor rooms. The base-board register (Fig. 24) usually gives the required capacity without resort to floor registers. Base-board registers can be connected to a flue 3 to 4 $^1/_2$ in. deeper than the studding by making it project 2 in. into the room at the floor line, and utilizing the 1 in. space occupied by the lath and plaster, a total increase in depth of flue of about 3 in. For upper-floor rooms, registers should be placed in inside partition walls, using convex registers for shallow stacks. As a general rule, warm-air registers should be so placed as to shorten leader and stack connections as much as possible.

8. FAN OR BLAST HEATING SYSTEMS

The mechanical indirect system of heating known as the fan system or blast system, particularly adapted to the warming and ventilating of large structures, consists of 3 units: 1. A heater of pipes, tubes, or cast-iron sections through which steam, hot water or hot gas is passed; 2. A fan or blower to circulate air over the heater surfaces, the air being the medium of heat transfer; 3. A system of ducts or pipes to convey the heated air from the heater. If the heater is located between the fan and main duct the system is termed *blow-through*. If the fan is installed between the heater and the duct, it is termed *draw-through*. (See Fig. 27.) The draw-through system is used for shops where compactness is desirable. The blow-through apparatus is used principally for hot and cold systems installed in schools and public buildings.

If ventilation is not required, or is relatively unimportant, the air simply may be recirculated, sufficient fresh air for ventilation being obtained by infiltration. The heat to be supplied to the heater in this case is the same as in a direct-radiation installation.

When ventilation is required, a cold-air intake is provided and sufficient fresh air is drawn into the system from outdoors to meet the ventilation requirement. The remainder of the air necessary for heating is recirculated. This is effected by an arrangement of ducts and dampers on the suction side of the fan. If the fresh air is to be washed or conditioned, the washer or humidifier and tempering coil is placed between the inlet for the recirculated air and the fresh-air intake. In factory work, the unit heater has largely supplanted the fan or blast system when heating is the only requirement. See Unit Heaters, p. 11–44.

ADVANTAGES OF THE FAN SYSTEM.—*The advantages of the fan system over direct radiation*, briefly, are: 1. It affords positive ventilation, entirely independent of changing climatic conditions; 2. When a standard humidity of air is to be maintained, as is desirable in heating and ventilating, and essential to the manufacture of some materials, the air-conditioning apparatus may be made integral with the system; 3. Less radiating surface is required for equal heating duty, with a consequent reduction in the number of steam-tight joints to keep in repair. 4. Air leakage being mostly outward, the building will be freer from drafts and more uniformly heated. If air is recirculated and no outside air is taken into the heating system from outside, this statement does not apply. The pressure of air in the building, even if all air enters the system from outside, is comparatively feeble, and some air will infilter around windows and doors on the windward side of the building, despite the often-made statement that the outward leakage prevents all infiltration of cold air. 5. The fan system is more easily regulated than direct radiation, and readily responds to changing outside temperature. 6. Air entering for ventilation, may be cooled in summer by circulating cold water or brine, previously cooled by mechanical refrigeration, through the heater. 7. Running the fan will, in itself, relieve oppressiveness in sultry weather, and if cold water is circulated through the coils, the difference is noticeable.

HEATER CALCULATIONS.—Let H = heat loss; H_1 = heat to be supplied by heater; H_2 = heat to be supplied by tempering coil; H_3 = heat to be supplied to humidifier, all in B.t.u. per hr. Let M_o = outside air introduced; M_r = recirculated air; $M = M_o + M_r$ = total air circulated, all in lb. per hr. Let T_o = temp. of outside air; T_1 = temp. of air entering heater; t = temp. to be maintained in room; t_1 = temp. of air leaving heater, t_2 = temp. loss in ducts; t_3 = temp. of air leaving ducts; t_4 = temp. of air leaving tempering coil; t_m = temp. of air entering ducts, all in deg. F.; n = number of occupants of room; Q = ventilation requirements, cu. ft. of air per hr. per occupant = 900 to 1800 (usual school requirements). Specific heat of air at constant pressure = 0.24. Weight of air per cu. ft. at 70° F. = 0.075 lb.

Amount of Air to be Circulated.

For heating, $M = H \div 0.24\,(t_3 - t)$ . . . . [6]

For ventilation, $M_o = 0.075 \times n \times Q$ . . . . [7]

Heat to be Supplied by Heater. $H_1 = 0.24\,(t_1 - T_1)\,M$ . . . . . . [8]

Temperature of Air Leaving Ducts. $t_3 = (H/0.24\,M) + t$ . . . . . . [9]

Temperature of Air Entering Ducts. $t_m = t_3 + t_2$.

Temperature of Air Entering Heater. *a.* When all air circulated is outside air, $T_1 = T_o$; *b.* When all air is recirculated, $T_1 = t$; *c.* When part of air is recirculated,

$$T_1 = \{M_o\,(T_o + 460) + M_r\,(t + 460)\} \div (M_o + M_r) \quad . . . . [10]$$

Temperature of air leaving the ducts, $t_3 = t_1 - t_2$. It depends on temperature T_1 of air entering heater, its velocity through clear area of heater, area of heating surface, steam temperature, and temperature loss in ducts. The usual range of t_3 is from 125° to 150° F. Tables 31 and 32 give values of t_1 for specific conditions. Values of t_2 depend on the location of the ducts. Heat loss from ducts in inside walls helps to heat the building, and t_3 may be taken as equal to t_1; that is, $t_2 = 0$, and $t_m = t_1$. Heat losses from ducts in outside walls or underground must be compensated by increasing t_1 by an amount equal to t_2.

A constant value of t cannot be maintained in several different rooms with different heat losses by controlling the temperature t_1 of air leaving the heater. Temperature t_3 usually will be different for each room. It is controlled by means of the double-plenum chamber system described below.

Air that is recirculated and outside air are passed through a tempering coil that raises it to a temperature t_4, usually from 64 to 70° F. Part of the tempered air passes through the heater. The remainder is by-passed and is mixed with the hot air leaving the heater at temperature t_1. Calculations for the tempering coil are the same as for the heater. The required proportions of heated and tempered air are found by the *method of mixtures* as follows: Let x and $(1 - x)$ = respectively the proportions by weight of heated and tempered air. Then

$$x\,(t_1 + 460) + (1 - x)\,(t_4 + 460) = t_m + 460 \quad . . . . . [11]$$

120° and 64° I

EXAMPLES.—Determine quantity of air to be circulated, and the heat to be supplied to it to offset heat loss from a room maintained at $t = 70°$ F., and whose heat loss is 120,000 B.t.u. per hr. Room contains 60 persons. Outside temperature T_o assumed as 0° F.

Solutions.—Several arrangements are possible. I. All circulated air drawn froı
Assume $t_2 = 5$. $t_3 = 120$. $t_1 = t_2 + t_3 = 125$.

$$M = M_o = H \div 0.24\ (t_3 - t) = 120{,}000/0.24\ (120 - 70) = 10{,}000 \text{ lb.}$$

$$H_1 = 0.24\ (t_1 - T_1) \times M = 0.24\ (125 - 0) \times 10{,}000 = 300{,}000 \text{ B.t.u.}$$

II. All air to be recirculated. Here $T_1 = t = 70$.

$$M = M_r = H \div 0.24\ (t_3 - t) = 120{,}000/0.24\ (120 - 70) = 10{,}000 \text{ lb.}$$

$$H_1 = 0.24\ (t_1 - T_1) \times M = 0.24\ (125 - 70) \times 10{,}000 = 132{,}000 \text{ B.t.u.}$$

III. Part of air to be recirculated, and 1800 cu. ft. of outside air per hr. per person to be su for ventilation.

$$M_o = n \times Q \times 0.075 = 60 \times 1800 \times 0.075 = 8100 \text{ lb.}$$

$$M = M_o + M_r = H \div 0.24\ (t_3 - t) = 120{,}000/0.24\ (120 - 70) = 10{,}000 \text{ lb.}$$

$$M_r = M - M_o = 10{,}000 - 8100 = 1900 \text{ lb.}$$

$$T_1 = [\{M_o\ (T_o + 460) + M_r\ (t + 460)\} \div (M_o + M_r)] - 460$$

$$= [\{(8100 \times 460) + 1900\ (70 + 460)\} \div 10{,}000] - 460 = 17.3° \text{ F.}$$

T_1 is the temperature of the mixture of outside and recirculated air entering the heater.

$$H_1 = 0.24\ (t_1 - T_1) M = 0.24\ (125 - 17.3) \times 10{,}000 = 258{,}480 \text{ B.t.u.}$$

IV. Room heated by direct radiation. Air for ventilation supplied by a fan system. This combination is called a split system. Air conditioned to maintain a constant relative humidity of 35% in room. Outside air is passed through a tempering coil to bring its temperature to 35° F. before it enters washer. With $t = 70°$ F., a relative humidity of 35% corresponds to a dew point temperature of 41° F. Air passing through spray chamber of air washer is saturated and leaves at a temperature of $T_1 = 41°$ F., at which temperature it enters the heater. Assume temperature t_3 of air entering the room to be 80° F. Then

$$M = M_o = n \times Q \times 0.075 = 60 \times 1800 \times 0.075 = 8100 \text{ lb.}$$

For heater, $H_1 = 0.24\ (t_3 - T_1) M = 0.24\ (80 - 41) \times 8100 = 75{,}816$ B.t.u.
For tempering coil, $H_2 = 0.24\ (t_4 - t_0) M = 0.24\ (35 - 0) \times 8100 = 68{,}040$ B.t.u.
For washer $H_3 = 0.73\ M = 59{,}130$ B.t.u.
It is assumed here that a washer with a water heater is used that will fully saturate the air. The heat to be supplied to the washer is the difference between the heat content of dry air entering the washer at 35° F. and of saturated air leaving it at 41° F., or 7.3 B.t.u. per lb.

$$\text{Total heat} = H_1 + H_2 + H_3 = 202{,}986 \text{ B.t.u.}$$

V. Constant temperature $t = 70°$ F. to be maintained in each of several rooms which have different heat losses, as given in Table 28. Ventilation to be provided at rate of 1800 cu. ft. per hr. per occupant. Determine temperature t_3 of entering air. Using room A-2 as an example,

$$M_o = Q \times n \times 0.075 = 1800 \times 53 \times 0.075 = 7125 \text{ lb.}$$

$$t_3 = (H/0.24\ M_o) + t = 21{,}000/(0.24 \times 7125) + 70 = 82.2° \text{ F.}$$

AIR SUPPLIED FOR VENTILATING PURPOSES ONLY.—A combination of direct radiation to offset the heat-loss H, and a fan system, to supply fresh air needed for ventilation, is considered best practice for schools and public buildings. The heater capacity usually is made sufficient to warm the air for ventilation to about 80° F.

HOT-AND-COLD OR DOUBLE-PLENUM-CHAMBER SYSTEMS.—In so-called Hot-and-cold or Double-plenum-chamber Systems all air drawn from outdoors first passes through a tempering-coil, designed to heat air to approximately 70° F. Part of the tempered air then passes through a heater and is raised to from 125° to 150° F. If varying proportions of the hot and tempered air are correctly mixed the resulting temperature T is controlled without varying the quantity of air discharged, which must remain constant on account of the ventilation requirement.

The two methods of distribution used are shown in Figs. 25 and 26. In the single-duct system, Fig. 25, the hot and tempered air meet at the entrance to the ducts, at the

Table 28.—Data for Example

Room Number	Number of Occupants, n	Ventilation: Cubic Feet per Hour at 70° F. $1800 \times n$	Ventilation: Weight per Hour, lb., M_o	Heat Loss, H	Temperature, T, of Air Leaving Ducts, by Formula
A-1	50	90,000	6750	32,000	89.5
A-2	53	95,400	7125	21,000	82.2
Hall	..	30,000	2250	4,000	77.4

end of the plenum-chamber. The temperature of the mixture is controlled by mixing-dampers, which may be operated by hand or automatic thermostatic control. The plenum-chamber is divided, and each duct serving a room has an independent set of mixing-dampers. In the double-duct system, Fig. 26, two ducts run from the plenum-chamber to the base of each vertical flue, carrying hot air and tempered air, respectively, which are mixed at the base of the flue. The mixing-dampers may be controlled by hand or by automatic thermostatic control through a compressed-air-operated damper.

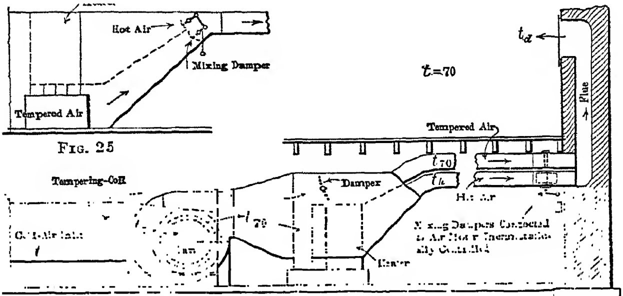

Fig. 25

Fig. 26

Figs. 25 and 26. Hot-blast Plenum Chambers

Blast Heaters

IRON PIPE-COIL HEATERS.—The standard pipe-coil heater for hot-blast work comprises 4 vertical rows of 1-in. pipe, spaced $2\,^1/_8$ to $2\,^3/_4$ in. centers, screwed into a cast-iron base. Nipples and ells cross-connect at the top the pipes in each row. The heater comprises a number of sections, each consisting of a base and its pipes, enclosed in a sheet-steel jacket, usually No. 22 gage. This type of heater has been supplanted largely by the cast-iron sectional and copper tube types. Fig. 27 shows types of heater jackets.

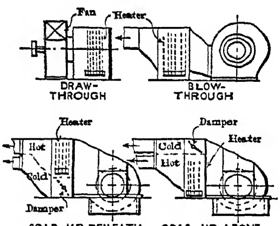

Fig. 27. Types of Heater Jackets

CAST-IRON INDIRECT HEATERS.—Special cast-iron sections for indirect heaters, such as the Vento, made by American Radiator Co., are used extensively in this class of work. A stack of several sections has fewer joints than a pipe-coil section of equal heating-surface. There is practically no deterioration of the cast-iron sectional type of heater, except for the right- and left-hand hexagonal nipples connecting the units of a stack. The four standard lengths of Vento heater-sections are indicated in Table 29, which includes other data needed in design. The Vento heater is designed for pressures not over 10 lb. per sq. in.

BRASS OR COPPER TUBE EXTENDED SURFACE HEATERS.—Some commercial heaters are built of copper tubing on which is wound a spiral copper ribbon, forming the extended surface. These are known under trade names as Aerofin, Arco Blast, Superfin, etc. This construction, due to its compactness and light weight, has largely supplanted the cast-iron sectional heater. See manufacturers' catalogs for physical data, temperature rise of air passing over various number of rows of pipe and resulting condensation for various steam pressures. These heaters also may be obtained for high-pressure work up to 350 lb. per sq. in., gage.

Table 29.—Vento Hot-blast Heater Data

Length of Section, in.	Heating-surface, Regular Units, sq. ft.	Inches on Centers		
		4 5/8	5	5 3/8
		Free Area of Unit Section, Square Feet		
40	10.75	0.52	0.62	0.72
50	13.50	0.65	0.77	0.91
60	16.00	0.78	0.92	1.08
72	19.00	0.94	1.10	1.30

TEMPERATURE RISE.—The temperature rise of air passing through blast heaters of various types has been well established by experiment. Manufacturers have published the results in the form of bulletins and catalogs. See Tables 30 and 31.

Example.—Determine size of Vento hot-blast heater necessary to heat a public building, whose calculated heat-loss H = 1,420,000 B.t.u. per hr. for 70° F. inside and 0° F. outside temperature;

Table 30.—Final Temperatures and Condensations, Vento Heaters

Regular section, standard spacing, 5-in. center to center, of loops. Steam, 5-lb., gage. C = condensation, lb. per hr. per sq. ft. of heating-surface. FT = final temperature of air leaving heater. Velocity measured through free are:

temperature T of air entering rooms to be approximately 120° F., and of air entering heater 0° F.; steam-pressure, 5 lb., gage.

Solution.—From Table 30, the number of stacks deep required for final temperature 120° and entering air 0°, using a velocity of 1000 ft. per min., is 5. Weight of air to be circulated per min. is

$$M = H/\{0.24(T - t) \times 60\} = 1{,}420{,}000/\{0.24(120 - 70) \times 60\} = 1972.$$

Free area required is $A = 1972/(0.075 \times 1000) = 26.3$ sq. ft.

From Table 29, with a 60-in. length of unit, 5 in. on centers, free area per section is 0.92 sq. ft. Number of sections, N, required across face of heater is, $N = A/0.92$, or $26.3/0.92 = 28$.

Heating-surface per section is 16 sq. ft. Total heating-surface, therefore, is $S = 5 \times 28 \times 16 = 2240$ sq. ft. and the total condensation C per hr., to be supplied by the boiler, or exhaust-steam, at 5-lb. pressure is (Table 30)

$$C = 2240 \times 1.56 = 3494 \text{ lb.}$$

* Net Face Area means only that area facing the tubes and does not include the headers or casing

SELECTION OF BLAST HEATERS.—The selection of a heater for a given service is based on the final temperature desired and on the net free area of pipe-coil or Vento heaters, and gross face area of copper tube heaters, required for a certain allowable velocity. That is, for specified initial and final temperatures and a given number of net sections, a certain final temperature results when the velocity has been fixed in advance. Good practice limits velocities to those given in Table 32. High velocities are objectionable in public buildings on account of the resulting noise. Resistance through the heater increases as the square of the velocity, with an increase in the power required.

Table 32.—Allowable Velocities, Ft. per Min., of Air Through Blast Heaters *

No. of stacks deep.......					
Velocity, public buildings.	1000–1500	1000–1300	1000–1200	900–1100	800–1000
Velocity, factories.......	1200–1600	1200–1600	1200–1600	1200–1500	1200–1400

* Referred to a temperature of 70° F. Allowable velocities for gross or face area of heater is approximately one-half tabular values.

RATING OF BLAST HEATERS.—The rating of an assembled heater of several sections (pipe-coil or copper tube type) or stacks (Vento type) is based on the temperature rise of the air passing over the heating surface for certain velocities through the free or unobstructed area of the heater-face. For convenience in rating, velocity is based on the volume of air at an assumed temperature of 70° F.

Let M = weight of air to be circulated through heater, lb. per min.; A = free area of heater, sq. ft.; V = veolcity of air, ft. per min., through free area based on 70° temperature; 0.075 = density of air at 70° F. Then $A = M \div 0.075V$.

9. DESIGN OF AIR DUCTS

ALLOWABLE VELOCITY OF AIR IN DUCTS AND FLUES.—To limit the resistance or pressure-loss in the duct system, velocities should be kept within the limits of Table 33. In public buildings, air should be delivered to the room at a velocity that will insure its movement to the desired points in the room without objectionable draft or noise when passing the register-grilles.

The velocity through the fan outlet, under the ordinary conditions that obtain in heating work, varies from 1500 to 2500 ft. per min.

SHEET-METAL PIPES AND DUCTS.—The recommended gage (U. S. Std. sheet-metal gage) for various sizes of galvanized sheet-steel pipes for heating and ventilating work, blowpiping and exhaust work, is given in Table 34.

PRESSURE LOSS.—The frictional resistance of air flowing through smooth sheet-metal ducts, termed pressure-loss, measured in inches of water, for 70° F. air, and for a length of duct of 100 ft., may be estimated by the formula

$$h = 0.000136 \times (R/A) \times v^2 \quad \quad [12]$$

where R = perimeter of duct, ft.; A = area of duct, sq. ft.; v = velocity of air, ft. per sec.; h = pressure-loss, in. of water-column. For round ducts, the above formula reduces to $h = 0.00055v^2/D$, where D = diam. of duct, ft.

Fig. 28 is based on this formula, and gives the diameter of a round duct for various velocities, and the pressure-loss or resistance for various quantities of air flowing.

EXAMPLE.—To find the size of a round duct to convey 1500 cu. ft. of air per min. at a velocity of 1800 ft. per min., and also the pressure-loss per 100 ft. of duct: locate 1500 on the right-hand side of the diagram, pass horizontally to the left to the intersection of the diagonal 1800-ft. velocity line. The duct nearest the required size is 12 in. diam. At this intersection pass vertically down to the base-line and read the pressure-loss of 0.48 in. of water-column.

PRESSURE LOSS OF RECTANGULAR DUCTS.—The simplest method of determining pressure-loss for rectangular ducts is to proportion the system for round ducts throughout, and transfer to rectangular sizes giving equal pressure-losses (not equal areas) by means of Table 35.

EXAMPLE.—A duct 12 in. diam. and 120 ft. long contains two 90° elbows, whose ratio of radius of throat to pipe diameter is 3; air flowing, 1500 cu. ft. per min. at a velocity of 1800 ft. per min. The total equivalent length of duct is $120 + (2 \times 4.8) = 129.6$ ft. The pressure-loss, from Fig. 28, is 0.48 in. per 100 ft. The loss is, therefore, $0.43 \times (129.6/100) = 0.62$ in. of water-column.

The pressure-loss for square elbows is $0.85v^2/2g$ in. of water-column for round pipes, and $1.25v^2/2g$ for square pipes; v = velocity, ft. per sec. The pressure-loss through register-grilles may be taken at 0.023 in. for a velocity of 400 ft. per min. through free area. The gross area of registers is about twice the free area. The pressure-loss in air-washers and humidifiers for a velocity of 500 ft. per min. through free area is 0.25 in. of water-column. The pressure-loss through Vento heaters is given in Table 37, and through Aerofin heaters in Table 31.

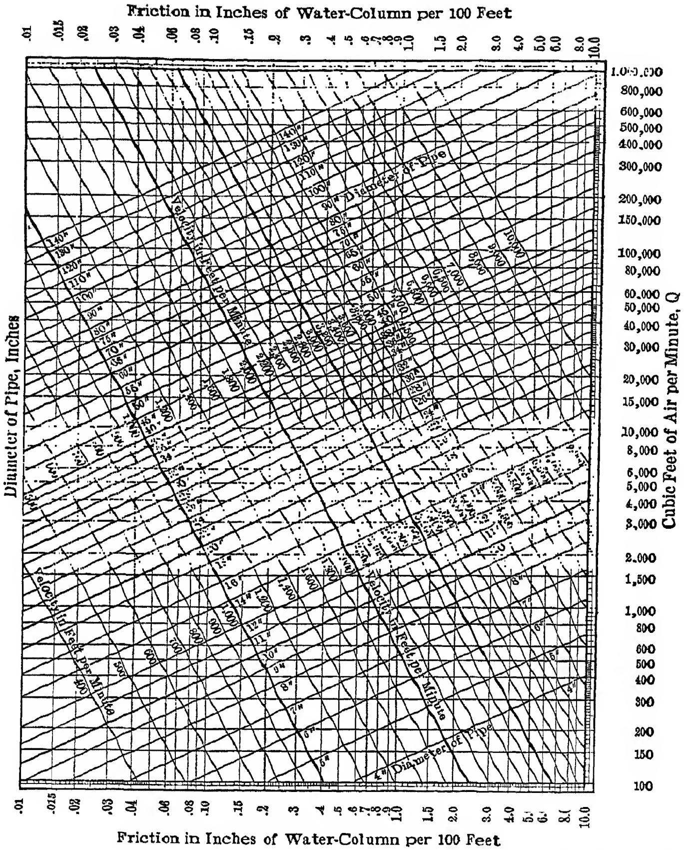

Fig. 28. Diameter of Duct for Various Velocities and Pressure Loss for Various Quantities of Air

EFFECT OF TEMPERATURE ON PRESSURE-LOSSES.—The preceding data on pressure-losses in ducts, registers and heaters are based on an air temperature of 70° F. For other temperatures, the pressure-losses are to be divided by the comparative volume of air at actual temperature to its volume at 70° F. See Table 38. For heaters use the average temperature of the air passing through the heater.

DESIGN OF DUCT SYSTEMS.—Two schemes are used to proportion air-ducts: 1. The velocity method; 2. The method of equal friction pressure-loss per ft. of length. Method 1 involves fixing the velocities (see Table 33) in the various sections, and the gradual reduction of the velocity from beginning of the duct to point of discharge. Pressure-loss is computed separately for each section having a different velocity, and the various pressure-losses are added together to obtain total pressure-loss. Method 2 is used principally in the design of duct systems for factory-heating. The velocity in the outlet farthest from the fan is fixed and the area of this branch is determined by volume of air to be delivered. Determine friction pressure-loss per 100 ft. of duct of this size by Fig. 28 and proportion remainder of the main for this same pressure-loss per 100 ft.

Example.—Method 1. In the single-duct system, Fig. 29, the risers are based on a velocity of 600 ft. per min. or 10 ft. per sec. and 400 ft. per min. or 6.6 ft. per sec., through free area of register-

Table 33.—Allowable Velocities in Fan Systems

In Public Buildings	Velocity, feet per min.	In Manufacturing Plants	Velocity, ft. per min. Employees Sitting	Employees Standing
Velocity through		Velocity through		
Free area, wall-registers.......	400– 500	Main ducts.....	1200–1500	1500–2400
Free area, floor registers.......	200– 300	Branches.......	600– 900	900–1500
Vertical flues to registers......	600– 750			
Connections to base of flues....	800–1000			
Main horizontal ducts.........	1500–2500

grille. Velocity in the longest main, B, is 900 ft. per min.; volume of air to be delivered, 2000 cu. ft. per min., at 120° F. Area of riser required is 2000/600 = 3 1/3 sq. ft. = 480 sq. in. An 18 × 27-in. riser (486 sq. in. area) is used. Area of main, B, is 2000/900 = 2.22 sq. ft. = 320 sq. in. Size of duct is 12 × 27 in. The diameters of round ducts of equivalent friction-losses (Table 35) are: for riser, 24 in.; main, B, 19.5 in.

Referring to Fig. 28, pressure-losses are: Riser, 0.032 in. per 100 ft.; main, 0.09 in. per 100 ft. The main has one elbow and the riser one elbow, with ratio of radius at throat to diameter assumed as 3, in both cases. Equivalent length of main B = 200 + (4.8 × 20/12) = 208 ft.; pressure-loss = 0.09 × (208/100) = 0.187 in. Equivalent length of riser = 34 + (4.8 × 24/12) = 44 ft.; pressure-loss = 0.032 × (44/100) = 0.014 in. Pressure-loss through register-grille is assumed as 0.023 in.

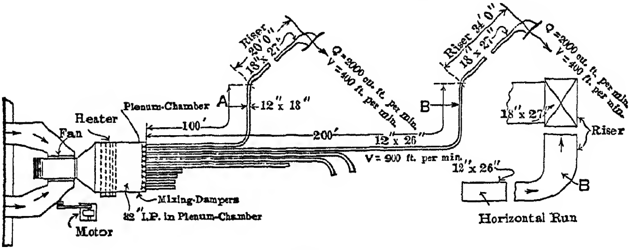

FIG. 29. Single Duct System

Total resistance of the duct system is 0.187 + 0.014 + 0.023 = 0.224 in. Assuming 5-section Vento heater to be used, with a velocity (based on free area) of 1200 ft. per min., pressure-loss through heater is 0.376 in. (Table 37.) Total resistance against which fan must operate is 0.224 in. + 0.376 in. = 0.60 in., based on 70° air. Assuming temperature of air to be 120°, resistance is (Table 38): 0.60 × (1/1.094) = 0.55 in. Method 2 is illustrated by example given under Application of Fan-blast Heating Data, below.

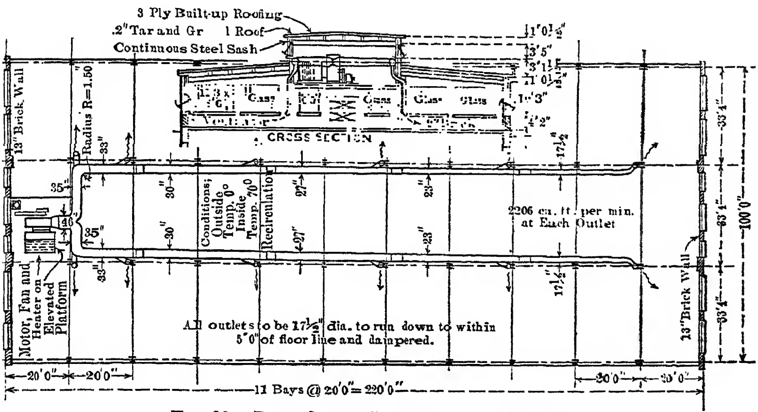

FIG. 30. Draw-through Blast System in a Factory

APPLICATION OF FAN-BLAST HEATING DATA.—The application of the preceding data may be illustrated by the design of a fan-blast draw-through heating system for the factory-building, Fig. 30; steam pressure to be 5 lb., gage. The calculated heat-loss (average inside temperature of 70° F. in zero weather) is as follows:

	Sq. Ft.		B.t.u. Transmitted per sq. ft.		Total B.t.u. per Hour.
1 5/8-in. roof	22,000	×	31.*	=	682,000
9-in. brick walls	1,830	×	25.	=	45,760
13-in. end walls	2,100	×	19.7	=	41,370
Side wall monitor	880	×	30.	=	26,400
Glass surface	7,300	×	79.	=	576,100
7/8 air-change per hr., cu. ft.	354,800	×	1.26	=	390,287
			Total	=	1,761,917 = H

Heater Calculations.—A heater made up of five 60-in. Vento stacks will be used. Air will be recirculated and will enter heater at an assumed temperature 10° F. lower than the average inside temperature, or (70 − 10) = 60° F. It will pass through free area of heater at a velocity of 1200 ft. per min., measured at 70° F. From Table 30, final temperature of air leaving heater will be 140° F. and condensation per sq. ft. of heating surface will be 1.23 lb. per hr.

M = 1,761,917 ÷ {60 × 0.24 (140 − 70)} = 1747 lb. of air to be circulated per minute, or from Table 38, 1747 × (15.1 ÷ 1.132) = 23,215 cu. ft. of air per min., measured at 70° F.

A = 23,215 ÷ 1200 = 19.34 sq. ft. of free area through heater (Table 32).
N = 19.34 ÷ 0.92 = 21 sections, width of heater (Table 29).
S = 21 × 5 × 16 = 1680 sq. ft., total heating surface (Table 29).
C = 1680 × 1.23 = 2066 steam condensed per hour (Table 30).

Design of Duct System.—The duct system in factory work ordinarily is designed on a basis of equal pressure loss per foot of length. Total air volume, measured at 140° F., is 1747 × 15.1 = 26,379 cu. ft. per min. (Table 38), and volume of air to be delivered by each of the 12 outlets is 26,379 ÷ 12 = 2198 cu. ft. per min. With an assumed discharge velocity at outlets of 1350 ft. per min. (Table 33), required area per outlet is 2198/1350 = 1.6 sq. ft., equivalent to 17 1/2 in. diam.

From Fig. 28, pressure-loss per 100 ft. of length of the last section of the 17 1/2-in. duct, discharging 2198 cu. ft. per min., is 0.20 in. of water-column. Since the duct system is to be designed for equal pressure-loss per foot of length, the remaining sizes of duct are determined by the intersection of the vertical 0.20-in. pressure-loss line with the horizontal cu. ft. lines for the quantities of air to be handled by the various sections of the duct. Each outlet should have a damper to equalize and adjust the flow of air. Total pressure-loss of system is estimated as follows:

Loss through heater	0.376 in. of water-column.	
" " 200 ft. pipe, 2 × 0.20	0.400 "	"
" " two 35-in. elbows	0.072 "	"
" " one 17 1/2-in. elbow	0.018 "	"
Total	0.866 "	"

The actual pressure-loss will be somewhat less than the above total, as the figures are based on

* Temperature of air, under side of roof a sumed to be (70 + = 82°. B.t.u. per sq. ft., U, = 0.38 × 82 = 31. (See Table 6.)

a density corresponding to an air temperature of 70° F. Usually no correction is made in practice for this difference.

The rated capacity of the fan required (see tables under Fans and Blowers, p. 1–63) for this installation is 26,379 ÷ 1.06 = 24,886 cu. ft. per min. (Table 39) at 7/8-in. static pressure or maintained resistance. The speed and horsepower as given by the fan tables should be multiplied by the factor 1.06.

RATING OF FANS.—The volume of air, cu. ft. per min., at 70° F., which a fan will deliver, varies with the resistance against which it operates. To correctly choose a fan from manufacturers' tables (see Fans and Blowers), the resistance (static pressure) must be determined by the duct-design, after the size of heater, and its resistance, have been determined. The speed and brake horsepower required to drive the fan also are stated in the tables. The temperature of air handled by the fan with draw-through apparatus is higher than 70°, except for a fan which is connected ahead of a tempering-coil, usually a heater 2 sections deep. The tabulated speed, volume and brake horsepower to maintain the pressure must be multiplied by the factors given in Table 39, for temperatures other than 70°. The factors in this table are the square roots of the ratios of the density of the air at 70° F. to its density at the temperature stated.

Table 39.—Factors for Speed, Volume and Brake Horsepower of Fans

Temperature, deg. F.....	0	100	120	130	140	150
Factor................	0.932	1.028	1.046	1.055	1.064	1.073

SELECTION OF MOTOR FOR FAN DRIVING.— Good practice will add 15% to the brake horsepower, as determined from the fan tables, for the rating of the motor. This allows for overload, due to fan being operated under somewhat different conditions of pressure and speed than those under which it was originally rated.

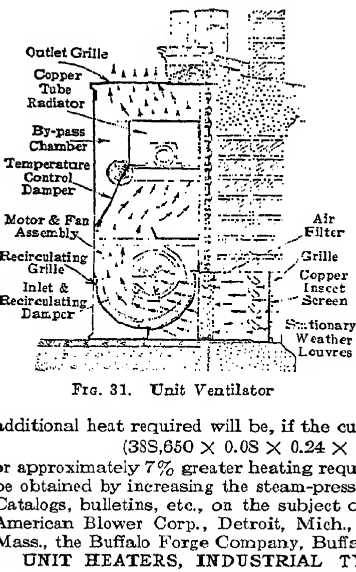

Fig. 31. Unit Ventilator

Fan Engine.—When high-pressure steam is available, an automatic high-speed engine often is used for fan-driving. The exhaust from the engine is used in the first section of the heater.

ADDITIONAL HEATING REQUIREMENT.—It may be desirable to so proportion heating-apparatus that the fan may be stopped at night and started about two hours before the shop is opened in the morning. It may be safely assumed that the temperature of the air in the building will not be below 30° F. when the fan is started, and that the air is all recirculated. Fan and heater must be of sufficient capacity to make up the heat loss from the building, including infiltration, and also to heat the contained air from 30° to 60° F. in two hours. Assuming the same data as given in the preceding example, the additional heat required will be, if the cubic contents of the building are 388,650 cu. ft.

$$(388{,}650 \times 0.08 \times 0.24 \times 30) \div 2 = 119{,}931 \text{ B.t.u. per hr.}$$

or approximately 7% greater heating requirement than previously calculated. This may be obtained by increasing the steam-pressure in the heater to approximately 10 lb., gage. Catalogs, bulletins, etc., on the subject of fan-blast heating may be obtained from the American Blower Corp., Detroit, Mich., the B. F. Sturtevant Company, Hyde Park, Mass., the Buffalo Forge Company, Buffalo, N. Y., and other manufacturers.

UNIT HEATERS, INDUSTRIAL TYPE.—Propeller-fan type unit heaters have outlet velocities ranging from 300 to 600 ft. per min. They ordinarily are suspended from the ceiling or structural framework of the building, at intervals of from 60 to 100 ft. The floor-type unit heater discharges warmed air through one or several outlets at velocities of 1000 to 1700 ft. per min. Some types will project and distribute the heating effect over a distance of approximately 200 ft. Most unit heaters are built with extended-surface copper tube heating surface. Unit heaters may be distributed through the central portion of a room, discharging toward the exposed wall surfaces, or around the walls, discharging at an angle with the walls toward the interior of the room. The discharge from the heaters should be so directed that rotational circulation of all the air in the room is set up by the discharge from the heaters.

The usual capacity rating of unit heaters is B.t.u. per hr. heating effect, based on recirculation of air in the room. Some makers state air volume delivered and temperature rise. The number of uniform-size unit heaters required in a room depends primarily

on the spacing necessary to obtain uniform heating. The required B.t.u. capacity of each heater is the calculated heat loss of the room divided by number of heaters to be installed. Capacities of unit heaters as made by one manufacturer are given in Table 40. Table 42 shows dimensions of several types.

Example.—A suspended-type unit heater installation for the factory building shown in Fig. 30 conveniently could consist of ten units, in two groups of five in each side bay near the outside walls. Required capacity of each unit = 1,761,917 ÷ 10 = 176,192 B.t.u. per hr. Air is to be recirculated at 70° F. Steam pressure, 5 lb. The nearest size of unit (Table 40) is a 2–18 unit, 2512 cu. ft. per min. delivery, 173,500 B.t.u. per hr., 1/4-Hp. motor; multiplying by factor 1.01 from Table 41 for 5-lb. steam and 70° air, 173,500 × 1.01 = 175,235 B.t.u. per hr.

UNIT VENTILATORS.—A considerable number of unit heaters, suitable for use in schools and public buildings ordinarily are designed for the ventilating requirement only, with sufficient direct radiation to provide for the calculated heat loss of the walls. The combination is termed a split system. The unit ordinarily is designed to heat to approximately 80° F. outside air drawn into the apparatus.

Unit ventilators ordinarily are placed under a window. They comprise a small ventilating fan, fan motor, and indirect heating surface of either cast-iron or extended-surface

* Exclusive of motor bracket.

copper coils, all enclosed in a finished sheet steel casing, with an outside and recirculating intake. Each intake has a damper, and all dampers usually are so connected that the full opening of one closes the other. The fan draws in either all outside air, all recirculated air, or a mixture of the two as may be desired by the manipulation of the dampers. The fan discharge may be by-passed around the heater, all passed through the heater, or a portion only by-passed by means of a damper ordinarily under thermostatic control. The temperature of the air leaving the unit is controlled by the by-pass damper, the volume of air leaving the unit remaining constant.

HEATING BY ELECTRICITY

The relations involved, and the underlying principles of electrical heating are expressed by the following equations:

$$I = E/R;\ R = kl/a;\ W = I \times E = I^2R;\ H = 3.415\,W = 3.415\,I^2R \text{ per hr.},$$

where I = current flowing, amperes; E = electromotive force or potential difference, volts; R = resistance of conductor, ohms; k = coefficient of specific resistance, ohms per sq. in. per ft. of conductor; l = length of conductor, ft.; a = area of cross-section, sq. in.; W = watts = volts × amperes; H = heating effect, B.t.u. per hr.

It is evident that the heating value of a conductor varies as the square of the current flowing and directly with the resistances. For given potential differences, the current varies inversely as the resistance; hence, increasing the resistance only, in such a case, actually would cut down the heat supplied. The resistance varies with the material, with the length of conductor, and inversely as the area of the conductor. For a conductor of given material and length, subjected to a definite voltage, there is a certain diameter and corresponding resistance which will give the maximum heating effect, which can be determined from the above equations.

The economy of electrical heating depends entirely on the cost of generating and distributing the electricity, as all the energy supplied, if the heater is of the direct type, is converted into heat at the radiator. In addition to this, account must be taken of the simplicity, additional convenience, reduced attendance and repairs, and small space occupied by the electrical equipment. The actual money value of these factors is hard to determine. Any comparison with other forms of heating usually is based on heating effect obtained per pound of coal burned, or per dollar paid for fuel and electricity. Only when electricity can be generated at a very low cost, as in certain hydro-electric plants, can it be used for heating on a basis of equal cost compared with the ordinary steam or hot-water system of heating.

Example.—A house heating boiler burns coal of 12,000 B.t.u. per lb. with 60% efficiency. The coal required to give the heating effect of 1 kw.-hr. is $3415/(0.60 \times 12{,}000) = 0.47$ lb. The cost of 1 kw.-hr. in a turbo-generating station with 90% combined mechanical efficiency is $1.00/0.90$ or 1.111 kw.-hr. for each kw. supplied for heating. With a generating set thermal efficiency of 15%, the coal required at 60% efficiency to produce 1 kw. for electrical heating is

$$(1.111/0.15) \times \{(3415/0.60 \times 12{,}000)\} = 3.5 \text{ lb.}$$

The relative cost of fuel at the same price per ton is, therefore, $3.5/0.47 = 7.5$ times as much when electrical generation by steam is employed.

VENTILATION

VENTILATION is the displacement of vitiated air from an inhabited room and its replacement with fresh air. It usually is expressed in the number of changes of air per hour. This is not strictly correct, as there is no positive change; the incoming air dilutes the foul air until it is suitable for respiration.

VENTILATION LAWS.—Many states have laws stating the amount of ventilation to be supplied to public and semi-public buildings, temperature limits, etc. These codes, and those of the various cities involved should be consulted before completing the design of any heating and ventilating system. Most states require 30 cu. ft. per min. per occupant of outside air to be introduced into school rooms to provide ventilation.

SYSTEMS OF VENTILATION.—Ventilation systems are classified as: 1. Natural ventilation in which the movement of air in flues, ducts, etc., is induced by the thermal head produced by the difference in density due to the difference in temperature between the column of air in the ducts and that of the outside atmosphere. 2. Mechanical ventilation in which the movement of air is maintained by a positively driven fan. With the mechanical system, air at any desired temperature may be positively circulated to all parts of the building, giving practically uniform ventilation, regardless of outside weather conditions. For data regarding fan capacities in mechanical ventilating systems, see Blast Heating, p. 11–33, and Fans and Blowers, p. 1–63. For data on capacity of ventilators in natural ventilation, see Table 2.

Ventilation systems also are divided into: *a*. Upward systems; *b*. Downward systems. Upward systems frequently are used for audience rooms. Air is supplied near the floor line through mushroom ventilators in the floor, through hollow pedestals in the chairs, or through floor registers. Vitiated air outlets are in the wall near the ceiling. The downward system generally is used in school rooms, hospitals, institutions, etc., where the occupants are not closely spaced. Air enters at 8 ft. or more above the floor; the vitiated air outlet usually is at or near the floor line. Inlets and outlets should be placed if possible in the same inside wall, the former being at least 7 or 8 ft. above the latter. Incoming air flows out across the room to the cold outside wall before it cools and drops to floor level. Practically uniform distribution of fresh air throughout the room thus is obtained. Theaters often are ventilated by a downward system, with the fresh air outlets located in the ceiling. See p. 11–60. Neither upward nor downward system can be characterized as superior. Each has its proper place and limitations.

REQUIREMENTS FOR GOOD VENTILATION.—Table 1 represents good ventilation practice as regards the amount of outside or new clean air to be introduced into rooms used for various purposes.

Assembly rooms	20 to 30	15 to 20	10 to 15	

DISTRIBUTION OF THE AIR.—In general, with upward or downward ventilation, definite provision to remove vitiated air should be made to insure uniform distribution and prevent short circuiting between air inlets and outlets. Multiple inlets and mushroom ventilators, Fig. 1, are used to give a better mechanical distribution of air in systems of upward ventilation in audience rooms with fixed seats. Air is supplied through a false floor or plenum chamber below the main floor. The mushroom ventilator heads, located under every second or third seat, are adjusted for a uniform discharge of tempered air over the entire seating area. The heads are mounted either on an adjustable spindle as shown, or on a non-adjustable spindle with a control damper. In either case, the adjustable head or the damper must be locked in the final adjusted position.

AUTOMATIC VENTILATORS.—The chief differences in the various types of automatic ventilators for natural ventilation lie in the degree to which the wind is utilized to produce additional ventilation. Four general classes of such ventilators are: 1. Stationary non-siphoning type; 2. Stationary siphoning type; 3. Rotary plain head type; 4. Rotary siphoning type.

Type 1 does not contemplate utilizing the wind to produce additional ventilating effect. Type 2 uses the wind to produce additional ventilating effect, by an ejector action. When there is no wind, ventilation is due to natural circulation.

The rotary or revolving head types (3 and 4) have a protecting cowl revolving on a central bearing. An opening in one side is always directed in the path of the wind through the movement of the cowl. The velocity of the wind creates a region of decreased pressure at the cowl opening which in turn creates additional ventilation.

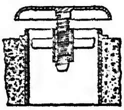

Fig. 1. Mushroom Ventilator

Average results of a series of tests conducted in 1920 by the Engineering Experiment Station of the Kansas State Agricultural College on different types of 10-in. automatic ventilators are given in Table 2. The object of the investigation was to determine the degree to which the various types utilized wind in producing additional ventilation. Approximate wind conditions were duplicated by a wind tunnel in which were produced wind velocities up to 10 miles per hr. Air velocities in tunnel and in ventilator were measured by an anemometer. The temperature within the tunnel and in the room ventilated being identical, there was no natural circulation of air, and all movement of air through the ventilator was produced by the wind currents. Actual installations of ventilators would obtain in most cases greater ventilation because of the influence of natural circulation. The amount of ventilation secured by natural circulation may be calculated, if the density of the internal and external air and the height of the ventilator above the floor are known. The tests indicated that the various types have certain well-defined advantages, but for all practical purposes little difference exists between ventilators differing slightly in design but of the same general type

EFFECT OF VITIATED AIR.—The presence of carbon dioxide, according to Dr. Ira Remsen, is not in itself dangerous to health except that it reduces the supply of oxygen by displacing it. Carbon dioxide is non-poisonous, but organic impurities exhaled with it may be a menace to health. The breathing of small quantities of decomposing organic matter and unhealthful gases are the dangers of poor ventilation. The carbon dioxide given off at the same time as the other impurities is more or less an indicator of the presence of real danger. A lowering of the oxygen supply below the point required by good ventilation causes lowered vitality and decreased production of industrial workers. Satisfactory ventilation consists in constantly supplying fresh air, free from dust and other impurities, at the proper temperature and with the proper moisture content and also in

removing vitiated air. This can be accomplished satisfactorily during the heating system only by mechanical means.

CAUSES OF AIR VITIATION.—Air is vitiated by: 1. Excess of carbon dioxide due to respiration, lights, etc. 2. Generation of heat by occupants, lights, etc., above that required for warming. 3. Water vapor in excess of or below that required for desired relative humidity. 4. Dust, either brought in by the air or carried by persons within the building. 5. Bacteria, due to respiration or otherwise. 6. Odors, due to occupants or to manufacturing processes.

The composition of pure air and respired air has been given by Prof. R. C. Carpenter as follows:

	O	N	CO_2	Water Vapor
Pure air..........	20.26%	78.00%	0.4%	1.50% (variable)
Respired air.......	16.2%	75.00%	4.0	5.0%

The respired air is at a temperature of 90° to 98° F. and is nearly saturated with water vapor.

The quantity of air required for each adult in order to maintain a CO_2 content of 7 parts, outside air containing 4 parts, per 10,000, is given by $C = (a \times b)/(n - 4)$, where C = cu. ft. per min., a and n = respectively, parts of CO_2 per 10,000 for respired air, and air of standard purity, and b = cu. ft. per min. of CO_2 per person = 0.25 ordinarily. See Table 3.

RELATION BETWEEN HUMIDITY AND TEMPERATURE.—Air, on being heated, has its capacity for absorbing moisture greatly increased, giving the sensation due to so-called "dry" heat. This causes excessive and unnatural evaporation of moisture from the skin and respiratory organs, which lowers the surface temperature of the body and causes a temperature sensation several degrees lower than the actual temperature of the room. The remedy for too low or too high humidity in a room is the introduction or decrease of moisture present in the air.

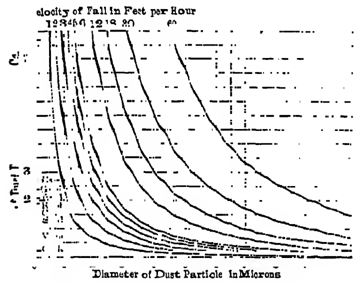

FIG. 2. Velocity of Fall of Dust

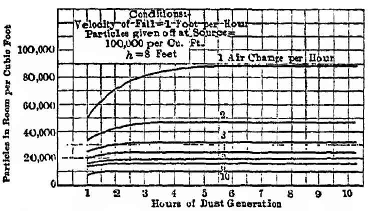

FIG. 3. Effect of Air Chambers on Dust Content

The relation of temperature and relative humidity to human comfort has been the subject of considerable research by the A.S.H.V.E. The results of this research have been published from time to time in the transactions of this society, to which the reader is referred. See A.S.H.V.E. 1932 *Guide* for comfort charts.

DUST.—Determination of dust includes both the amount actually present in a given volume of air and the examination as to its character, such as abrasive, metallic or fibrous. Soluble filters of pure sugar are used to screen out dust particles and the sugar then is dissolved.

O. W. Armspach (*Jour.* A.S.H.V.E., Dec., 1920) reports an investigation and tests carried out by the Research Bureau of the A.S.H.V.E., and the U. S. Bureau of Mines, with the following conclusions: The dust content in a room depends on: 1. Density of material, velocity of fall of particles and size of the room. The dust will accumulate until a definite content is reached, depending on the rate of fall and the number of air

Table 3.—Values of C for Various Values of n from 5 to 30

n = Vitiation allowed. Parts of CO_2 per 10,000 in the room air.
C = Cu. ft. of air containing 4 parts of CO_2 per 10,000 to be supplied per person or equivalent. A person = 0.6 cu. ft. CO_2 per hr.

n =	5.0	5.5	6.0	6.5	7.0	7.33	7.5	8.0	9.0	10.0	15.0	20.0	30.0
C =	100.0	66.6	50.0	40.0	33.3	30.0	28.6	25.0	20.0	16.6	9.1	6.2	3.8

changes. 2. The total dust given off by various machines when handling different materials can be determined from the average count of dust particles resulting in the room. 3. Dust conditions can be improved by providing the proper number of air changes. There is, however, a limit to this number, and usually 5 changes per hour are sufficient. 4. For equal conditions of air dustiness, as the density of the material increases, the weight per cu. ft. decreases. All dust determinations should be on the basis of the number of particles per cu. ft. From a formula developed in the investigation, the chart, Fig. 2, was prepared, showing the velocity of fall for various kinds of dust. This chart, for example, shows that a particle of 2 microns diameter and a density of 8 will fall at the same rate as a particle of a diameter 5.75 microns and a density of 1. Another formula developed shows the effect of change of air on dust content. The curves, Fig. 3, for dust of 2 microns diameter falling with a velocity of 1 ft. per min. and based on 100,000 particles per cu. ft. given off at the source, are plotted from this formula.

AIR FILTERS.—The use of some form of air filter is becoming a recognized necessity for the removal of dirt and dust from the air in a heating and ventilating system, or for the air supply to air compressors, internal combustion engines, etc. Air filters often are used in conjunction with air washer equipment when the removal of fine dust particles is considered important. They are distinguished from air washers in that they remove dirt and dust without using a water spray, and hence, do not change temperature or relative humidity of air passing through the filter.

All types of filters should fulfill the following requirements: 1. Efficient in dirt removal. 2. Interpose low resistance to air flow. 3. Possess large dust holding capacity. 4. Easy to clean and handle. Air filters are classified as: 1. Dry filters; 2. Viscous filters.

Dry Filters were the first type to be used. They comprise a fine mesh cloth, felt or paper screen through which the air is filtered or strained. Several types of dry air filters are available. They are cleaned by rapping, by reversing the air flow, or by supplying new filter areas.

Viscous Filters have largely superseded the dry type. Their cleaning action depends on the dirt impinging on a metal surface coated with a viscous fluid. All filters of this type operate on the principle of adhesive impingement. The viscous material employed should be odorless, fireproof and germicidal in its action. This type of filter is constructed in units of various standard sizes so that practically any area of filtering surface may be obtained by the use of one or more units.

AIR CONDITIONING

AIR CONDITIONING generally is understood to mean the simultaneous control of temperature, relative humidity, air motion, air distribution and ventilation within an enclosure. Air conditioning systems are used in theaters, churches, auditoriums, schools, restaurants, offices, homes, etc., to produce or effect comfort for occupants by maintaining a temperature and relative humidity which will lie in the so-called "comfort-zone." The comfort zone for both winter and summer has been established by the A.S.H.V.E. Research Laboratory. While the art of air conditioning properly may be regarded as a recent development, its principles are not new. A system embodying many of the principles now used was proposed for the U. S. Army hospitals by G. H. Knight in 1864.

Air conditioning systems are used in industry to maintain the temperature and relative humidity that is most desirable for the process involved. For many industrial processes the most desirable temperature and relative humidity has been fairly well established. See A.S.H.V.E. *Guide*, 1934.

The *addition* of moisture to air being circulated is humidification; the *removal* of moisture is dehumidification.

HUMIDIFICATION usually is effected by passing air through a finely-divided water spray, in an air washer. This consists of a sheet-metal housing, enclosing one or more banks of spray nozzles. The air passes through the spray and then over bent plates, called eliminators. The latter abruptly change the direction of flow and remove free water held in suspension. Larger dust particles also are removed in the washer, but for complete dust elimination an air filter must precede the washer.

In some industrial plants, a steam jet is used for humidification. When both humidification and dehumidification are required for year-round operation an air washer is used. Recirculated spray water is heated for humidification in winter, and cooled for dehumidification in summer.

Surface-type coolers are used quite generally for summer comfort cooling. Cold water is circulated through the coils of the cooler, or a refrigerant, as freon, methyl chlor-

ide, etc., is evaporated in the coils. When temperature of cooling medium is lower than temperature of air entering cooler, dehumidification results. Artesian well water, if available, may be used as a cooling agent. Artificial refrigeration, however, is usual for comfort cooling.

HUMIDITY is the water vapor (steam or moisture) mixed with air. The maximum weight of vapor which a given enclosure will contain depends only on the temperature (see the Steam Tables), regardless of the presence or absence of any other vapor or gas. That is, the weight of vapor is exactly the same whether air is present or not. The pressure of the vapor is in accordance with Dalton's Law (see p. 1-08), and depends only on the temperature, irrespective of the presence of air.

Saturated Air.—Air is saturated when it has mixed with it the maximum possible amount of vapor, which amount varies with temperature. The vapor itself under this condition also is saturated (quality $x = 1$). If the air is not saturated, the contained vapor is superheated. The *actual humidity* of the air, in meteorological work, is the number of grains (1 lb. = 7000 grains) or pounds of water vapor contained in 1 cu. ft. of a mixture of air and vapor at the observed temperature.

Relative Humidity, or degree of humidity, is the actual amount of moisture (grains or pounds) contained in 1 cu. ft. of the mixture divided by the amount which 1 cu. ft. of the mixture would hold at the same temperature if saturated. This condition is stated as percent relative humidity.

A common interpretation of this term in engineering computations, is the ratio of actual weight (lb.) of vapor mixed with 1 lb. of dry air to the weight (lb.) of vapor mixed with 1 lb. of dry air in a saturated mixture at the same temperature.

Wet- and Dry-bulb Temperatures are the observed temperatures as indicated by wet- and dry-bulb thermometers respectively.

Dew-point Temperature is the temperature corresponding to saturation (100% relative humidity) for a given weight of vapor. Any lowering of temperature produces a contraction of volume and partial condensation. Air with any amount of vapor or relative humidity has a dew-point, as temperature may be lowered to a temperature where condensation begins.

EXAMPLE.—Required the weight of vapor carried by 1 lb. of air in a saturated air-vapor mixture at 60° F. and atmospheric pressure (14.7 lb. per sq. in., or 29.92 in. Hg, absolute, at sea-level). *Solution.*—Let p and p_1 = respectively, atmospheric and absolute partial pressures of air; p_2 = absolute partial pressure of the vapor corresponding to the temperature; all pressures in lb. per sq. in. Then $p = p_1 + p_2 = 14.7$ lb. at sea level.

From the steam tables, at 60° F., $p_2 = 0.26$; density = 0.000828 lb. per cu. ft.; $p_1 = 14.70 - 0.26 = 14.44$. From the relation $PV = MRT$ (see p. 3-75), where $R = 53.35$ for air, $T = 459.6 + 60 = 519.6$, $P = 144 \times 14.44$, $M = 1$,

$$V = (53.35 \times 519.6)/(144 \times 14.44) = 13.33 \text{ cu. ft.} = \text{vol. of air.}$$

As the air and vapor occupy the same space, the volume of vapor also is 13.33 cu. ft., whence the weight of saturated vapor in the mixture is $13.33 \times 0.000828 = 0.01104$ lb. Weight of vapor per cu. ft. of mixture = $0.01104/13.33 = 0.000828$ lb. = $0.000828 \times 7000 = 5.796$ grains.

TOTAL HEAT OF DRY AND SATURATED AIR.—The total heat of dry air is $h = C_a t$, where h = total heat, B.t.u. per lb.; C_a = specific heat of air = 0.24 (usual figure); t = temperature of air, deg. F. In saturated air the "heat of the liquid" usually is neglected, the error introduced thereby being negligible in air conditioning calculations. The total heat per 1 lb. of dry air in the saturated air-vapor mixture is the heat required to raise the temperature of 1 lb. of dry air from 0° F. to saturation temperature t, and to evaporate the weight W of vapor in the mixture. Thus

$$h_m = C_a t + rW \qquad [1]$$

where h_m = total heat of mixture, B.t.u. per lb.; r = latent heat of vapor at temperature t. For saturated air at 56° F., $r = 1060.3$, $W = 0.00954$ lb. Then (see Table 10, p. 1-08)

$$h_m = (0.24 \times 56) + (1060.3 \times 0.00954) = 23.555 \text{ B.t.u.}$$

TOTAL HEAT OF PARTIALLY SATURATED AIR.—A non-saturated air-vapor mixture may become saturated by an adiabatic process (see below) at the wet-bulb temperature. The total heat of the mixture is the same as the total heat of saturated air at the wet-bulb temperature, as given by the saturated air table, p. 1-08, or the psychrometric chart, Fig. 1. This relation is used in determining the total heat of partially saturated air.

WEIGHT OF VAPOR IN MIXTURE.—Assume a saturated mixture of 1 lb. of dry air, containing W lb. of vapor at temperature t, to be heated at constant pressure to a dry-bulb temperature of t_d, with a corresponding wet-bulb temperature of t_w. If the mixture is cooled at constant pressure back to t, t is the dew-point temperature for a combination of dry- and wet-bulb temperature t_d and t_w, and weight W lb. of vapor in the mixture is the same amount as contained in saturated air at the dew-point temperature. Thus if

dry- and wet-bulb temperatures are known, the dew-point temperature can be determined from the psychrometric chart, and consequently the value of W.

Method of Mixtures.—If x lb. of air be mixed with y lb. of air at dry-bulb temperatures t_1 and t_2 respectively, the resultant dry-bulb temperature is

$$t_3 = (xt_1 + yt_2)/(x + y) \quad \text{. . . . . [2]}$$

If W_1 and W_2 = weight of moisture per 1 lb. of air at dry-bulb temperatures t_1 and t_2 respectively, then the weight of moisture per 1 lb. of air in the mixture is

$$W_3 = (x\,W_1 + y\,W_2)/(x + y) \quad \text{. . . . . [3]}$$

From the psychrometric chart, Fig. 1, the dew-point corresponding to W_3 can be found. These relations often are used in air conditioning work.

ADIABATIC SATURATION OF AIR.—Air not completely saturated, when passed through a spray or over the surface of water housed in a completely insulated enclosure, will pick up vapor evaporated from the water. Dry-bulb temperature t_d of the leaving air will be lower than that of the entering air. If leaving air is saturated, its temperature will be the same as the wet-bulb temperature t_w of the entering air, which remains constant during the process. Since no external heat is supplied, and as heat is necessary to evaporate water, evidently the heat exchange has been between the air passing through the apparatus and the water. Such an exchange without transfer of external heat is termed an adiabatic process. Let W_1 = initial vapor content, lb. per lb. of dry air, corresponding to dry- and wet-bulb temperatures t_d and t_w respectively; W_2 = final vapor content corresponding to temperature t_w; r_w = latent heat corresponding to t_w, B.t.u. per lb. of vapor; C_a = specific heat of dry air = 0.24; C_s = specific heat of vapor = $0.4423 + 0.00018t_d$. Then heat to evaporate weight of vapor added to mixture = $r_w(W_2 - W_1)$ B.t.u. per 1 lb. of dry air, and $r_w(W_2 - W_1) = (C_a + C_s\,W_1)(t_d - t_w)$;

$$W_1 = \frac{r_w\,W_2 - C_a(t_d - t_w)}{r_w + C_s(t_d - t_w)} \quad \text{. . . . . [4]}$$

This psychrometric method of determining the weight of vapor mixed with or carried per 1 lb. of dry air was devised by W. H. Carrier in 1911.

Air Washers

The ability of a washer to *cool* air depends on fineness of spray, water pressure at the nozzles, arrangement of nozzles, number of banks of nozzles through which air passes, and direction of spray discharge from the banks.

HUMIDIFYING EFFICIENCY of an air washer, considered as a cooling device, is

$$E = \{1 - (t_{dl} - t_w)/(t_{de} - t_w)\} = (t_{de} - t_{dl})/(t_{de} - t_w) \quad \text{. . . . . [5]}$$

where E = efficiency, percent; t_{de} and t_{dl} = dry-bulb temperatures of entering and leaving air, respectively; t_w = constant wet-bulb temperature. Values of E attained in practice with various arrangement of nozzles are as follows: 2 banks upstream, 1 bank downstream, E = 1.00; 2 banks upstream, E = 0.95; 1 bank upstream, 1 bank downstream, E = 0.85; 1 bank upstream, E = 0.80; 1 bank downstream, E = 0.65.

Air washers are rated at from 400 to 500 cu. ft. of air per min. per sq. ft. of cross-sectional area through the spray chamber. The pump and spray nozzles should supply from 5 to 6 gal. of water per 1000 cu. ft. of air per min., the individual spray nozzles being rated at 1 1/2 gal. per min. The friction loss of air through a washer varies with the type. For 500 ft. per min. velocity it is approximately 0.25 in.

Psychrometric Chart and Heat Exchange Diagram (Fig. 1)

EXAMPLES IN THE USE OF CHART AND DIAGRAM.—Required the relative humidity for a dry-bulb reading of 84° F. and a wet-bulb reading of 66° F.

The intersection of a horizontal line through 66° F. on the *saturation curve*, and the vertical through 84° F., dry bulb on the base line gives, approximately, 37% for the relative humidity. The *dew-point* temperature is found by tracing the corresponding *constant weight vapor line* to its intersection with the *saturation curve*, giving 56° F. for the above condition. The actual weight of vapor per pound of dry air may be read directly from the saturation curve for the *dew-point* temperature of 56° F. and is 66.8 grains or 0.00955 lb.

Humidifying.—Assuming a room temperature of 70° F. and 40% relative humidity to be maintained when outside temperature is 0° F. Locate intersection of vertical 70° F. dry-bulb temperature with 40% relative humidity curve, follow the *constant weight vapor line*, passing through the intersection, to its intersection with the saturation curve or 45° F. corresponding to 0.0063 lb. or 44.2 grains of vapor per lb. of dry air. This is then the temperature at which saturated air must leave washer, and is the temperature for which thermostat controlling spray water heater must be set. See Fig. 2.

The heat per pound of dry air required for the tempering coil and water heater is read at the right of the diagram, and is 17.5 B.t.u. to raise temperature of incoming air from 0° F. to 45° F.

and saturate it at this temperature. The additional heat required for the reheater will depend upon the final temperature desired for air entering the room.

Air Cooling.—Entering air 89° F., dry bulb, and a relative humidity of 50% corresponding to a wet-bulb temperature of 74.5° F., wet-bulb depression (89 − 74.5) or 14.5 degrees. If the *humidifying efficiency* of a washer is 60%, then temperature drop will be 14.5 × 0.60 or 8.7° F. Temperature of leaving air = (89 − 8.7) or 80.3° F. Wet-bulb temperature remains constant at 74.5°. See Fig. 3.

Drying.—Outside air temperature 80° F. and 40% relative humidity; heater to raise its temperature to 110° F., at which temperature it is introduced into drier. Air to leave drier, 70% saturated. From intersection of vertical 80° F. dry-bulb temperature line and 40% relative humidity curve, follow the diagonal *equal weight of vapor line* until it intersects vertical 110° F. line corresponding to

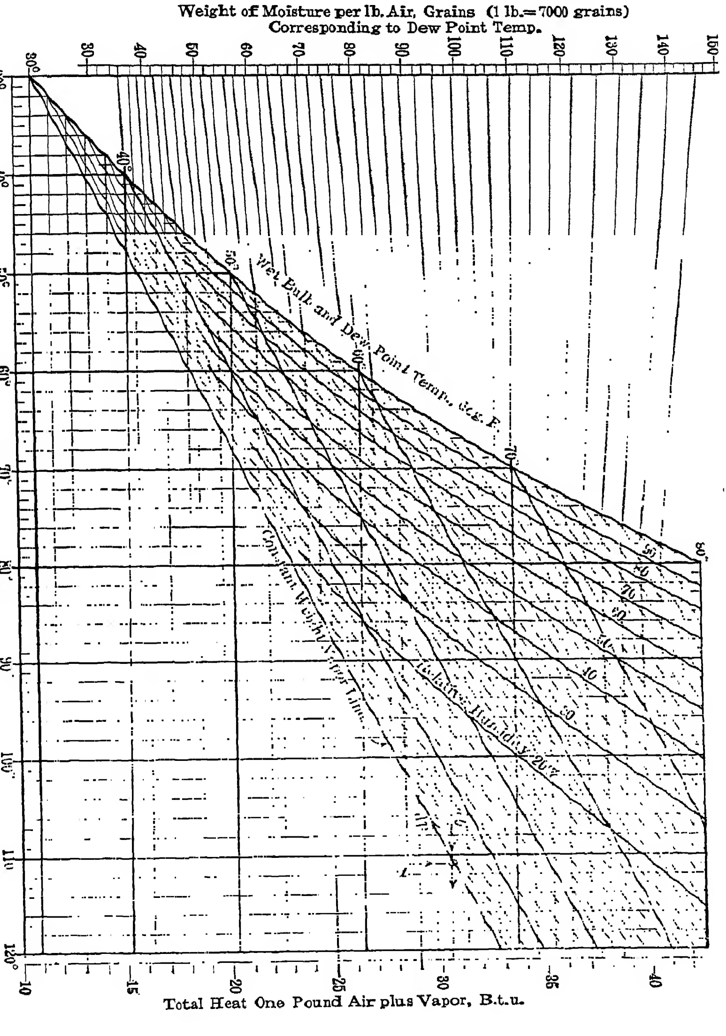

FIG. 1. Psychrometric Chart

73.5° wet-bulb. Read horizontally to the left to the intersection with the 70% curve. The corresponding dry-bulb temperature is 80.5° F., which is the required temperature of leaving air.

The weight of moisture evaporated per lb. of dry air circulated is the difference between the weight of vapor per lb. of dry air for 80.5° F. and 70% humidity and 80° F. and 40% humidity or 112.2 − 63.1 = 49.1 grains or 0.007 lb.

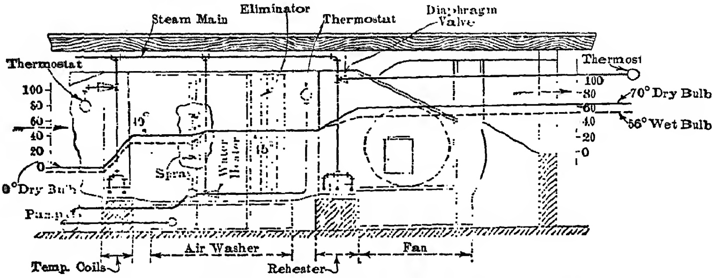

Fig. 2. Temperature Relations in Humidifying Apparatus

COMFORT COOLING.—Air is recirculated, and only enough outside air introduced to provide for ventilation requirements, approximately 10 to 15 cu. ft. per min. per occupant. Inside dry-bulb temperature to be maintained at breathing line should not exceed 10 to 15° F. below outside design dry-bulb temperature. The minimum dry-bulb temperature of air leaving cooler or washer depends largely on the distribution, which should be such as to prevent cold drafts over the occupants. Normally this temperature should be not less than dew-point temperature to be maintained in the room. A rule-of-thumb method for limiting minimum room inlet air temperature for horizontal outlets is: 2° F. per each foot of height of bottom of outlet above floor.

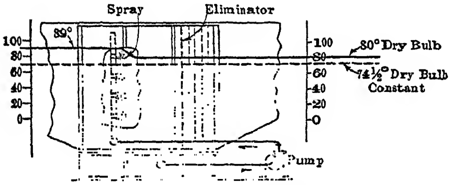

Fig. 3. Temperature Relations in Air Cooler

Weight of air to be circulated depends on sensible heat to be removed. The sensible heat load to be removed from the room is made up of: 1. Motors, electric lights and electrical heating appliances = total watts × 3.41 B.t.u. per hr. 2. Occupants at rest in 80° F. air, 225 B.t.u. per hr. per person. 3. Heat transmission of windows, walls, roofs and floors, based on the inside design temperature and outside design temperature dif-

ference. Sun effect and heat transmission should not both be calculated for the same surface. 4. Sun effect on roofs and windows; see Table 1. 5. Heat loss from insulated steam pipes (approximately 90 B.t.u. per sq. ft. of pipe surface per hr.). 6. Infiltration of air = lb. of air per hr. × 0.24 × temperature difference between outside and inside air.

The so-called latent heat load is the heat to be removed by the washer or cooler to condense moisture that is to be removed from the air circulated through the cooler or washer. See formula [13].

Air Conditioning Calculations

Notation.—t_{od}, t_{op}, t_{ow} = respectively, dry-bulb, dew-point and wet-bulb design temperatures of outside air; t_{id}, t_{ip}, t_{iw} = respectively, dry-bulb, dew-point and wet-bulb design temperatures of inside air; t_{ed}, t_{ep}, t_{ew} = respectively, dry-bulb, dew-point and wet-bulb temperatures of air entering cooling apparatus; t_{ld}, t_{lp}, t_{lw} = respectively, dry-bulb, dew-point and wet-bulb temperatures of air leaving cooling apparatus; t_{rd}, t_{rp}, t_{rw} = respectively, dry-bulb, dew-point and wet-bulb temperature of air entering room; w_o, w_i, w_e, w_l, w_r = weight of vapor per 1 lb. of dry air, corresponding to dew-point temperatures with the same subscripts; h_1, h_2 = respectively, total heat, B.t.u. per 1 lb. of air-vapor mixture entering and leaving cooling apparatus, corresponding to wet-bulb temperatures t_{ew} and t_{lw}; H_s = computed estimate of sensible heat to be removed, B.t.u. per hr., due to occupants, lights, electrical machinery, heat transmission, sun effect, infiltration, etc.; H_v = sensible heat to be removed, B.t.u. per hr. due to air introduced for ventilation; H_l = latent heat load, B.t.u. per hr.; W_1 = weight of vapor added to room air by occupants, infiltration and other sources, lb. per hr.; each occupant at rest in 80° F. air gives off 0.17 lb. of vapor per hr.; W_2 = weight of vapor added to room return air by ventilation requirements, lb. per hr.; M = weight of air to be circulated through room and cooling apparatus, lb. per hr.; M_o = infiltration, lb. per hr.; M_v = ventilation requirements, lb. per hr. = $60n$ × cu. ft. of outside air per person × 0.075; n = number of occupants; c = cu. ft. per min. of standard air, 70° F.; 0.24 = specific heat of air at constant pressure. Then

$$W_1 = 0.17n + M_o(w_o - w_i) \qquad [6]$$

$$W_2 = M_v(w_o - w_i) \qquad [7]$$

$$M = H_s/0.24(t_{id} - t_{rd}) \qquad [8]$$

The weight of air M is based on sensible heat to be removed from room. It does not include sensible heat to be removed by cooler from outside air drawn in at the cooler for ventilation. This latter must be included in the sensible heat to be removed by the cooler.

The air leaving cooler and entering room must contain a weight of vapor of

$$w_r = w_i - (W_1/M) \qquad [9]$$

The corresponding dew-point temperature t_{rp} is found from the chart, Fig. 1.

DEHUMIDIFYING AIR WASHER (Fig. 4A).—The air leaves a dehumidifying air washer in a saturated condition at temperature t_{ld}, which is the dew-point temperature of air entering the room, or $t_{ld} = t_{rp}$. The saturated air must be warmed by a heater, or by mixing room air by-passed around the washer, to a final dry-bulb temperature of t_{rd}. Dry-bulb temperature of air entering cooling apparatus is, by method of mixtures,

$$t_{ed} = \{1 - (M_v/M)\}t_{id} + (M_v/M)t_{od} \qquad [10]$$

Weight of moisture per 1 lb. of air entering cooling apparatus is, by method of mixtures,

$$w_e = \{1 - (M_v/M)\}w_i + (M_v/M)w_o \qquad [11]$$

corresponding to a dew-point temperature of t_{ep}. Dry-bulb temperature of t_{ed} being known, wet-bulb temperature t_{ew} is obtained from the psychrometric chart, and h_1 thus is determined. The heat to be extracted from air circulated by the cooling apparatus is $M(h_1 - h_2)$ B.t.u. per hr., or

$$\text{Tons of refrigeration} = M(h_1 - h_2)/12{,}000 \qquad [12]$$

The cooler must condense the weight of vapor $(W_1 + W_2)$, and also must remove the sensible heat load $(H_s + H_v)$.

$$H_v = 0.24(t_{od} - t_{id})M_v \qquad [13]$$

Latent heat load may be approximated as

$$H_l = 1060(W_1 + W_2) \qquad [14]$$

in which 1060 is the assumed latent heat of vapor at the temperature at which it is condensed. This assumption is not strictly correct. For most practical purposes

$$\text{Tons of refrigeration} = (H_s + H_v) + H_l/12{,}000 \qquad [15]$$

This approximation may be used for a by-pass dehumidifying washer or a surface cooling

unit, but not for a dehumidifying washer without by-pass. In the latter, the heat to be removed by the washer is somewhat greater.

DEHUMIDIFYING WASHER WITH BY-PASS (Fig. 4B).—To avoid necessity of reheating to dry-bulb temperature t_{rd}, the saturated air leaving the washer at dew-point temperature t_{lp}, and also to reduce materially the refrigeration required, a return air by-pass around the washer is essential. Let x, y and z represent the fractional part of M that is outside air for ventilation, recirculated air through washer, and by-passed air around washer, respectively. Then $x + y + z = 1$.

By the method of mixtures we may write the equations

and $$z\,t_{ip} + (x + y)t_{lp} = t_{rp} \qquad [17]$$

Equation [17] is based on the fact that for comparatively small temperature ranges, dew-point temperatures may be substituted, without appreciable error, for the weight of vapor per lb. of dry air.

Subtracting [17] from [16], $z = (t_{rd} - t_{rp})/(t_{id} - t_{ip})$; substituting value of z in [17], $t_{lp} = (t_{rd} - z\,t_{id})/(x + y)$. By method of mixtures, $t_{ed} = (x\,t_{od} + y\,t_{id})/(x + y)$, and $w_e = (x\,w_o + y\,w_i)/(x + y)$, which is the weight of vapor per lb. of air entering washer. The corresponding dew-point, t_{ep} of air entering washer thus is ascertained. Corresponding wet-bulb temperature t_{ew} is given by the psychrometric chart, and h_1 is found in the saturated air table, p. 1–08. The value of h_2, from the saturated air table, corresponds to temperature t_{lp}. Tons of refrigeration required is found by the equation [12].

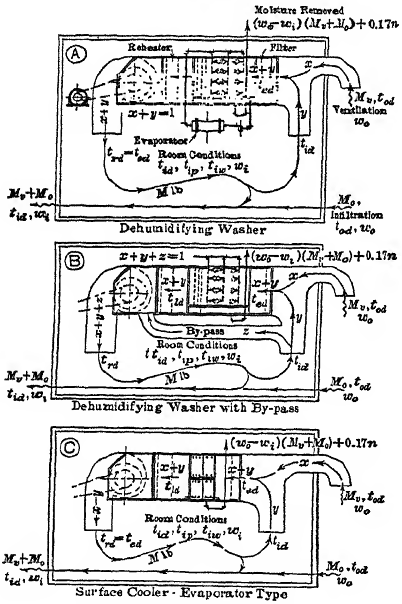

FIG. 4. Dehumidifying Washers and Surface Cooler

EVAPORATOR-TYPE COOLING SURFACE (Fig. 4C).—The heat transfer rate of any type of air cooling is a function of the velocity of air through free area of coils, and of the temperature of coil surface. The following data apply to a common type of evaporator cooling surface made of 5/8-in. copper tubing wound with a continuous copper fin, 8 fins per inch, coils being placed 1 7/16 in. centers. Velocity of air through gross face area of cooling coil enclosure should not be less than 400 ft. per min., to avoid carrying over free moisture. These coils are largely used for direct expansion cooling surface with freon and methyl chloride refrigerants.

One manufacturer furnishes assembled unit coils in sheet-metal casings. Unit casings may be obtained with overall heights of 20 9/16 in. with 12 rows of tubes across face, or 29 in. with 18 rows of tubes across face. Net face area, sq. ft., of unit is $A = \{(\text{casing height, in.} - 3)/12\} \times \{\text{tube length, ft.} - (8.5/12)\}$. Tube lengths obtainable vary from 1 ft. 6 in. to 6 ft. 6 in., in multiples of 6 in. Units are obtainable 1 to 3 rows of tubes deep in direction of air flow. Usually 3 to 5 tube rows depth of cooler is required, assembled from units available. An automatic refrigerant expansion valve is used for each row of tubes in the cooler. Capacity of valves required must be proportioned for the cooling load per row as shown in Table 2.

$$\text{Face area of cooler, sq. ft., } A = M/(0.075 \times 400) \qquad [18]$$

The relation between temperature of coil surface and temperature of refrigerant is $(t_x - t_s) = (H_s - H_v) + H_l$, or

$$t_s = t_x(h_1 - h_2)M/AH \qquad [19]$$

where t_s = temperature of refrigerant in evaporating coils, deg. F.; t_x = temperature of coil surface, deg. F.; H = heat absorbed, B.t.u. per hr. per sq. ft. of face area per deg.

Table 2.—Capacity of Refrigerant Expansion Valve Required in Evaporator Coolers

	No. of Rows Depth in Direction of Air Flow		
	3	4	5
	Proportion of Total Load		
1st Row..	0.417	0.346	0.305
2nd Row.	.319	.265	.234
3rd Row.	.264	.220	.194
4th Row.	....	.168	.148
5th Row.	....	....	.119

temperature difference between t_s and t_x; other notation as before. Values of H are given in Table 3.

Determination of Temperature t_S.—1. Locate on psychrometric chart, Fig. 1, the conditions of the air entering and leaving cooler, wet- and dry-bulb temperature being known. 2. Between the points so located draw a straight line to intersect the saturation line. See Fig. 5. Temperature corresponding to this intersection is required temperature of coil surface t_x. 3. Determine temperature of refrigerant by equation [19].

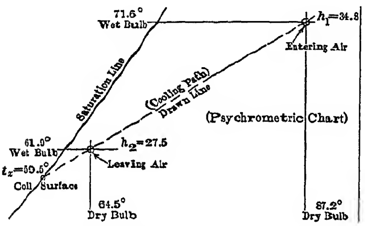

Fig. 5. Determination of Temperature of Refrigerant

Number of Tube Rows, Depth of Cooler depends on the ratio R of the sensible heat to the total heat to be extracted.

where h_x = total heat, B.t.u. per lb., of saturated air corresponding to temperature t_x of coil surface; other notation as before. Table 3 shows the maximum value of R for a given number of tube rows depth.

Reference to the psychrometric chart shows the relation

$$R = (h_1 - h_2)/(h_1 - h_x) = (t_{ed} - t_{ld})/(t_{ed} - t_x) \qquad [21]$$

[22]

Equation [22] enables surface temperatures for various tube loads to be determined.

Table 3.—Relation of Tube Row Depth and Heat Absorbed in Cooler

No. of Tube Rows in Depth...	2	3	4	5	6
R (max.).....................	0.544	0.682	0.770	0.839	0.900
Heat absorbed, H *..........	800	1200	1600	2000	2400

* B.t.u. per hr. per sq. ft. of face area per deg. F. temperature difference between refrigerant and coil surface, based on a heat transfer of 26.21 B.t.u. per hr. per sq. ft. of cooling surface per deg. temperature difference. 1 sq. ft. of face area = 15.9 sq. ft. of surface per tube row.

Example.—Required the face area of evaporative-type surface cooler, number of tube rows depth and temperature of refrigerant required for the following conditions: 10° F. cooling; occupancy, n = 100 persons; outside design conditions, t_{od} = 95° F., t_{ow} = 74.6° F. (38% relative humidity), t_{op} = 66° F., w_o = 0.01370 lb.; inside design conditions, t_{id} = 85° F., t_{iw} = 71° F., t_{ip} = 64° F., w_i = 0.01276 lb.

Solution.—Assume temperature of air entering the room $t_{rd} = t_{ld}$ = 64.5° F., and sensible heat to be removed H_s = 91,363 B.t.u. per hr. Weight of air to be circulated through room and cooler, equation [8],

$$M = 91{,}363/0.24\ (85 - 64.5) = 18{,}570 \text{ lb. per hr.} = 4127 \text{ cu. ft. per min.}$$

Air required for ventilation, M_v = 4050 lb. per hr.

Assume infiltration M_o = 11,600 lb. per hr.

Weight of vapor added to room air by occupants, etc., equation [6],

$$W_1 = (0.17 \times 100) + 11{,}600\ (0.01370 - 0.01276) = 27.9 \text{ lb. per hr.}$$

Weight of vapor to be added to room by ventilation air, equation [7],

$$W_2 = 4050\ (0.01370 - 0.01276) = 3.81 \text{ lb. per hr.}$$

$$W_1 + W_2 = 27.9 + 3.81 = 31.7 \text{ lb. per hr.}$$

Air must leave cooler and enter room with a vapor content of, equation [9],

$w_2 = w_3 = 0.01276 - (27.9/18{,}570) = 0.0112$ lb. per lb. of dry air, which corresponds to a dew-point of 60.5° F., a wet-bulb temperature of 61.9° F. and a heat content h_2 of 27.5 B.t.u. per lb.

Dry-bulb temperature of air entering cooler is, equation [10],

$$t_{ed} = \{(1 - (4050/18{,}570)\}85 + (4050/18{,}570)\ 95 = 87.2° \text{ F.}$$

Air entering cooler carries a weight of moisture, equation [11],

$$w_1 = \{1 - (4050/18{,}570)\}0.01276 + (4050/18{,}570)\ 0.01370 = 0.0129 \text{ lb. per lb. of air}$$

which corresponds to a dew-point of 64.5° F., a wet-bulb temperature of 71.6° F. and a heat content h_1 of 34.8 B.t.u. per lb.

Tons of refrigeration, equation [12], = 18,570 (34.8 − 27.5)/12,000 = 11.3.

By the approximate method, equation [15],

$$\text{Tons of refrigeration} = \{91{,}363 + 9720 + (1060 \times 31.7)\}/12{,}000 = 11.2$$

Face area of cooler, at 400 ft. per min. face velocity is, equation [18], A = 4127/400 = 10.3 sq. ft.

Locate on psychrometric chart, Fig. 1, initial and final conditions of air entering cooler. A line between the points so found intersects saturation line at t_x = 59.5° F. See Fig. 5.

Determine tube row depth by equation [21] and Table 3. R = (87.2 − 64.5)/(87.2 − 59.5) = 0.82, which from Table 3, calls for a 5 row depth of cooler with a value of H = 2000.

Temperature of refrigerant is, equation [19],

$$t_s = 59.5 - \{(34.8 - 27.5)\ 18{,}570/(10 \times 2000)\} = 52.9°\ \text{F.}$$

For weights of refrigerants to be handled by the compressor, compressor displacement, cu. ft. per min., and horsepower required, see section on Refrigeration.

UNIT COOLERS consisting of an assembly of fan, various numbers of rows depth of coils and a dry type air filter are obtainable from several manufacturers. These assembled units are used largely for comfort cooling of restaurants, stores, offices, etc. Unit coolers, consisting of a direct expansion cooler and fan, similar to unit heaters, are used

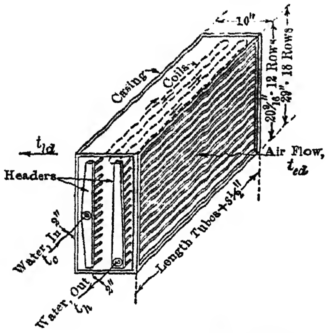

Fig. 6. Unit of Continuous Tube Water Cooler

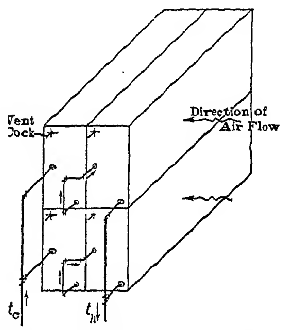

Fig. 7. Assembled Cooler of Four Units

in cold storage rooms in which the air simply is recirculated. Units in which ammonia is the refrigerant are obtainable from a number of manufacturers.

SURFACE TYPE COOLERS WITH CHILLED WATER SUPPLY.—A type of air cooler used in air conditioning is made of copper tubes 5/8 in. diam., with 8 copper ribbon tinned fins per inch of extended surface. The continuous coils are connected, at the beginning and end of run, into a bronze header. See Figs. 6 and 7. Header inlet and discharge connections are 2 in. diam. The coils are assembled in a sheet-metal casing, obtainable with face heights of 12 tubes (20 9/16 in. height of casings), and 18 tubes (29 in. height of casing). Assembled units may be obtained varying in length of finned tube from 2 ft. to 10 ft. in multiples of 6 in. Overall length of casing is (tube length + 8 1/2 in.). Depth of casing in all cases is 10 in.

The net tube area, sq. ft., is

$$(\text{length of tube across face, ft.}) \times \{(\text{casing height, in.} - 3)/12\}.$$

Rated heat transfer surface of these coils is 15.4 sq. ft. per row of tube depth per sq. ft. of face area. The number of tube rows depth also is the number of passes the water makes across the unit. The quantity of water flowing through each unit of the cooler is

$$\text{Gal. per min. (g.p.m.)} = vN/1.235 \quad . \ . \ . \ . \ . \ . \ . \ . \quad [23]$$

where N = number of tube rows high; v = velocity, ft. per sec.

Face area of cooler A = cu. ft. per min. ÷ allowable face velocity V, ft. per min.

Number of tube rows depth N required is

$$N = S/(A \times K \times F \times T_m) \quad . \ . \ . \ . \ . \ . \ . \ . \ . \quad [24]$$

where $S = HR$ = sensible heat to be transferred; H = total heat to be transferred, B.t.u. per hr.; R = ratio of sensible heat to total heat to be abstracted; A = face area

of cooler, sq. ft.; K = sensible heat transfer from air to water per sq. ft. of face area per deg. mean effective temperature difference between air and water per row depth per hr. (see Table 4); T_m = mean effective temperature difference between air and water $= (d_1 - d_2)/\log_e(d_1/d_2)$, where d_1 and d_2 are the greatest and least differences of temperature between entering and leaving air and water. Values of H and R are as follows:

$$H = 0.75 \times \text{cu. ft. per min.} \times (h_1 - h_2);$$

where h_1 and h_2 = respectively initial and final heat content of air passing through cooler, t_{ed}, t_{ld} = respectively, entering and leaving dry-bulb air temperatures, deg. F.

Initial and final water temperatures obviously must be lower than dew-point temperature of leaving and entering air if condensation is to occur. Entering water temperature may be assumed 8 to 10° F. lower than dew-point of entering air.

Table 4.—Values of F and K in Equation 24

Face Velocity of Air ft. per min. V	Water Velocity, v, ft. per sec.*					R	Water Velocity, v, ft. per sec.*				
	1	2	3	4	8		1	2	3	4	8
	Values of K						Values of F

* For wet coil surfaces, with initial water temperature above 50° F., multiply tabular values by 1.35; for water temperatures below 50° F., by 1.50.

Table 6.—Water Friction Loss per Row of Tubes Depth

Length of Tube Unit Across Face, ft.	Water Velocity through Tubes, ft. per sec.				
	1	2	3	4	8
	Friction, ft. head of water				
2	0.10	0.50	1.20	2.20	8.40
4	.15	0.75	1.80	2.80	10.60
6	.20	1.00	2.00	3.45	13.00
8	.22	1.10	2.40	4.02	15.30
10	.25	1.13	2.80	4.70	17.60

Example.—Air entering cooler: Dry-bulb, 95° F.; wet-bulb, 75° F.; dew-point, 66.5° F.; h_1 37.81 B.t.u. per lb.

Air leaving cooler: Dry-bulb, 63.7° F.; wet-bulb, 60.0° F.; dew-point, 58.0° F.; h 26.18 B.t.u. per lb.

H = 1,046,700 B.t.u. per hr. = 17,445 B.t.u. per min. Equivalent volume of standard air to be circulated through cooler = 20,000 cu. ft. per min. = 90,000 lb. per hr.

Face velocity V = 580 ft. per min. Water velocity v = 5 ft. per sec. Initial temperature t_e of water = 50° F., or 8° F. below dew-point of entering air.

Required the number of rows of tubes in cooler.

Solution.—Assume each cooler unit to be 18 tubes high, in parallel. Water required per unit, equation [23], is g.p.m. = 5 × 18/1.235 = 73 gal. per min.

Face area of complete cooler = A = 20,000/580 = 34.5 sq. ft., indicating a cooler 2 units high with 8 ft. length of tubes. Total g.p.m. for both units = 2 × 73 = 146, or 146 × 8.33 = 1213.2 lb. per min.

Temperature rise of water = 17,445/1213.2 = 14.4° F.

Final temperature of water = 50 + 14.4 = 64.4° F., which is lower than the dew-point of entering air.

Maximum temperature difference between air and water at air inlet of cooler is (95 − 64.4) = 30.6° F.

Maximum temperature difference between air and water at air outlet of cooler is (63.7 − 50) = 13.7° F.

Mean effective temperature difference is $(30.6 - 13.7)/\log_e (30.6/13.7) = 20.06$.

$$\text{Arithmetical mean} = \{(95 + 63.7)/2\} - \{(64.4 + 50)/2\} = 22.15$$

Ratio of sensible heat to total heat removed by cooler is

$$R = 0.24\ (95.0 - 63.7)/(37.81 - 26.18) = 0.646$$

Sensible heat S = 1,046,700 × 0.646 = 676,168 B.t.u. per hr.

By interpolation in Table 4, for $V = 580$ and $v = 5$, $K = 190$; for $R = 0.646$ and $v = 5$, $F = 0.889$.

Then, equation [24], $N = 676{,}168/(34.5 \times 190 \times 0.889 \times 20.06) = 5.78$, indicating the use of a 6-row cooler.

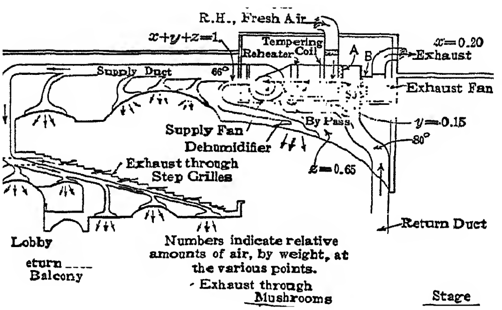

FIG. 8. Air Conditioning of Theater

AIR CONDITIONING A THEATER.—Applying the formulas and data above given for the sensible and latent heat loads and usual outside design dry-bulb temperatures (90° to 95° F.) and 60% relative humidity, the relative weight of fresh outside air, recirculated air, and by-passed air are about as indicated in Fig. 8. That is, $x = 0.20$, $z = 0.65$, $y = 0.15$. Usually the refrigeration requirement is 13.5 seats per ton, or 74.3 tons per 1000 seats.

GASOLINE ENGINES

TABLE OF CONTENTS

DIESEL ENGINES

GAS ENGINES

GASOLINE ENGINES

INTERNAL COMBUSTION ENGINES

DIESEL ENGINES

By Edgar J. Kates

A Diesel engine is a prime mover actuated by the gases resulting from the combustion of a liquid or pulverized fuel, injected in a fine state of subdivision into the engine cylinder at or about the conclusion of a compression stroke. The heat generated by the compression to a high temperature of air within the cylinder is the sole means of igniting the charge. After being ignited, the charge burns and expands, thus converting the heat energy of the fuel into work.

The thermal efficiency of Diesel engines has advanced from 13.5% efficiency of the Hornsby-Akroyd hot-surface oil engine in 1890 to the 41% efficiency (brake Hp. basis) of a 5500-Hp. two-cycle marine engine tested in 1934.

High-compression, self-ignition engines, now being built in the U.S. to which the generic name Diesel is applied, are the outcome of two parallel developments.

The first practical petroleum engine was produced by Julius Hock in Vienna in 1870, and the first compression oil engine of Brayton was built in the United States about 1873. The Hornsby-Akroyd oil engine was the first to meet with undoubted success in 1886-1890. The chief feature of this design was its extreme simplicity of construction. For a complete history of Petroleum Engines, see Gas and Petroleum Engines by W. Robinson; American Diesel Engines by L. H. Morrison.

The Diesel engine, patented in 1892, was designed originally by Dr. Rudolf Diesel to operate on the Carnot or isothermal cycle, and to use pulverized coal as fuel. This engine was unworkable. It was modified to use oil as fuel, and to maintain a nearly constant pressure in the cylinder during the injection of fuel. See Fig. 1. This was the progenitor of the air-injection Diesel engine, which uses a blast of compressed air to inject highly atomized fuel into the cylinder.

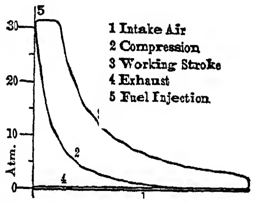

Fig. 1. Diesel Engine Cycle

The solid-injection Diesel engine atomizes the fuel by means of its own pressure, without the use of blast air. It is a development of the low compression, hot-bulb engine. It operates either on the cycle shown in Fig. 2, where the combustion takes place almost instantaneously, or on the so-called dual cycle, Fig. 3. In this cycle the first part of the combustion is at constant volume and the latter part at nearly constant pressure.

1. TYPES OF DIESEL ENGINES

CLASSIFICATION.—Diesel engines may be classified as: 1. *a*, 4-cycle; *b*, 2-cycle. 2. *a*, Single-acting; *b*, double-acting. 3. *a*, Vertical; *b*, horizontal; *c*, radial. 4. By speed. In 1935, rotative speeds ranged from 95 to 2500 r.p.m., and average piston speeds from 690 to 2330 ft. per min. 5. *a*, Air injection; *b*, solid injection; the latter may be subdivided into, b_1, direct injection; b_2, antechamber; b_3, auxiliary air chamber. 6. By size (horsepower). In 1935, Diesel engines were built in sizes of 5 Hp. to 22,500 Hp.

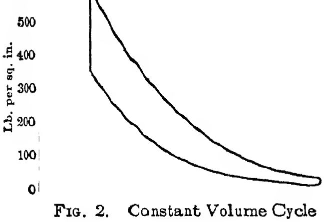

Fig. 2. Constant Volume Cycle

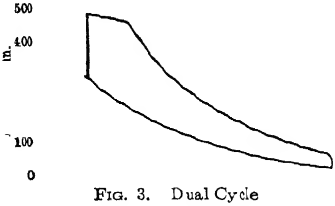

Fig. 3. Dual Cycle

CYCLES OF OPERATION.—All commercially used Diesel engines operate on one of the following cycles: *a*. The 4-cycle (4-stroke cycle, Otto cycle, or Beau de Rochas cycle) completed in four strokes of the piston, *viz.*, 1. Air inlet. 2. Compression. 3. Expansion. 4. Exhaust. See Fig. 4B. *b*. 2-cycle (2-stroke-cycle) where the processes are completed in two strokes of the piston, *viz.*, 1. Expansion (compression stroke having just been completed); at the end of the expansion stroke, exhaust ports are uncovered by the piston, the burnt gases exhausted and pure air at a slight pressure enters the cylinder; 2. Compression, or inward stroke of the piston, which closes the exhaust ports; fuel injection occurs as compression is completed. See Fig. 4A.

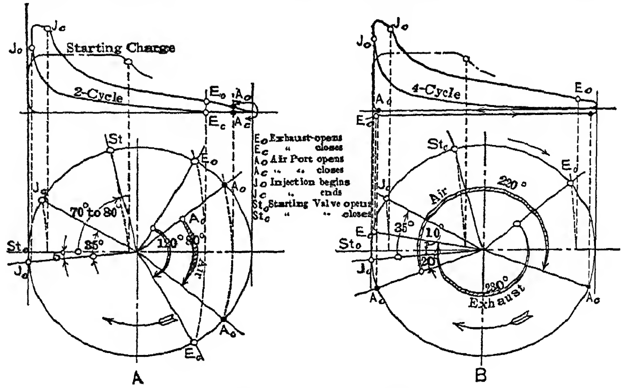

FIG. 4. Operation Cycles

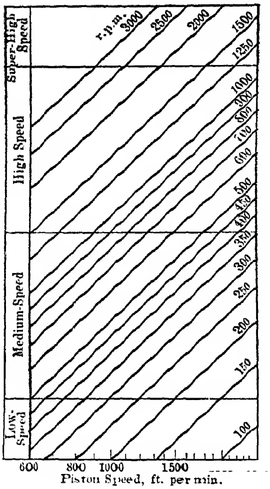

FIG. 5. Speed Classification Chart

Goldingham gives relative advantages and disadvantages of 2-cycle and 4-cycle engines as:

Advantages.—4-Cycle: 1. More complete combustion of fuel. 2. Lower fuel consumption. 3. Greater accessibility where the crank-case is open and moving parts in view. 4. Use of lower grades of fuel without a tendency to carbonize on piston, rings and exhaust passages.

2-Cycle: 1. No exhaust valves, air inlet valves or valve motion. 2. Power developed by piston displacement per unit of volume, 75% to 90% greater than with a 4-cycle type. 3. More even crank effort. 4. Lighter fly-wheel than with 4-cycle type.

Disadvantages.—4-Cycle: *a*. Variable crank-pin effort, requiring heavy fly-wheel. *b*. Greater total weight per horsepower. *c*. Exhaust and air-inlet valves and valve motion necessary.

2-Cycle: *a*. Inferior combustion of fuel and smoky exhaust. *b*. More lubrication and cooling water required. *c*. Increased fuel consumption. *d*. Possible leakage of air with crank-case compression.

SPEED.—Design and construction of Diesel engines are influenced by speed. Increase in rotative speed causes: 1. Increased number of reversals of reciprocating parts. 2. Shortened periods for the various cycle events, as intake of air, exhaust, and particularly injection of fuel. 3. Increase in acceleration of reciprocating parts, accompanied by increased inertia forces on rotating parts. 4. Increased noise due to increased inertia forces and velocities. 5. Larger stresses from torsional vibrations and critical speeds. 6. Increased peripheral speeds of bearings, gears, chain drives. 7. Increased linear speeds of reciprocating wearing surfaces. 8. Increased piston displacement per unit of time, with increased gas velocities through intake and exhaust-valve openings.

Engines commonly are classified as to speed by rotative speed and average piston speed. V. L. Maleev and E. C. Magdeburger (*Trans.* A.S.M.E., OGP–54–5, 1932) show that

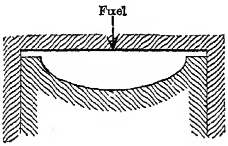

FIG. 6. Combustion Space of Air Injection Engine

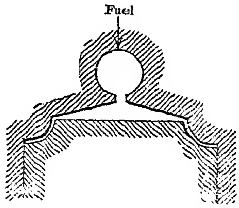

FIG. 7. Antechamber or Precombustion System

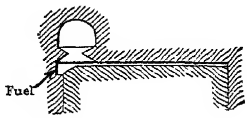

FIG. 8. Auxiliary Air Chamber System

neither of these by itself is suitable. They proposed the characteristic (R.p.m. × piston speed, in ft. per min.) ÷ 100,000. The division lines are:

Speed Class.	Low	Medium	High	Super-high
Speed Characteristic.	Below 3	3–9	9–27	over 27

Any engine may be quickly classified as to speed by means of Fig. 5.

COMBUSTION SYSTEMS.—The principal combustion systems are: 1. Air-injection (blast-injection); fuel is blown into the cylinder and atomized by air at 800 to 1200 lb. per sq. in. Fig. 6 shows shape of combustion space in an air-injection engine. 2. Solid-injection (mechanical injection, airless injection, pump-injection); fuel is precompressed to 800 to 6000 lb. per sq. in., and is atomized by passing through one or more small orifices.

Solid-injection system may be classed as: 1. *Direct injection*, or *single-chamber*. Fuel is injected directly into an undivided combustion space of shape similar to that of Fig. 6. 2. *Antechamber*, or *Precombustion Chamber*, Fig. 7. The combustion space comprises two parts, the antechamber and the main space, joined by a constricted passage. Fuel is injected into the antechamber and is partly burned. The resulting rise in pressure in the antechamber ejects the remaining fuel and hot gases into the main chamber, where the fuel mixes with the air and burns. 3. *Auxiliary Air Chamber*, Fig. 8, often is confused with the antechamber type, because the combustion space similarly is in two parts joined by a constricted passage. The important difference is that the fuel does not burn in the auxiliary air chamber. During the compression stroke, air is forced into the auxiliary

Table 1.—Relative Advantages and Disadvantages of Various Combustion Chamber Types

Direct injection or single chamber See Fig. 6	Antechamber or precombustion chamber See Fig. 7	Auxiliary air chamber See Fig. 8
	Advantages	
Best thermal efficiency.	Low fuel injection pressure.	Low fuel injection pressure.
High mean effective pressures.	Inexpensive fuel injection system.	Inexpensive fuel injection system.
Start from cold without electric heating coils.	Uses fairly viscous fuels.	Uses fairly viscous fuels.
Simple cylinder head design.		Better thermal efficiency and mean effective pressures than antechamber.
Maximum space for valves.		
	Disadvantages	
High fuel injection pressure.	Greater surface-volume ratio than in direct injection. Greater heat loss through jackets.	Lower thermal efficiency and mean effective pressure than direct injection.
High cylinder pressure.		
Sensitive to more viscous grades of fuel.	Lower thermal efficiency; lower mean effective pressures.	Requires heating coils or higher compression for quick starting.
	More difficult to start; requires heating coils or higher compression.	

air chamber, which acts as an air reservoir. Just before top dead center, fuel is injected into the passage between the air reservoir and main combustion space, and combustion starts in the passage. As the piston moves down, air flows out of the air reservoir, both by pressure difference and by inertia effect, meeting the injected fuel in the passage. Pure air for combustion thus is continually supplied to the burning fuel, and the products of combustion pass into the cylinder.

Table 1 summarizes the advantages and disadvantages of the various types of combustion chambers used in solid-injection engines.

FIELDS OF APPLICATION.—The principal fields of application and the types of Diesel engines generally used are: 1. Oil pipe line pumping. Formerly horizontal, now (1935) generally vertical. Two- or four-cycle, slow speed, air or solid injection. 2. Marine propulsion. Vertical, 2- or 4-cycle, air or solid injection. Slow speed for direct drive, medium speed for gear or electric drive. 3. Electric central stations. Vertical, 2- or 4-cycle, slow or medium speed, air or solid injection. 4. Ice-making and refrigeration. Vertical or horizontal, 2- or 4-cycle, slow speed, air or solid injection. 5. Industrial plants, cotton-gins, etc. Vertical or horizontal, 2- or 4-cycle, slow or medium speed, air or solid injection. 6. Construction equipment. Vertical, generally 4-cycle, medium speed, solid injection. 7. Locomotives and rail cars. Vertical, 4-cycle, medium or high speed, solid injection. 8. Auto trucks and buses. Vertical, 4-cycle, high speed, solid injection. 9. Airplane propulsion. Radial, 4-cycle, high or super-high speed, solid injection.

2. THERMODYNAMICS OF DIESEL ENGINES

For general subject of thermodynamics, see Section 4. The Diesel engine is a heat engine whose purpose is to convert the combustion energy of its fuel into mechanical energy. The air which unites with the fuel always is precompressed to raise its temperature so that it will ignite the fuel injected near the end of the compression stroke, and to increase efficiency by subsequent expansion of the burned charge. In any internal combustion engine, compression before ignition extends the range of effective expansion.

Fig. 9 from *Diesel Power*, Dec., 1933, shows the heat balance throughout the range of load. Engines of different makes will show considerable variation.

Power and Efficiency Formulas

DISPLACEMENT of an engine is the volume, cu. ft. per min., swept by the piston or pistons during the power strokes. It is equal to (Number of cylinders × area of each piston, sq. ft. × stroke, ft., × number of power strokes per minute).

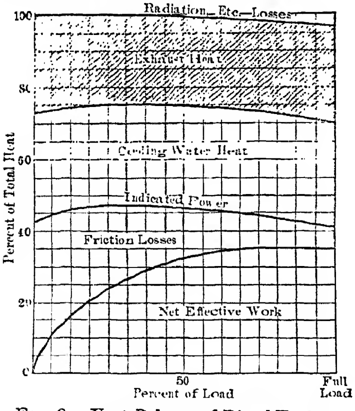

FIG. 9. Heat Balance of Diesel Engine

VOLUMETRIC EFFICIENCY is the ratio V_a/D, where V_a = volume of air, cu. ft. per min., at intake temperature and pressure, induced and compressed, and D = displacement.

INDICATED HORSEPOWER of an engine cylinder is the horsepower developed in the cylinder. The formula is

$$\text{I.Hp.} = (\text{M.i.p.} \times L \times A \times N) \div 33{,}000 \quad [1]$$

where M.i.p. = mean indicated pressure, lb. per sq. in.; L = stroke of piston, ft.; A = net piston area, sq. in.; N = number of power strokes per min.

MEAN INDICATED PRESSURE (M.i.p.) of an engine cylinder is average net pressure, lb. per sq. in., acting on piston throughout one cycle.

BRAKE HORSEPOWER (B.Hp.) is the horsepower delivered by the shaft at the output end. The formula is

$$\text{B.Hp.} = 2\pi l n W/33{,}000 \quad . \quad . \quad . \quad [2]$$

where l = distance between shaft center and bearing point of brake arm, ft.; n = revolutions per minute of brake shaft; W = net weight on brake arm, lb.

BRAKE MEAN EFFECTIVE PRESSURE (B.m.e.p.) is

$$\text{B.m.e.p.} = (\text{B.Hp.} \times 33{,}000)/(L \times \quad [3]$$

PISTON SPEED is the total feet of travel made by each piston in one minute. The formula is

$$\text{Piston Speed} = 2 \times \text{stroke in feet} \times \text{r.p.m.} \qquad [4]$$

INDICATED THERMAL EFFICIENCY is the ratio of the heat equivalent of 1 Hp.-hr. (2545 B.t.u.) to the heat units actually supplied per I.Hp.-hr., based on the higher heating value of the fuel.

BRAKE THERMAL EFFICIENCY is the ratio of the heat equivalent of 1 Hp.-hr. to the heat units actually supplied per B.Hp.-hr., based on the higher heating value of the fuel.

MECHANICAL EFFICIENCY is the ratio of brake horsepower to indicated horsepower.

HEAT LOSSES IN INTERNAL COMBUSTION ENGINES are: *a.* Loss through externally cooled walls, when gases are at maximum temperature and during compression; *b.* Throttling of air inlet and back pressure during exhaust; *c.* Incomplete combustion at maximum temperature and loss through exhaust. The distribution of heat energy in a typical Diesel engine at full load is:

	B.t.u. per B.Hp.-hr.	Percent of heat in fuel
Brake work	2545	33
Friction	680	9
Heating of jacket water	2100	27
Heat in exhaust gases	2200	28
Radiation, etc.	255	3
Total	7780	100

THERMODYNAMIC ANALYSIS OF INTERNAL COMBUSTION ENGINE CYCLES (Goodenough and Baker, *Bull.* No. 160, Univ. of Ill., 1927).—In a theoretical analysis of the cycle of an internal combustion engine three degrees of approximation may be observed. 1. The simplest and crudest system of analysis gives the so-called air standard, which is still used to estimate the engine efficiencies. This analysis assumes that the medium throughout the cycle is air or a gas with the same properties. During the combustion phase the air is supposed to receive an amount of heat equal to the heat of combustion of the fuel. The specific heat of air usually is taken as constant. The air standard efficiency deduced from this analysis always is from 10 to 25% higher than the efficiency obtained from more accurate analyses.

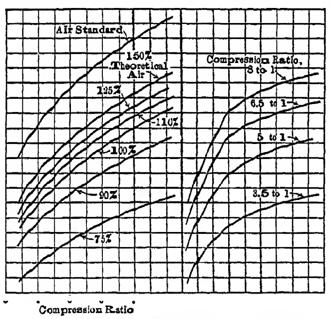

Fig. 10. Variation of Efficiency with Compression Ratio and with Mixture Strength for Otto Cycle

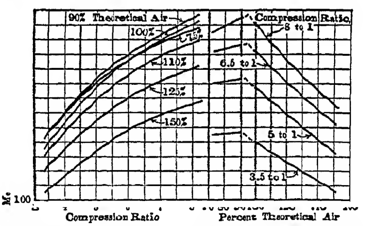

Fig. 11. Variation of M.E.P. with Compression Ratio and Mixture Strength for Otto Cycle

2. The properties of the actual gas mixtures are used. The medium compressed is a mixture of fuel and air; the medium expanding adiabatically after combustion is an entirely different mixture of different properties. In this analysis, it is assumed that combustion is complete before adiabatic expansion begins.

3. It is well known that at the maximum pressure and temperature attained in the cycle, combustion is incomplete, and that, due to dissociation of CO_2 and H_2O at temperatures above 2500° F., the mixture will contain unburned CO and H_2 at the beginning of adiabatic expansion. As the temperature falls during expansion, combustion continues, and at the end of expansion it is practically complete. The third system of analysis takes account of these phenomena.

For the Otto cycle the effect of compression ratio and mixture strength on thermal efficiency is shown in Fig. 10. The effect of these factors on mean effective pressure is

shown in Fig. 11. Corresponding relations for the Diesel cycle are shown in Figs. 12 and 13.

As a result of studies based on the third system of analysis, Goodenough and Baker concluded: 1. Efficiency increases with compression ratio, *i.e.*, the higher the compression the higher the efficiency, other conditions being unchanged. 2. For the same compression, efficiency increases with amount of air used. A lean mixture gives higher efficiency than a rich mixture. 3. Mean effective pressure is a maximum when air supply is somewhat less than 100% of the theoretical amount (Fig. 11). The mixture for maximum power is a mixture of relatively low efficiency. 4. Ideal efficiencies obtained from various liquid fuels are practically the same. 5. Efficiencies of the Diesel cycle, as a group, range higher than efficiencies of the Otto cycle. However, a comparison of the two efficiencies at the same compression ratio (r = 8) shows the Otto cycle inherently to be more efficient than the Diesel cycle. The superior efficiency of the Diesel cycle is due to the high compression ratio permitted by the system of operation.

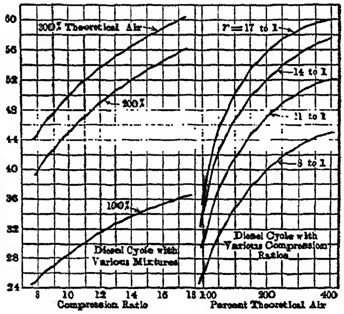

FIG. 12.—Effect of Compression Ratio and Mixture Strength on Efficiency of Diesel Cycle

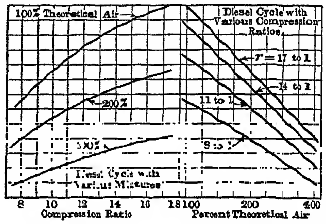

FIG. 13. Effect of Compression Ratio and Mixture Strength on M.E.P. of Diesel Cycle

Ellenwood, Evans and Chwang (*Trans*. A.S.M.E., OGP–50–5, 1928) present Fig. 14, showing in convenient form the efficiency of an ideal Diesel engine using petroleum. A useful temperature-entropy diagram for air and the diatomic gases O_2, N_2 and CO is given by H. A. Everett in *Mech. Engg.*, Mid-Nov. 1926, p. 1329.

COMPRESSION PRESSURES AND TEMPERATURES.—The temperature of the air charge at the end of compression must be high enough to ignite the fuel. The relations of pressures and temperatures at beginning and end of the compression stroke are expressed by $(T_2/T_1) = (P_2/P_1)^{n-1/n}$, where T_1, T_2 = respectively, temperatures

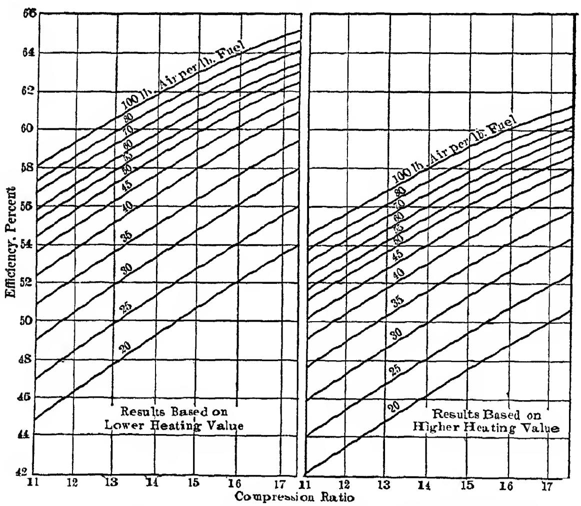

FIG. 14. Efficiency of Ideal Diesel Engine Using Petroleum Oil

(absolute) at beginning and end of compression; P_1, P_2 = respectively, initial and final pressures (absolute). For adiabatic compression, $n = 1.408$. In an actual engine, however, loss of heat occurs, and the value of n is about 1.35. These relations are shown graphically in Fig. 15.

3. RESEARCH ON INJECTION PHENOMENA

The development of light-weight, high-speed engines for automotive use has led to considerable useful research on injection and combustion phenomena. Outstanding work has been done by the National Advisory Committee for Aeronautics at Langley Field, Va., Pennsylvania State College, State College, Pa., H. R. Ricardo, A. L. Bird, and the Royal Aircraft Establishment in England, and F. Sass, K. Neumann and R. Kuehn in Germany.

A few of the significant findings are abstracted below. See original reports mentioned for full details.

FACTORS IN THE DESIGN OF CENTRIFUGAL TYPE INJECTION VALVES FOR OIL ENGINES (Nat. Advis. Comm. for Aeronautics, Report No. 268, 1927).—The general method was to record the development of single sprays by high-speed photography, taking 25 consecutive pictures of the moving spray at a rate of 4000 per second. Investigations were made of effects on spray characteristics of the helix angle of helical grooves, ratio of cross-sectional area of orifice to that of the grooves, ratio of orifice length to diameter, and position of the seat. Sprays were injected at 6000, 8000 and 10,000 lb. per sq. in. pressure into air at atmospheric pressure, and into nitrogen at 200, 400, and 600 lb. per sq. in. pressure. Orifice diameters were from 0.012 to 0.040 in.

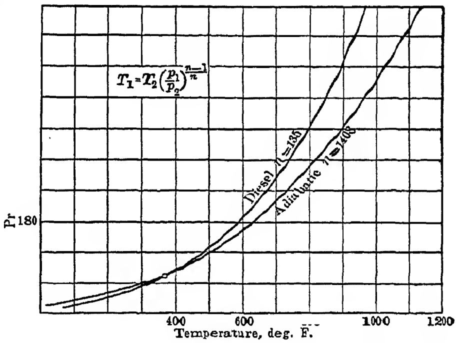

FIG. 15. Relation of Pressure and Temperature of Air

Decreasing the pitch of the helical grooves, thus increasing the centrifugal force applied to the spray, increased the spray cone angle considerably; percentage increase was much less in dense air than in atmosphere. Spray penetration decreased as centrifugal force applied increased. About twice the spray volume per unit oil volume was obtained with a high centrifugal spray as with a non-centrifugal spray. Spray cone angle increased, and spray volume-oil volume ratio, and spray penetration decreased with increase in ratio of orifice area to groove area. Maximum spray penetration occurred at a ratio of orifice length to diameter of about 1.5. Slightly greater penetration was obtained with the seat directly before the orifice.

EFFECT OF ORIFICE LENGTH-DIAMETER RATIO ON FUEL SPRAYS FOR COMPRESSION-IGNITION ENGINES (N.A.C.A. Report No. 402, 1931).—With a plain stem in the injection valve and an increase in length-diameter ratio of the orifice from 0.5 to 10, rate of spray-tip penetration decreased to a minimum between ratios of 1.5 and 2.5, reached a maximum between ratios of 4 and 6, and again decreased as ratio was increased to 10. Exact position of maximum and minimum points depended upon orifice diameter. Spray cone angle was affected but little by variation either of diameter of orifice or length-diameter ratios greater than 4.

With a helically grooved stem in injection valve, ratios at which highest penetration occurred ranged between 5 and 7. Spray cone angle increased with increased ratio of orifice area to groove area.

N.A.C.A. APPARATUS FOR STUDYING FORMATION AND COMBUSTION OF FUEL SPRAYS. (N.A.C.A. Report No. 429, 1932).—The report includes result of tests to determine effect of air temperature, air flow, and nozzle design on spray formation. Compression temperature has little effect on penetration of fuel spray, but does affect dispersion. Air velocities of about 300 ft. per sec. are necessary to destroy the spray core. Effect of air flow on spray is controlled to a certain extent by design of injection nozzle. Results of tests on combustion of spray show that when ignition occurs after spray cut-off, ignition may start almost simultaneously throughout the combustion chamber or at different points in the chamber. When ignition occurs before spray cut-off, combustion starts around the edge of the spray, and spreads throughout the chamber.

FUEL VAPORIZATION AND ITS EFFECT ON COMBUSTION IN A HIGH-SPEED COMPRESSION-IGNITION ENGINE (N.A.C.A. Report No. 435, 1932).—Tests were made to determine whether or not fuel injected into a high-speed compression-ignition engine vaporizes appreciably during the time available for injection and combustion. Effects of injection advance angle, fuel boiling temperatures, fuel quantity, engine speed, and engine temperature were investigated. The results show that an appreciable amount of fuel is vaporized during injection even

though temperature and pressure in engine are too low to cause ignition either during or after injection. When conditions are such as to cause ignition, the vaporization process affects combustion.

INJECTION LAG IN A COMMON-RAIL FUEL INJECTION SYSTEM (N.A.C.A. Technical Note No. 332, 1930).—Injection lag increased lineally with increase in injection tube length, but was not affected by the bore of the tube. Lag increased slightly with increase of valve opening pressure, and decreased materially with increase of injection pressure. Initial pressure in injection valve tube before timing valve opened did not affect injection lag, if injection pressure was considerably in excess of valve opening pressure.

INVESTIGATION OF THE DISCHARGE RATE OF A FUEL-INJECTION SYSTEM (N.A.C.A. Technical Note No. 373, 1931).—Fuel discharged by a cam-operated pump and automatic injection valve was collected in a rotating receiver. Ninety-eight percent of the fuel was discharged during an interval of 25 deg., whereas the period from start to stop of the fuel spray was 68 deg.

EFFECT OF HIGH VELOCITIES ON DISTRIBUTION AND PENETRATION OF A FUEL SPRAY (N.A.C.A. Technical Note No. 376, 1931).—High-speed moving pictures were taken of the formation and development of fuel sprays from an automatic injection valve. Sprays were injected normal to, and counter to, air at velocities from 0 to 800 ft. per sec. Air was at atmospheric temperature and pressure. Results were: 1. Air velocities of approximately 400 ft. per sec. are necessary to break up the central core of a fuel spray from a single, round-hole orifice during the injection period in a high-speed compression-ignition engine. 2. Lower velocities have little effect on the main body of the spray during injection, but break up the spray at the end of injection.

PHOTOMICROGRAPHIC STUDIES OF FUEL SPRAYS (N.A.C.A. Technical Note No. 424, 1932).—Photomicrographs were taken of fuel sprays injected into air at various densities in order to study spray structure and the stages in the atomization of fuel. Fuel leaves the nozzle as a solid column, is ruffled and then torn into small, irregular ligaments by action of the air. The ligaments quickly are broken into drops by the surface tension of the fuel. The photomicrographs also show that dispersion of a fuel spray at a given distance from the nozzle increases with increase in jet velocity, or increase in air density.

4. SUPERCHARGING

SUPERCHARGING.—The amount of energy that can be produced in a given size of Diesel cylinder, charged with air in the ordinary way, is limited by the amount of fuel that can be burned efficiently in the air available. By artificially increasing the amount of air, more fuel can be burned efficiently and more energy produced. The artificial increase of combustion air supplied to the cylinder before fuel injection is called supercharging.

The best known systems of supercharging are the Rateau and the Buchi. Both provide the supercharging air by means of turbine-driven centrifugal blowers, using exhaust gases of the engine as motive fluid. By proper adjustment of compression ratio and air excess, supercharged engines are not subjected to higher temperatures or higher maximum pressures than exist in similar normally-charged engines, although average cylinder pressures are higher. Pressure of the supercharging air is about equal to pressure of the exhaust gases, generally 18 to 20 lb. per sq. in., absolute. Engine capacity is increased 30 to 40%.

According to Max Rotter (*Trans.* A.S.M.E. OGP-53-9, 1931), in the Buchi system the speed of the blower and, therefore, the pressure of supercharging air automatically adjust themselves to the existing engine load, due to variation of exhaust pressure with load. High efficiency results, with a flat fuel-consumption curve. The Buchi system is suitable for continuous operation, and has been applied exclusively to four-cycle engines.

The Sulzer system primarily is intended to increase overload capacity of a two-cycle Diesel engine. Supercharging air is furnished by a compressor, attached to the engine, whose action is so controlled by the engine governor that supercharging occurs only at the higher engine loads. Automatic valves in the upper tier of Sulzer scavenging ports for normal scavenging and charging are supplemented by timed valves, controlling delivery of supercharging air to the cylinder. Air furnished by the supercharging compressor is admitted only toward the end of the charging period. Engine capacity temporarily may be increased as much as with the Buchi system, but fuel efficiency of the engine is affected adversely about 5%, due to the power consumed by the supercharging pump, even when not in action.

Another system of supercharging has been applied to German 4-cycle engines to accomplish the same purposes as the Sulzer system. Supercharging air is furnished by a compressor attached to the engine. In addition to the normal admission valve, a timed supplementary piston valve delivers excess atmospheric air to the admission valve during the earlier part, and of supercharging air during the latter part, of the suction stroke. Dimensions and power consumption of the charging compressor are less than they would be if all charging air were furnished by it, but fuel consumption at all loads is increased.

Complete tests of the Buchi system were made by Prof. A. Stodola, Zurich, Switzerland. (See *The Shipbuilder*, June, 1928, p. 413.) The tests were made on a 4-cycle, 6-cylinder engine, standard

except for the addition of the exhaust-gas turbo-blower supercharger. The normal rating of the engine without supercharger was 850 Hp. at 167 r.p.m. With the turbo-blower, output was increased to 1275 Hp., with combustion and exhaust temperatures the same as at normal rating. Even at 1652 B.Hp. output, engine exhaust was absolutely clear. At 1275 B.Hp., fuel consumption was 0.391 lb. per B.Hp.-hr. The lower calorific value of the fuel used was 18,240 B.t.u. per lb. The same engine, without supercharging, consumed 0.408 lb. of fuel per B.Hp. per hr. The turbo-supercharging improved fuel consumption of the engine tested by about 4%, due to increase in mechanical efficiency from 72 to 80.2% referred to normal rating of the engine.

Another feature of the Buchi system is the reduced amount of heat passing through walls of piston, cylinder, and cylinder head, *i.e.*, 1620 B.t.u. per B.Hp. per hr. at full load. An engine of a similar speed, with uncooled pistons and a fuel consumption of 0.41 lb. per B.Hp.-hr., showed a loss through the cooling water of 28.7% of the heat value, equal to 2130 B.t.u. per B.Hp. per hr.

5. HEAT RECOVERY

The heat energy of the fuel supplied to the Diesel engine finally is distributed as actual work at the engine crank-shaft, frictional losses, heating of cooling water in engine jackets, heat in the exhaust gases, and miscellaneous heat radiation to atmosphere. Table 2 gives a typical heat balance. The jacket water heat, 27% of the heat in the fuel, almost equals the heat utilized as work. Jacket water heat can be utilized directly in the form of warm water. About 40% of the exhaust, or 11% of the heat of the fuel, can be recovered by passing it through a simple heat exchanger with a moderate amount of surface. By thus utilizing jacket and exhaust heat, an additional recovery of about 38% may be obtained, corresponding to about 4500 B.t.u. per kw.-hr.

Although the exchanger reclaims less than one-third of the total heat recovered, it is important in that it raises the temperature of the water higher than would be safe in the engine jackets. Thus if water enters the engine jackets at 40° F. and leaves them at 140°, it will leave the exhaust heat reclaimer at about 180° F. This final temperature rise makes the water useful where a temperature of 140° would be too low. Exhaust heat also can be used to make steam, but only part of the jacket water can be evaporated. However, if the quantity of steam needed is small, and the rest of the jacket water can be used as warm water, all the heat can be recovered.

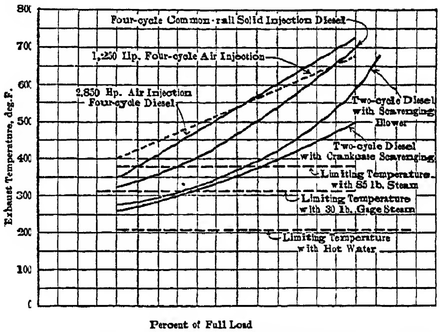

Fig. Representative Exhaust Temperatures of Various Diesel Engines

EXHAUST HEAT RECOVERY.—At full load (at the point a heater could be installed) the exhaust of a heavy-duty 4-cycle engine will be at 650° to 800° F. A 2-cycle engine exhaust will be at 450° to 600° F. Heat recovered will vary in proportion to temperature drop in exhaust gas as it passes through the boiler. More heat can be recovered in heating water than in generating steam. In steam generation, heat recovery is greater with low-pressure than with high-pressure steam, as the temperature limits are lower in generating low-pressure as compared with high-pressure steam. For practical purposes, gas temperature leaving an exhaust-heat boiler should be above 250° F., although a temperature as low as 200° F. will not cause the water vapor to condense. Fig. 16 (*Diesel Power*, Dec., 1933) shows representative exhaust temperatures of different types of engines at various loadings.

Table 2.—Heat Balance of Diesel Engine

	B.t.u. per B.Hp.-hr.	Percent	Useful Percent	Heat Recoverable, B.t.u. per B.Hp.-hr.
Brake work	2545	33	33	....
Friction	680	9	....	....
Jacket water heat	2100	27	27	2100
Exhaust gas heat	2200	28	11	880
Radiation, etc.	255	3	....	....
Total	7780	100	71	2980 = 4500 B.t.u. per kw-hr.

The quantity of heat recoverable from the exhaust gas at any load may be estimated roughly from the formula

$$Q = (\text{B.Hp.} \times C \times D)/4 \quad . \quad . \quad . \quad [5]$$

where Q = recoverable heat, B.t.u.; B.Hp. = brake horsepower at the load in question; C = a constant (approximately 12 for 4-cycle engines, 20 for 2-cycle engines); D = temperature drop of exhaust gases through heater, deg. F.

Exhaust heaters may be fire-tube, water-tube or thimble-type, and in general, are similar to the corresponding types of fuel-fired boilers, except that heating surfaces are larger. They are compact and inexpensive. When used with modern high-grade Diesel engines, they are quite easy to keep clean, as little or no soot is deposited. They also are effective silencers.

The recovery of waste heat from Diesel engines is especially valuable in mild weather, if it permits shutting down a fuel-burning boiler or discontinuing purchased steam. A good use for this heat is in a combination steam and Diesel plant, where the Diesel jacket water at, say, 140° F. goes directly to the feedwater heater, thus recovering about 27% of the heat of the Diesel fuel. The utilization of heat in the jacket water serves a double purpose. It effects a reduction in heat required from other sources, and also eliminates equipment for cooling jacket water, or the expense of wasting it.

Table 3 gives the results of tests of a Foster-Wheeler water-tube muffler-boiler, with 1400 sq. ft. of extended heating surface, connected to a 4000-Hp. Hooven-Owens-Rentschler double-acting, 2-cycle, 4-cylinder, air-injection Diesel engine.

Table 3.—Test of Boiler Utilizing Diesel Engine Exhaust Gases

Steam pressure, lb. per sq. in., gage	43.5
Back pressure on engine exhaust, in. of water	6.00

6. COMBINED DIESEL-STEAM POWER PLANTS

Diesel engines have been used in conjunction with steam engines to obtain greater overall economy in production of both power and heat. When all the exhaust of a steam power unit can be used for processes requiring heat, power is produced as a by-product. The boiler plant practically would be as large and burn as much fuel if it produced steam solely for heating. If the demand for heat is not large enough or uniform enough to utilize all the exhaust from engines or turbines, some exhaust heat is wasted. This waste may be reduced by the addition of Diesel engine capacity to carry the load when there is no demand for heat, or to carry that portion of the load that exceeds the demand for exhaust steam.

The advantages of such a combination plant are: 1. The Diesel engine is compact and self-contained. It easily can be installed in an existing plant. 2. It need not interfere with operation of the steam plant. 3. Investment is moderate. 4. The same staff can operate and maintain steam and Diesel equipment. 5. The Diesel equipment is an emergency reserve for the steam plant. 6. Heat in Diesel jacket water generally can be used to advantage. If desired, an exhaust gas boiler may be used to recover the Diesel exhaust heat. 7. The foregoing combine with the fuel efficiency of the Diesel engine to give low operating costs.

Exhaust-use Factor

The economy of a steam plant supplying power and heat depends on the exhaust-use factor, *i.e.*, a ratio representing the proportion of the total steam power that is by-product. Before adding a Diesel engine to an existing steam power plant, the exhaust-use factor must be determined accurately.

In determining the amount of by-product power, figures for power and heat requirement should be measured over short periods for each different operating condition. Daily

averages may lead to large errors; longer periods, as a week or a month, are practically worthless, as long periods disregard the diversity of demands for power and heat. Even if daily average process or heating steam demand exceeds average power demand, there always are periods when conditions are reversed. When power demand exceeds heating demand, some or all of the exhaust steam is wasted. Hence, the exhaust-use factor should be determined by readings for periods of one hour or less, taken at various times of the day, week and year.

The addition of a Diesel engine to a steam-power plant may improve overall economy by: 1. Increasing exhaust-use factor of steam plant. 2. Replacing expensive *prime steam power* (steam engine power corresponding to wasted exhaust steam) with less expensive Diesel power. In such case, steam units are loaded to the point of best overall economy for the entire plant, and the Diesel generates the remainder of the power.

In a study of the joint use of the Diesel and steam engines in a definite project, it is best to select arbitrarily several different combinations of commercial sizes of Diesel and steam engines. With existing steam plant, only the amount of Diesel power to be added is determined. For each combination a series of charts is made for all seasons of the year, based on curves of hourly demands for power and heat. These charts should show: 1. Amount of steam needed to supply heating load. 2. Amount of by-product power that can be produced from that steam. 3. Amount of additional power that Diesel equipment can generate. 4. Amount of prime steam power, if any, that must be produced if Diesel plant cannot generate all power required in excess of by-product steam power. From these charts may be computed the quantities of coal and the Diesel fuel that will be used, thus determining for each combination the annual cost of boiler and Diesel fuel. To the fuel costs must be added cost of attendance, repairs, ash-disposal, water and supplies. Costs will vary with each combination, depending on relative capacity and kw-hr. output of the steam and Diesel parts of the combination. The sum of these items is total annual operating cost, to which are added fixed charges, as taxes, interest, amortization and insurance. The resulting overall annual costs of the several combinations then can be compared.

7. AUTOMATIC DIESEL PLANTS

Automatic electric-generating units driven by gasoline engines, as farm-lighting outfits, have been used for twenty years; the automatic multiple-unit Diesel-electric power plant is a recent development. Up to August, 1935, four such plants, based upon patents of C. F. Strong, had been installed. All supply direct current.

This type of plant consists of several Diesel-electric generating units, operating in parallel with a storage battery and a battery booster, all controlled automatically. The generating units start and stop in accordance with load requirements; line voltage is maintained constant, regardless of load surges; all supply services to engines are fully controlled and safeguarded. Engines are started by supplying battery current to their

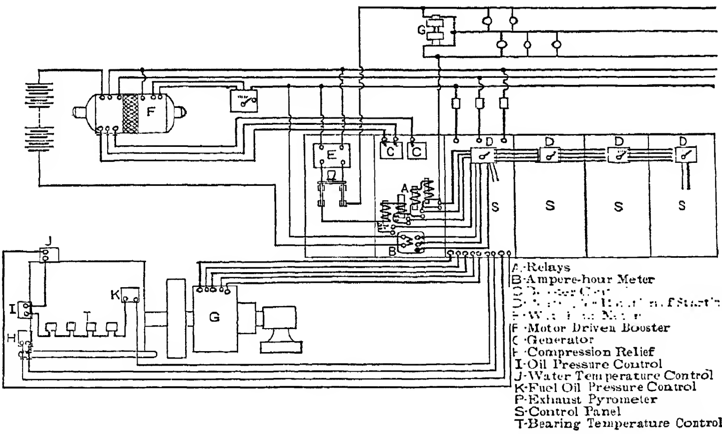

Fig. 17. Diagram of Automatic Control System

generators, the battery-booster regulation maintaining constant voltage on the line during starting. Battery and booster also absorb line load surges, and prevent flicker of lights.

To insure reliability, a spare unit is installed, with controls so arranged that any unit failing to start, or developing trouble while running, automatically is stopped and disconnected, and the spare unit started in its place in less than 30 seconds. The storage battery meanwhile supplies any deficiency in power. A unit disconnected from the circuit, due to trouble, automatically transmits a signal to a central office.

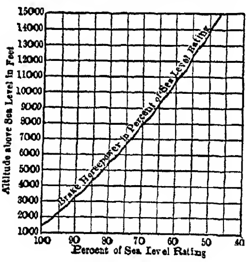
A diagram of the Strong automatic control system for a 4-unit plant is shown in Fig. 17. The control panel of the switchboard has, for each engine, a spring-loaded relay in series with the line. The relays are adjusted to act with an increase of load on the building feeder lines, and cause the engines to start. The switchboard relays are set to keep but one engine in operation if the current flowing to the building lines does not exceed a predetermined value. When current increases beyond the capacity of the first engine, second, third and fourth units are started successively in accordance with the load. As load decreases the engines are stopped in sequence. The operating units thus have an economical load factor. While idle, exhaust valves are held open by a spring opposing a solenoid, to prevent compression in the cylinders. Also, the governor mechanism holds open the by-pass valves of the fuel pumps, preventing injection of fuel into the cylinders. When the load requires starting an engine, the generator acts as a motor, using battery current, bringing the engine up to about half speed. The solenoid operating the compression relief mechanism then is energized and full compression thrown on the engine.

To insure continuity of service, each generating unit is entirely independent, the only common points being the main fuel storage tank and the switchboard bus-bars. Each generating unit is controlled by its own automatic switching panel. Safeguards are provided for jacket water temperature, lubricating oil pressure and main bearing temperature. In case of derangement the engine affected is stopped automatically, and the spare unit started in its place.

8. STANDARD DIESEL ENGINE PRACTICE

The following is an abstract of tentative (1935) standard practices of the Diesel Engine Manufacturers' Assoc., as given in the book of standards of the association.

STANDARD SEA-LEVEL RATING of a Diesel engine is the net brake horsepower that engine will deliver continuously when in good operating condition and located at not over 1500 ft. above sea level, with atmospheric temperature not over 90° F. and barometric pressure not less than 28.25 in. of mercury. The standard rating must be such that the engine will deliver an output of 110% of rating, with safe operating temperatures for two out of any 24 hours.



rsepowe
ngines
Altitudes

Net Brake Horsepower is horsepower delivered to the engine crank-shaft coupling, less any power consumed by certain separately-driven auxiliaries, if used, *i.e.*, injection-air compressor (for air-injection type engines), scavenging air pump or blower (for supercharged engines), and pumps for circulating lubricating or piston-cooling oil through engine or oil cooler. No deductions are made for power to drive such auxiliaries when mechanically driven by the engine. No deductions are made for auxiliaries intermittently operated, or governed in size or operation by special conditions of plant apart from the engine, *viz.*, centrifuges, compressors for starting-air, and pumps for oil-transfer, circulating water and raw water.

RATINGS AT HIGHER ALTITUDES.—The net brake horsepower capacities of a normal supercharged Diesel engine at various altitudes, in percent of sea-level rating, are given in Fig. 18. The power that a Diesel engine can deliver decreases with increase in altitude. The resultant decrease in atmospheric density decreases horsepower by: 1. Decreasing amount of oxygen available for combustion. 2. Decreasing possible rate of heat absorption. The reduction in rating due to an increase in altitude is not exactly in proportion to the decrease in barometric pressure because horsepower required to overcome internal friction remains nearly constant for all altitudes.

CAPACITY AND FUEL-CONSUMPTION GUARANTEES.—Guarantees of brake horsepower capacity and fuel consumption are based on tests conducted by the engine builder on his shop test floor. Brake horsepower capacity guarantees for non-super-

charged engines are contingent on an air-intake pressure of not less than 28.25 in. of mercury, and air-intake temperature of not over 90° F. Sea-level fuel-consumption guarantees are made in fractions of a pound per net brake horsepower at half, three-quarters and full loads, when operating at rated revolutions per minute. Such guarantees are referred to a fuel oil of a high heat value of 19,000 B.t.u. per lb. All sea-level fuel-consumption guarantees are contingent on the following conditions: 1. Intake-air temperature between 40° and 90° F., inclusive. 2. Barometric pressure of intake air between 28.25 and 30 in. of mercury, inclusive. 3. Fuel oil to conform to engine builder's specifications for type of engine involved. In adopting these standard practices, the engine builder absorbs the differences in performance caused by three variables. Since these variables may operate adversely in a cumulative way, fuel-consumption guarantees are subject to a tolerance of 5%.

Standard fuel consumption guarantees are not made for quarter load, because tests at this load are inaccurate and not reproducible. The fuel consumption rate at the guarantee points increases with increase in altitude, principally because of the different full-load ratings. Fuel consumption for altitude operation is guaranteed, therefore, on a basis of the rate at corresponding *horsepower* load under sea-level conditions.

FIELD TESTS FOR HORSEPOWER CAPACITY AND FUEL CONSUMPTION.—Horsepower capacity, fuel consumption or other tests made after the engine is installed in its ultimate location, are made in accordance with the Field-test Code.

LUBRICATING OIL CONSUMPTION.—The same Diesel engine if installed in several plants in succession, would show different rates of lubricating oil consumption, so material is the influence of plant conditions and operation on lubricating requirements. These conditions are beyond the control of the engine builder, and it is not feasible to guarantee lubricating oil consumption.

STANDARD EQUIPMENT FOR STATIONARY ENGINES.—The standard of minimum equipment furnished with stationary engines is as follows:

Engine fly-wheel, unless weighted rotor (fly-wheel-type) generator is to be driven; extension shaft and outboard bearing; engine piping to common inlet and outlet nozzles; exhaust manifold or individual exhaust pipes to conduit below floor; air-inlet manifold; strainer-type fuel oil filter; strainer-type lubricating oil filter; lubricating oil sump tank; force-feed lubricator (if required by design); all necessary lubricating oil pumps and coolers; all necessary piston-cooling oil pumps and coolers (for oil-cooled pistons); lubricating oil pressure gage; thermometers for engine circulating water; thermometers for piston-cooling oil or water (if pistons are cooled); piston-oil cooler (for oil-cooled pistons); safety, or relief, valves; synchronizing device, hand or pneumatically operated; a set of tools, but not including any tools that can be purchased in the open market (these are not duplicated for a plant where two or more engines are installed); a minimum set of spare parts; such platform and steps or stairs as may be required; drilled and tapped holes for exhaust-temperature measuring devices, but not including such devices; drilled and tapped holes for attachment of indicator, but not including indicator, indicator cocks or reducing motion; complete foundation bolts, including generator and exciter bolts if these units are to be driven; the services of an erection superintendent, from the time the building and foundations are ready and the machinery is at the site, until 7 days after the equipment is ready for commercial operation.

STANDARD GOVERNOR PERFORMANCE.—Two types of governors commonly are furnished: 1. Centrifugally-powered type. 2. Relay-powered type. The choice depends on the class of service.

Centrifugally-powered governors will conform to the following standards: 1. Governor will control engine speed to within 3% above or below mean speed, at all loads between no-load and full-load for gradual changes in load. 2. Governor will control the momentary engine speed change to within 5% above or below mean speed, at all loads between no-load and full-load, for sudden changes in load, where engines are intended for parallel operation. 3. Stabilization period will not exceed 20 seconds. 4. Sensitiveness will not exceed $^1/_4$ of 1%. 5. Under constant load there will be no hunting; with the load changing there will be no persistent false governor movements.

Relay-powered governors will conform to the following standards: 1. Governor will control the engine speed to within 3% above or below the mean speed, at all loads between no-load and full-load for gradual changes in load. 2. Governor will control the momentary engine speed change to within 5% above or below the mean speed, at all loads between no-load and full-load, for sudden changes in load, where engines are intended for parallel operation. 3. Stabilization period will not exceed 10 seconds. 4. Sensitiveness will not exceed $^1/_{100}$ of 1%. 5. Under constant load there will be no hunting; with the load changing there will be no persistent false governor movements. 6. The speed-droop will be adjustable during operation from zero to 6%. 7. Average frequency control, commercially accurate, may be specified when the governor is adjusted to zero speed-droop.

STANDARD OF PARALLEL OPERATION.—It is standard practice to build engine-generator units capable of running in parallel with other generating units, provided that

such other generating units are: 1. Capable of operating in parallel with each other. 2. Equipped with proper damper windings. 3. Equipped with voltage regulators with adequate cross-current compensation.

TORSIONAL VIBRATION AND CRITICAL SPEEDS.—Standard practice is so to co-ordinate the assembly of each engine and driven equipment that the peak of any deleterious critical speed for a constant-speed unit will not fall within a range of speed of 10% of the rated speed of the unit.

9. SELECTION AND INSTALLATION OF STATIONARY DIESEL ENGINES

(Abstracted from Standard Practices of Diesel Engine Manufacturers' Assoc., 1935.)

SELECTION OF SIZES.—The general principles to be followed in the selecting of Diesel engines are: 1. The most efficient load range, from the standpoint of fuel economy, is from half load to full load. 2. A small engine is practically as efficient as a large one. 3. Dependence should not be placed on overload capacity to handle regularly recurring peak loads. 4. Additional engines easily can be added at any future date.

LOAD VARIATION is presented most effectively in curve form, using successive power demands as ordinates and hours of the day as abscissæ. Number and size of engines should be selected to conform with load conditions.

OVERLOAD CAPACITY.—While Diesel engines are rated to allow some overload capacity for short periods, this should not be utilized to handle routine peak loads. Any predictable load should be within the combined ratings of the engines.

POWER TRANSMISSION.—Diesel engines may be direct-connected to driven machinery if starting torque can be limited to less than 50% of full-load torque.

CLUTCHES.—Torque delivered by a Diesel engine reaches full-load value at 25% to 35% of full load speed. Machinery requiring a high starting torque, but requiring only normal torque immediately after starting, may be driven by Diesel engines through clutches. A flour mill line-shaft is a typical instance.

CLUTCH PULLEYS.—For belt drives clutch pulleys should be on the driven, rather than on the driving, shaft. If driving shaft location is essential for the clutch, driving pulley should be on a quill.

ELECTRIC, HYDRAULIC AND PNEUMATIC DRIVES.—Where prolonged high starting torque is required, electrical, hydraulic, pneumatic, or a combination clutch and sliding gear drive is necessary. Such transmissions are used in Diesel locomotives, shovels and drag lines.

MACHINERY LAYOUT.—In designing a Diesel plant, machinery should be laid out first and buildings designed around it. Good natural light contributes to lower operating costs. Ample space should be allowed around each engine. When engines and auxiliaries have been worked into the floor plan, a work room and store room should be added. All floors should drain to one or more drains. The engine builder's specifications of minimum headroom from top of engine to bottom of crane hook should be observed.

SPACE FOR FUTURE UNITS.—If more horsepower possibly will be needed at a future date, space should be allowed for it in the building, or the building so designed that it can be extended. Doorways should permit the introduction of future units and parts for present units.

CRANES.—The best crane layout provides runways on either side of the building for a traveling crane that can serve the entire floor area. The crane may be hand operated, but with two or more engines, cost and time of erection can be reduced if the hoist is motor-driven. Individual cranes may be mounted on I-beam tracks over each engine center line, extending sufficiently beyond units to allow easy landing of parts.

ARRANGEMENT OF TWO OR MORE ENGINES.—The most compact arrangement for two or more engines is side by side. This permits locating engine auxiliaries at one side of the room and driven apparatus with appurtenances at the opposite side.

FOUNDATIONS.—Manufacturers supply foundation drawings with each engine sent out. These drawings usually apply for a bearing of hard pan, confined gravel, hard clay, or rock. If such firm sub-soil lies considerably below the minimum depth required, the foundation may be designed in the regular way, but supported on piling. An alternative construction is a reinforced slab supported by reinforced concrete pillars. An expert foundation engineer should be consulted where special conditions exist.

Minimum Depth for Foundations should be sufficient to prevent settling from frost, vibration, or influence of loads borne by adjacent ground, irrespective of firmness of sub-soil. If solid rock exists at less than the recommended depth, excavation should be

carried a foot or two into the rock to secure firm anchorage; in no event should absurdly shallow foundation be allowed.

Foundation Over Underground Water.—An engine foundation never should be located over underground water without the advice of an experienced foundation expert, nor without full details being given to the engine builder.

Foundation Bolt Template.—The bolts should be supported by a template, carefully leveled, resting on the foundation forms. Each bolt should be surrounded with iron pipe or stove pipe, supported by the bottom washer, and stopped with waste at the upper end to prevent entrance of concrete.

Pouring the Concrete.—The foundation should be of concrete, one part cement, two parts sand, and four parts broken stone or gravel (1 in. maximum). The entire foundation should be poured at one time, with no more interruptions than are required for proper spading and ramming. The top should be level, and left rough and clean for grouting. After pouring, the top should be covered and wet down twice daily until the forms are removed at the end of the third or fourth day. The engine should not be placed on the foundation until ten days have elapsed, nor operated until another ten days have passed.

Leveling the Engine.—The engine should be leveled by wedges resting on steel plates on the top of the foundation, and grouted in with a thin mixture of one part cement and two parts sand. The grout should fill the pipes around the foundation bolts. The leveling wedges should be removed after grout has thoroughly set.

PIPING AND WIRING should be located in trenches with side walls and floors of concrete at least 4 in. thick, and covered by removable steel plates. Inlet, exhaust, fuel oil, lubricating oil, circulating water, and air piping trenches should be drained. Generator lead trenches should drain to their respective fly-wheel and generator pits through 3-in. drains. All piping should be supported in trenches by racks. To avoid fire hazard, fuel and lubricating oil piping should not be located in the same trench with exhaust piping.

INSULATING FOUNDATIONS AGAINST VIBRATION.—Engines in residential districts, hotels, office buildings, or department stores should be set on cork-insulated foundations to minimize vibration. All piping from engine to off-foundation locations should have flexible joints to prevent transmission of vibration. (See Section on Vibration, vol. 3 of this series.)

FUEL STORAGE.—Fuel oil storage tanks may be of steel or concrete. Concrete tanks should be painted inside to prevent absorption of oil. If near a railroad siding, the minimum aggregate fuel storage should be 1 1/4 to 1 1/2 the capacity of an average tank car. If the siding is some distance from the fuel storage, an unloading pump at the siding may be advisable.

Heating Fuel Oils.—The trend is toward heavier fuel oils. Even at present (1935) it often is economical to burn an oil which may need heating in cold weather before it can be pumped from an outside tank. Heating coils, therefore, are recommended for storage tanks. They should be arranged around the suction pipe and have no joints within the tank.

Fuel Level Indicators.—If records are to be kept, a sounding pipe and float-operated indicator are essential. If tank is located outside, the indicator should be enclosed.

Locating Fuel Tanks.—Storage tanks are best located above ground. Where local conditions call for a buried tank it should be set on a firm foundation and surrounded with soft earth, well-tamped sand, or encased in concrete. With a concrete casing, the tank manhole should be accessible in the bottom of a well. Before locating a fuel storage or day tank, local laws and ordinances applying should be consulted.

FUEL HANDLING SYSTEMS.—A common system of handling fuel oil is by means of individual day tanks for each engine. Oil is pumped from the main storage to the day tank, whence it flows by gravity to the engine pump. Engines sometimes are equipped with a supply pump which draws fuel directly from the main storage tanks.

Day Tanks.—Day tanks above the floor line should have gage glasses to permit measurement of fuel consumed. Day tanks below the floor should have float or pressure-operated gages.

Fuel Oil Piping and connections should be made up tighter than is customary for water piping. Wrought-iron, steel or preferably brass or copper pipe may be used for lines between fuel strainer and engine. Unions should be of brass without gaskets. Piping should be located so that oil cannot come in contact with hot exhaust piping.

Fuel Oil Filtering or straining usually is sufficient purification for fuel oils; poorer grades often must be centrifuged. Filtering elements may be metal screens, cloth bags, or thin washers held tightly together by king bolts. Filters should be of duplex construction so that one half may be cleaned while the other half is in operation.

Care of Fuel Pumps, spray nozzle valves, air injection compressors and scavenging compressors should be carried on according to a regular schedule. See p. 12–32.

AIR FILTERS.—If air drawn into an engine contains much dirt and dust, liner wear results. A good air filter will remove practically all dust and dirt from intake air without materially lowering air pressure at intake valves.

COMPRESSION PRESSURE.—A Diesel engine will not function properly unless compression pressure is maintained at or near the point specified by its builder. Compression pressure may decrease because of valves seating poorly, too great piston clearance, or poor piston rings. Users should learn from the engine builder the proper method of indicating engine cylinders for compression pressure, and of maintaining valves, piston clearance and piston rings.

EXHAUST TEMPERATURES.—Relative cylinder loading can be checked by observing exhaust temperatures of the several cylinders, which should be not more than 50° F. apart. Temperatures can be measured either by exhaust pyrometers or suitable thermometers.

EXHAUST PIPING should be as direct as possible and free from 90 deg. short-turn elbows. The pipe to the muffler never should be smaller than the size of connection on exhaust manifold on the engine. Exhaust lines preferably should be standard steel pipe with screwed connections up to 6-in. pipe, and flanged connections for 6-in. pipe and over. Cast-iron pipe may be used. The line must be designed to allow for the expansion due to a 1000° F. variation in temperature.

MUFFLERS usually are of cast iron or of sheet steel, but can be any kind of a chamber which promotes gradual dispersion of exhaust gases. Concrete chambers filled with stone or with coke sprinkled with water are effective mufflers. Cast-iron or steel mufflers, if connected to a straight length of exhaust piping, should be on rollers or provided with expansion joints.

STARTING AIR SYSTEM.—On low-pressure starting systems, such as are used for mechanical injection engines, standard lap-welded steel pipe, with globe valves of the best materials and workmanship, should be used. On high-pressure (500–1000 lb. per sq. in.) starting systems, seamless drawn steel tubing or copper tubing should be used, with needle valves.

Tanks for starting air should meet the requirements of the insurance companies and comply with state and local codes.

LUBRICATING OIL SYSTEMS.—Lubricating oil systems for Diesel engines vary somewhat, but the main connecting-rod, and cam-shaft bearings generally are force-feed lubricated; cylinders, including air-compressor cylinders, usually are drop-feed lubricated. Pure mineral oil should be used for power cylinder lubrication and mineral oil, or specially compounded compressor oil should be used, sparingly, in injection and scavenging compressor cylinders. Physical specifications for crank-case lubricating oil do not furnish a sure indication of its suitability. Users must rely on the experience with various oils of the engine builder, and should choose from oils recommended by him.

Clarification.—Lubricating oil may be clarified by straining through wire gauze or filtering cloth; by settling, with or without chemicals; or by centrifuging. Centrifuging may be: 1. By the batch, all oil of the engine system being run through a centrifuge periodically. 2. By the continuous method, wherein a small amount of the oil continuously is by-passed through a centrifuge which operates whenever the engine operates.

Lubricating Oil Piping including centrifuge system pipe, may be black iron pipe; copper or brass pipe is preferable.

Acidity of Lubricating Oil.—When high-sulphur fuel oil is used, the crank-case oil should be examined frequently for acidity. Manufacturers can recommend treatment to neutralize acid oil.

Lubricating Oil Coolers.—The efficiency of lubrication is not impaired if crank-case oil remains below 135° F. With a tendency toward higher temperatures, a lubricating oil cooler must be used, and the oil cooled to 90 to 100° F. A rising temperature of oil as it drains to the sump indicates a hot bearing, and oil pressure should be raised until the engine can be shut down and investigated.

COOLING WATER.—In the simplest cooling water system, water passes through the engine system once and then is rejected to waste. This system is feasible only where a large and inexpensive supply of suitable soft water or sea water exists. The sodium salts of sea water do not tend to give trouble, while salts of calcium, magnesium, aluminum and iron frequently do. Surface water, water in lakes, and water in rivers frequently hold salts in solution by virtue of dissolved CO_2. In a circulating water system, the CO_2 may become liberated and the salts deposited. Such deposits defeat the purpose of the cooling system by insulating the metal surfaces and retarding the flow of heat. Water should be analyzed if the least doubt exists about its suitability for cooling system use.

Treatment of Hard Water.—Hard water may be softened by passing through a layer of Zeolite, which absorbs the calcium, magnesium, aluminum and iron, in exchange for sodium. The Zeolite is rejuvenated by passing a solution of common salt through it. This system is satisfactory if properly supervised. The water should be tested frequently for hardness, and engine jackets should be inspected frequently for scale. The temperature of water from cylinders and heads usually should not exceed 120° F. maximum, as the tendency of salts to precipitate increases at higher temperatures.

Scale Removal from engine jackets usually can be effected by a treatment with an acid solution. Manufacturers can recommend the exact procedure in such cases.

Raw Water Cooling Systems.—With a limited supply of fairly good water, engine circulating water can be sent over a cooling tower or through a spray pond. See p. 9–16. Such systems should be completely drained and replenished with fresh water at regular intervals, as hardness in the water, even if moderate at the start, continually concentrates due to additions of make-up water and evaporation of pure water.

Double Circuit Cooling Systems.—Engine cooling water passes through a heat exchanger, where it is cooled by raw water which is recooled in a cooling tower or spray pond. As the loss of engine circulating water in a properly set-up system is slight, the best grade of water can be used, *viz.*, rain water, distilled water, or water thoroughly treated. The heat exchanger may be a series of pipe coils with raw water flowing outside, or it may be a shell-and-tube cooler, with raw water passing through the tubes.

Radiator Cooling is a variation of the double circulating system. The soft water passes through a radiator, similar to an automobile radiator, and is cooled by air, circulated through the radiator by a fan. The radiator system can be thoroughly satisfactory.

CIRCULATING WATER PIPING AND TEMPERATURES.—Circulating water should be under a static head at the circulating water header on the engine. If the circulating water is at all hard, discharge from the cylinder head and piston cooling system should not exceed 120° F. No bad effect is traceable to somewhat higher discharge temperatures with soft water. Air compressor cylinders should be kept as cool as possible. With equal loads in power cylinders, outlet water temperatures should be within 5° F. of the average.

The spread between the inlet and outlet circulating water temperatures should be held within 30 to 40° F. depending on the engine. A greater spread will result in strains in the cylinders. If double-circuit circulation is used, the temperature rise through the engine cylinders and heads should be held to one-half the above, since the temperature of the raw water is not lower than can be produced in a cooling tower.

Amount of Water which should be circulated in a single-circuit system, with inlet water at 90° F. and outlet water at 120° F., is about 0.2 gal. per min. per rated Hp. This amount should be increased to about 0.4 gal. per min. per rated Hp. for double circuit systems, with the temperature rise limited to 15° F.

Circulating Water Piping should be of wrought iron or steel, galvanized. The best gaskets are rubber with cloth insertions.

Stopping and Starting.—The circulating water system should operate for 20 minutes after stopping an engine. The flow should not be reduced suddenly, as, for instance, when the engine is running too cold. Cold water never should be turned into a hot engine. If the installation is in a freezing climate, circulating water should be drained from all parts of the engine, whenever it is shut down for more than short periods.

TYPICAL LAYOUT OF DIESEL POWER PLANT.—Figs. 19 and 20 from Hammond, Diesel Power Plant Layout, show a plant layout, designed for economical construction and operation, with provision for plant extension.

SPECIFICATION FOR DIESEL-ELECTRIC POWER PLANTS.—A form of specification in considerable detail, for Diesel-electric generating plants, will be found in "Standard Practices," published (1935) by the Diesel Engine Manufacturers' Assoc., New York.

10. VARIATIONS IN DIESEL ENGINE DETAILS *

ATTACHED PUMPS.—Smaller engines usually have built-in circulating water pumps. Larger engines usually require the installation of motor-driven pumps. Some 2-cycle engines have built-in scavenging pumps or blowers; others require motor-driven equipment.

FLY-WHEELS.—The dimensions and weight of fly-wheels for Diesel engines depend on the equipment to be driven by the engine; its engineering data must be analyzed and evaluated with respect to parallel operation of alternating-current generators and torsional vibration. Fly-wheels may be of one- or two-piece construction, and must have suitable

fly-wheel effect for the purpose intended. Some types of engines require but little fly-wheel effect, which may be incorporated in the generator rotor. Generators with weighted rotors are specified as fly-wheel type, or weighted-rotor type, as distinguished from standard engine type.

ENGINE EXTENSION SHAFTS.—The length and diameter of extension shafts of Diesel engines vary with type and speed of engine, type of generator or other driven equipment, and critical speed or torsional vibration conditions. Fly-wheel type generators usually are mounted on short extension shafts; standard engine type generators require longer extension shafts. Exact dimensions cannot be determined until the driven equipment is selected and its engineering data analyzed.

FLY-WHEEL-BARRING DEVICES are required for rotating the engine to its starting position or for adjustment and repair. The three types of barring devices used are manually, pneumatically or electrically operated. The first two types usually are supplied by engine builders. Slow-speed engines up to about 750 Hp. generally have manually-operated fly-wheel barring devices.

PYROMETERS, if used, may be attached to and made a part of the engine, or may be mounted on the switchboard or engine-room wall.

OIL COOLERS for lubricating oil are standard equipment, where climatic conditions require them. Sizes and types are selected by the engine builder.

BEDPLATES.—When engine-generator sets are mounted on concrete foundations, general practice is not to use an extension of the engine base or separate sub-base to support the generator, exciter and outboard bearing.

RIGHT- AND LEFT-HAND ENGINES.—An engine is right-hand if the controls are on the right-hand side when the engine is viewed from the fly-wheel end. There is little, if any, advantage in a stationary plant with two engines, in having one engine right-hand and the other left-hand.

11. ECONOMICS OF DIESEL POWER

Stationary Plants

The most common application of Diesel engines in stationary plants is the driving of electric generators. The annual reports of the Oil Engine Power Cost Sub-committee of the A.S.M.E. contain many data on the operating costs of over 100 Diesel-driven electric generating plants of all ages and types located in various parts of the U. S. In a study of operating costs of a well-run plant with modern engines, L. H. Morrison used these data and plotted separately fuel consumption, lubricating oil consumption, engine and other repairs, and supplies. These were plotted against plant kilowatt-hour output per kilowatt capacity, which is a measure of the use of the plant. Fuel and lubricating oil costs were adjusted to prices of 4 cts. and 50 cts. per gal., respectively. Repairs include additional labor used on repairs. Median lines then were established with as many plants above as below the lines. Since many of the plants plotted were not of modern design, and some had inferior attendance, Morrison took for his criterion for modern, well-run plants the average costs of those above the median lines. Fig. 21 (*Diesel Power*, Nov., 1932) shows costs with fuel at 4 cts. per gal., and also at 5 cts. per gal.

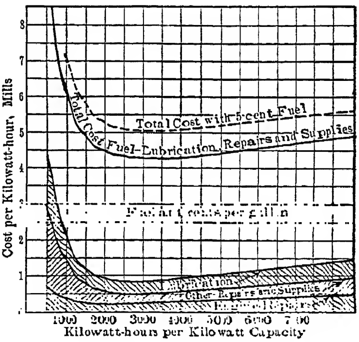

Fig. 21. Operating Cost Excepting Labor of Diesel Plants

ATTENDANCE.—Fig. 21 does not include labor, *i.e.*, attendance cost. The A.S.M.E. report shows that the better plants employ, as a rule, only one man per shift. Plants over 1500 kw. may need a second man on one shift, especially in lighting plants where the evening load varies rapidly. Wages vary widely and plant executives must establish this item for themselves.

OPERATING COST.—On the basis of one-shift operation, engineer's wages of $2250 yearly, and 4-cent fuel oil, Morrison gives total operating costs, including labor, as shown in Table 4. In the smaller Diesel plants, especially factory power plants, arrangements often can be made for part-time attendance, thus reducing the cost to less than that shown in Table 4.

Table 4.—Operating Costs of One-shift Diesel Plants

Based on fuel oil at 4 cents per gal., and attendant's wage of $2250 per year.

Plant Capacity, kw.	Yearly Output, kw.-hr. per kw. Capacity			
	1000	2000	3000	4000
	Operating Cost, Cents per kw.-hr.			
250	1.518	0.899	0.730	0.654
500	1.068	.674	.580	.542
1000	0.842	.561	.505	.486
2000	.730	.505	.467	.458

FIXED CHARGES per kilowatt-hour generated in a Diesel power plant depend on many factors, among which are: *a*. Amount of investment, which depends on size and type of engines and completeness of accessory equipment; *b*. Probable useful life of plant; *c*. Annual output of plant; *d*. The rate of interest.

Diesel engines cost (1935) $25 to $45 per rated horsepower. To this must be added cost of electric generators, switchboards, wiring, foundations, fuel oil storage tank, piping, measuring instruments, etc., which vary widely. A complete Diesel-electric plant, installed, may cost from $60 to $250 per kilowatt capacity. The useful life of most Diesel engines in stationary service is determined not by the actual wearing out of the engine, but by changes in need for the engine. The wearing parts of a Diesel engine plant comprise only a small proportion of the total cost; the life of an engine kept in repair is indefinite. The management of a Diesel plant must decide its probable useful service life. Funding periods are taken as high as 20 years, and as low as 10 years. From 12 to 15 years are usual periods.

STATIONARY DIESEL ENGINES, NON-ELECTRICAL DRIVE.—The foregoing figures are based on electric drive and the costs are on a kilowatt-hour basis. Diesel engines also are used for mechanical drive, for example, to drive ammonia compressors and oil pipe-line pumps. To obtain mechanical cost from electrical cost, an approximately correct factor is $^2/_3$, *i.e.*, cost per B. Hp.-hr. at the engine shaft equals $^2/_3 \times$ cost per kw-hr. generated. This relation is exactly true for an electrical efficiency of 89.4%.

Typical Operating Records of Stationary Diesel Engine Plants

MUNICIPAL ELECTRIC PLANT.—Table 5 shows costs of 1933 for the municipal Diesel-electric plant of Hudson, Mass. (L. D. Wood, *Diesel Power*, Mar., 1934). The plant consists of two 615-kw., one 460-kw. and one 835-kw. units. Current generated was 5,135,900 kw.-hr., gross, 4,543,900 kw.-hr., net. Overhead charges include both depreciation and bond retirement, as required by state regulations. If the smaller item, depreciation, be disregarded, the total cost per kilowatt-hour distributed becomes 9.93 mills.

Table 5.—Operating Costs of Hudson, Mass. Municipal Diesel Engine Plant

	Cost for Year 1933		Cost per kw.-hr. Generated, Mills	Cost per kw.-hr. Distributed, Mills
Production Expenses				
Superintendence and Labor	$14,846.61		2.87	3.27
Fuel	14,929.91		2.9	3.29
Water	269.18		0.05	0.06
Lubricants	1,844.17		0.36	0.41
Maintenance				
Station Structures	1,709.38		0.33	0.37
Diesel Plant Equipment	523.89		0.11	0.12
Diesel Engines	1,132.49		0.22	0.25
Accessory Electric Equipment	45.27		.0	.0
A. Total Production Expenses		$35,300.90	6.84	7.77
Distribution Expenses		11,953.11	2.3	2.63
Utilization Expenses		1,542.60	0.3	0.34
New Business Expenses		1,511.59	0.29	0.33
General Expenses		31,250.28	6.1	6.88
B. Total Operating Expenses		$81,558.48	15.83	17.95
Overhead Costs Chargeable to Production				
Depreciation	$5,000.00		0.97	1.10
Bond Interest	1,800.00		0.35	0.4
Bond Retirement	7,500.00		1.46	1.65
Insurance and Additional Labor	500.00		0.09	0.11
C. Total Overhead		$14,800.00	2.87	3.26
Total chargeable to production (A+C)		$50,100.90	9.71	11.03

FACTORY ELECTRIC PLANT.—Many factories have good load factors, better than the ordinary municipal electric plant, and Diesel engines have been found economical even in plants that are quite small. Table 6 gives the performance and costs of a 40-kw. Diesel unit supplying power to a factory, with auxiliary electric service furnished by a public utility.

Table 6.—Operating Record and Costs for 4 Months' Operation of 40-kw. Diesel-Electric Plant with Public Utility Auxiliary Service

Diesel Unit Data. Current generated, 40,327 kw.-hr.; hours run, 1532 1/4; average running load, 26.3 kw.; average running load factor, 65.7%; fuel oil consumed, 4734 gal.; lubricating oil consumed, 84 3/4 gal.

Diesel Operating Cost	Total	Per kw.-hr.	Public Utility Service
Fuel oil (6.55 c. per gal.)	$309.50	$0.0077	Current purchased, 8879 kw.-hr.
Lubricating oil (46 c. per gal.)	39.00	.0010	Max. demand (30 min.) 27 kw.
Maintenance reserve	60.50	.0015	Price per kw.-hr. 0.0478
Attendance and supervision	176.00	.0043	Total cost $424.04
Total!	$585.00	.0145	
Credit for coal saved by using Diesel heat	100.00		
Net cost	$485.00	$0.0120	

Totals, Diesel Plus Public Utility

Current generated and purchased	49,206 kw. hr.
Maximum demand	67 kw.
Load factor	24.4%
Total cost, Diesel plus public utility	$909.04
Total cost, Diesel plus public utility, per kw.-hr.	$0.0185
Comparative cost, if all purchased	$1980.00
Saving effected by Diesel plant	$1071.00
Annual saving, assuming Diesel heat used 6 mo. per year	$2990.00

OFFICE BUILDING ELECTRIC PLANT.—One of the first Diesel-electric plants for supplying the entire requirements of an office building was installed in 1932 in the 18-story building, No. 1 Park Ave., New York. The plant is fully automatic, and consists of four 180-kw. Diesel direct-current generating units operating in conjunction with a storage battery. The latter starts the engines, and provides good voltage regulation despite an irregular load. The jacket water, discharged at about 140° F., is pumped to the building's hot water service tank. Operating costs (*Diesel Power*, Mar., 1935) during 1934 were:

Total power generated	1,500,000 kw.-hr.
Fuel oil, at 6.4 cents per gallon	$9,000
Lubricating oil, at 50 cents per gallon	750
Maintenance parts, labor, supervision	5,550
	$15,300
Less credit for hot water	900
Total generating cost	$14,400
Generating cost per kw.-hr.	0.96 cents

ICE PLANTS.—Fuel and lubricating oil consumption and costs of eight Diesel-driven ice plants, in different parts of the U. S., are given in *Diesel Power*, Mar., 1935. Plant capacity ranged from 12 to 98 tons of ice per day. Ammonia discharge pressure ranged from 120 to 190 lb. per sq. in. Average costs, covering a week or more during the summer were: Fuel oil, per ton of ice, 4.79 gal.; cost per gal., delivered, 5.41 c.; cost per ton of ice, 25.9 c.; lubricating oil, per ton of ice, 0.0533 gal.; cost per gal. delivered, 50 c.; cost per ton of ice, 2.66 c. Combined cost of fuel and lubricating oil per ton of ice produced, 28.56 c. Although the fuel oil per ton of ice varied in the eight plants from 3.62 to 6.25 gal., the total cost of fuel and lubricating oil per ton of ice produced varied only from 23.9 to 34.2 cents.

Performance Data, Stationary Plants

A.S.M.E. REPORT ON OIL-ENGINE POWER COST.—The outstanding tabulation of records of performance and operating costs of Diesel engines in stationary electric generating plants is the annual report on oil-engine power cost, compiled from original sources by the A.S.M.E. Subcommittee on Oil-Engine Power Cost.

The 1933 report includes information from 156 oil-engine generating plants, containing 398 engines, totaling 216,010.5 rated B. Hp., with a total net output of 259,209,519 kw.-hr. The information on production cost includes type of plant, load, size, hours operated, load factors, costs of fuel

lubricating oil, attendance, supplies and repairs. The data on engine details and operating information comprises the following items for each engine in each plant:

Engine Data
- Engine desig
- Engine cycle
- Injection system
- Scavenging system
- Trunk piston or crosshead
- Rated B.Hp.
- Equivalent kw. (90% generating efficiency)
- Number of cylinders
- Cylinder dimensions, bore × stroke, in.
- Rated r.p.m.
- Generator rating, kv.-a
- Year in which engine started work
- Engine-hours operated in reported period

Lubrication
- Total new lubricating oil used, gal.
- New lubricating oil for cylinder lubrication only, gal.
- Unfit lubricating oil discarded, gal.
- Rated Hp.-hr. per gal. of new lubricating oil
- Lubricating oil treatment

Fuel
- Fuel oil used, gal.
- Nature of fuel oil used
- Is fuel centrifuged?

Output
- Gross output, kw.-hr.
- Gross kw.-hr. per gal. of new lubricating oil
- Gross kw.-hr. per gal. of fuel oil

Loading
- Running engine capacity factor
- Running plant capacity factor
- Peak load during reported period, gross kw.
- B.M.E.P. at rated B.Hp., lb. per sq. in.
- B.M.E.P. at peak load (90% generating efficiency)

Miscellaneous
- Piston cooling
- Air filters
- Type of cooling system
- Average temperature of incoming cooling water, deg. F.
- Average temperature of outgoing cooling water, deg. F.
- Purpose for which jacket water heat is utilized
- Purpose for which exhaust heat is utilized
- Plant altitude, ft. above sea level

Maintenance and Repairs
- Cost of engine regular upkeep, dollars
  - Material
  - Extra labor
- Cost of repairs for engine accidents, dollars
  - Material
  - Extra labor
- Total engine maintenance in dollars per rated B.Hp. per yr.
- Major engine parts renewed during reported period
- Number of enforced engine shut-downs
- Total duration of enforced engine shut-downs, hr.
- Total engine maintenance time not included in enforced shut-down, time, hr.

Attendance
- Number of shifts in period
- Number of hours per shift
- Number of attendants per shift
- Output per man-hour, net kw.-hr.

Plant Altitude
- Feet above sea level

In addition to the tabulated data, the following charts on which the plants are separately plotted, are shown: 1. Lubricating oil economy *vs.* plant running capacity factor. 2. Fuel economy *vs.* plant running capacity factor. 3. Total production cost *vs.* plant yearly output. Two charts, in simplified form, are reproduced in Figs. 22 and 23.

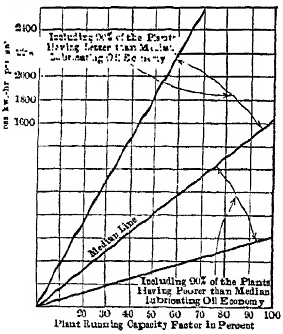

FIG. 22. Lubricating Oil Economies of 120 Full Diesel Plants

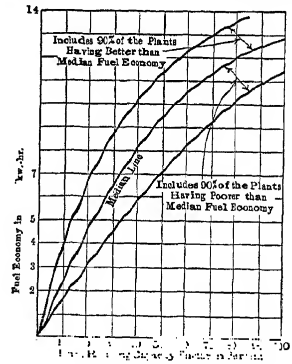

FIG. 23. Fuel Economies of 122 Full Diesel Plants

Economics of Diesel Power, Marine Plants

The wide diversity in conditions of marine service make detailed cost figures of limited value. The economics of Diesel application are better indicated by the extent of use. L. R. Ford (at the A.S.M.E. annual meeting, Dec., 1934) gave the status of Diesel engine propulsion in various classes of marine service as follows:

1. River and Harbor Craft. Includes tugs, work boats, ferries and dredges. Progress

in Diesel propulsion of tugs is such that in some localities the steam tug probably will disappear. Work boats and ferries are being powered increasingly with Diesel engines. The number of Diesel-operated dredges is growing.

2. Lake, Bay and Sound Craft. Includes ferries, passenger vessels, freight boats, fishing vessels, tugs, and self-propelled barges. Diesel propulsion is progressing in this class, with the exception of the larger passenger vessels in the East and the large cargo and passenger vessels on the Great Lakes. In 1934, about 125,000 Hp. of Diesel engines were installed in vessels of this class in the U. S.

3. Ocean Going Vessels. Includes coastwise and intercoastal types of passenger ships, combination passenger and cargo ships, cargo ships and tankers. The world's motorship tonnage increased from 1,540,463 tons in 1922 to 10,604,526 in 1934. Steamship tonnage decreased 10.1% in the same period. Of 1,217,366 tons of ships under construction throughout the world on Sept. 30, 1934, 729,131 tons was motorship tonnage. Of 324,712 tons of tankers under construction, 87.8% were being fitted with Diesel engines.

POWER TRANSMISSION FROM DIESEL ENGINE TO PROPELLER.—In many vessels, desirable propeller speed is much lower than desirable engine speed. Direct-drive, which is simplest, demands a compromise, the Diesel engine being of slower speed and larger dimensions than otherwise would be necessary. Alternatives are: 1. Diesel-electric drive; one or more engines drive generators to supply electric energy to a propulsion motor on each propeller shaft. 2. Diesel-gear drive: engine power is transmitted through reduction gears, with or without a clutch, to the propeller shaft or shafts.

L. B. Jackson gives advantages of Diesel-electric drive as: 1. Control is easy and highly refined. Pilot has complete control. 2. More reliable. With several generating units, one or more can be stopped without stopping propulsion. 3. Flexible as to engine room layout. 4. Overload torque can be developed at low propeller speeds without overloading engines. 5. Power can be measured accurately and easily. 6. Electric energy for auxiliaries can be obtained from main engines. 7. Low maintenance cost, because engines run at constant speed, and electric drive absorbs all shocks. 8. Engine sizes can be standardized.

Advantages of the Diesel-gear drive are: 1. Lower cost than electric drive. 2. Less complication. 3. Less space. 4. Smaller losses. Gear drives, however, may be noisy and suffer from vibration unless well designed and built with extreme precision.

Diesel engines in motorboats and aircraft eliminate the fire hazard that exists with gasoline fuel.

Economics of Automotive Diesel Engines

The first applications of Diesel engines to automotive services were in railroad switching locomotives (in 1925 in the U. S.), and in contractors' machinery such as shovels and drag-lines. With the development of engines of lighter weight, there has been since 1931 wide application of Diesel engines to trucks, tractors and buses, railcars and high-speed streamlined railroad trains.

The principal advantage of the Diesel engine over the gasoline engine in these services is lower fuel cost, due to its ability to use a cheaper fuel and also its smaller consumption of fuel. The reduced fuel consumption results from: *a.* Inherently better fuel efficiency at full load, due to higher gas pressures; *b.* Diesel part-load efficiency more closely approaches full-load efficiency than does that of the gasoline engine. *c.* Torque characteristics are more favorable. Fig. 24 (*Auto. Ind.*, Aug. 5, 1935) shows variation of fuel consumption with load factor of a Diesel engine and a gasoline engine built by the same manufacturer, and of approximately equal power. Both engines developed the same maximum torque, 390 lb.-ft., at rated speed, 850 r.p.m. When slowed by increasing load, maximum Diesel engine torque was 440 lb.-ft. and maximum gasoline engine torque was 413 lb.-ft., both at 600 r.p.m.

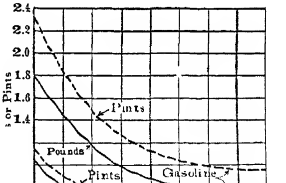

FIG. 24. Comparison of Specific Fuel Consumption of Diesel and Gasoline Tractor Engines

DIESEL ENGINES IN TRUCKS.—The data in Table 7 for Diesel and gasoline engines, obtained from truck owners, were reported by Ben J. Selbst in *Diesel Power*, May, 1934. The vehicles in each comparison operated under identical conditions.

DIESEL LOCOMOTIVES.—The Diesel engine develops little power while starting, and direct drive is impractical. Mechanical transmission, *i.e.*, gearing, generally is used on Diesel locomotives of the sizes used for factory switching and general hauling. A manufacturer gives the following operating record of two 13-ton locomotives, equipped

Table 7.—Comparative Operating Records of Diesel Engine and Gasoline Engine Trucks

	Tank Wagon Milk Truck		Truck and Trailer	
	Gasoline	Diesel	Gasoline	Diesel
Total trip mileage	220	220	1015	1015
Payload, lb.	39,322	39,322	37,000	37,000
Payload, tons	19.661	19.661	18.5	18.5
Total ton-miles hauled	4325	4325	18,800	18,800
Fuel consumption, gal.	75	35	360	175
Fuel consumption, miles per gal.	2.93	6.3	2.82	5.8
Ton-miles per gal.	57.6	123.5	52.3	107.2
Fuel cost, cents per gal.	11.625	4.75	11.5	4.0
Total fuel cost	$8.72	$1.66	$41.40	$7.00
Cost of fuel per 100 ton-miles	$0.202	$0.0344	$0.22	$0.037
Ratio of fuel cost	5.9	1	6.0	1
Ratio of fuel price	2.45	1	2.9	1

with 90-Hp. Diesel engines, used in tropical plantation service. The record covers a three-month period during which the locomotive traveled 8206 miles in 1409 hours.

	Per mile	Per service hour
Fuel consumed, gal.	0.1960	1.191
Lubricating oil consumed, gal.	0.0043	0.053
Cost figures:		
Operator	$0.0303	$0.176
Lubricating oil	.0116	.067
Service cost	.0075	.044
Repair cost	.0036	.021
Fuel cost	.0213	.124
Total operating cost	$0.0743	$0.432

Diesel-Electric Locomotives.—Up to 1935 the larger Diesel locomotives, for switching and light passenger service, almost universally have used electric transmission, *i.e.*, a Diesel engine-driven electric generator supplies energy to traction motors driving the wheels. This system involves considerable equipment and investment cost but gives ideally simple control.

Operating data of Diesel and steam locomotives gathered by Am. Elect. Ry. Assoc. and Am. Ry. Assoc., and tabulated in their 1932 committee reports are summarized by A. H. Candee (*Diesel Power*, May, 1934) as follows: 1. Diesel fuel costs per 100 ton-hr. approximate 25% of steam fuel cost, with oil at 5c. per gal. and coal at $3.00 per ton. 2. One gallon of fuel oil in switching service is equivalent to 140 lb. of coal. 3. Diesel engine lubrication approximates 8.76c. per 100 ton-hr. of locomotive switching service. 4. "Other lubrication" cost is 35% of steam locomotive lubricating cost. 5. Total cost of fuel, engine lubrication, locomotive lubrication and "other expenses" of Diesel locomotives is 33% of corresponding steam locomotive costs. 6. Diesel locomotive repair costs for industrial switching service are lower than are indicated for trunk line railroads, and lower than steam locomotive repair costs.

Diesel Streamlined Trains.—Many railroads in the U. S. are (1935) experimenting with complete light-weight streamlined trains of articulated cars, and equipped with one or more light-weight, high-speed Diesel-electric units. These trains are capable of exceedingly high speeds and low operating cost.

The Chicago, Burlington and Quincy R.R. operates twin "Zephyrs" 440 miles daily between Chicago, Minneapolis and St. Paul. These are three-car trains, designed for 110 miles per hour. The motive power is a 600-Hp., 750-r.p.m., 8-cylinder, 8 × 10-in. uniflow 2-cycle, solid injection Diesel engine, scavenged by a rotary blower. The operating expenses per mile of the "Zephyrs" during May, 1935, and also of a corresponding 5-car steam train are given as follows:

	Zephyr	5-car Steam Train
Fuel	$0.0141	$0.1190
Water		.0068
Lubricants	.0108	.0034
Wages of crew	.1709	.2360
Train supplies and expenses	.0311	.0468
Terminal expenses	.0351	.0375
Maintenance of power plant	.0188	
Maintenance of train	.0356	
Locomotive repairs		.1466
Passenger car repairs		.0800
Locomotive supplies		.0019
Engine house expenses		.0263
Lounge car attendant		.0077
Total	$0.3164	

11. TESTS OF DIESEL ENGINES

THE A.S.M.E. TEST CODE for Internal Combustion Engines is applicable to Diesel engine tests. See p. 16–44.

The Society of Automotive Engineers has developed Diesel engine Testing Forms, which primarily are adapted to the testing of automotive-type engines. These are abstracted below. Complete codes may be obtained from the S.A.E.

S.A.E. CODE.—A complete engine test includes the determination, at different speeds, of: Maximum horsepower; fuel economy at rated load, and at 125%, 75%, 50% and 25% of rated load at each speed; friction horsepower. These data are plotted against r.p.m. to give the following curves: Maximum brake horsepower; maximum torque; maximum brake M.E.P.; friction horsepower; mechanical efficiency; fuel per B.Hp.-hr. at rated loads, and at 125%, 75%, 50% and 25% of rated load; brake thermal efficiency at rated load, and at 125%, 75%, 50% and 25% of rated load.

No readjustment may be made during a test, except as required for actual changes of speed and load. The engine should be run-in sufficiently to show no appreciable change in friction before and after a 30 min. run at normal rated speed and load. Before a test run, the engine must be brought to a condition of sustained operation under the conditions of the run, and all loads, temperatures, etc. must remain substantially constant during the run.

Number of Runs.—For horsepower and fuel economy tests runs should be made at intervals - 20% of rated r.p.m., and also at the lowest steady operating speed.

Duration of Runs.—Prior to any test, engine should run at least 1 hr. at maximum load at desired r.p.m. The test runs at 125%, 100%, 75%, 50% and 25% of rated load, should be made in the sequence given, and should continue at least 30 min. before readings are taken. Duration of fuel consumption tests should be at least 5 min.; a longer period is desirable. Friction-horsepower tests should be at least 1 min. duration. Maximum speed variation during a run, ±10% of stated r.p.m. of test run.

Dynamometer and Brake Loads.—Dynamometer should be carefully balanced before brake-load readings are recorded. Brake-loads should be measured with accurately calibrated platform or beam scales. Connection of dynamometer arm to scales should be by knife-edges, calibrated spring-balance and tripod, or suitable linkage. Accurate counterbalance or tare loads must be provided. The platform or beam scales are kept balanced during a run, and load registered must be substantially constant.

Revolutions per Minute should be taken by positively-driven counters, which engage and disengage at beginning and end of runs. Difference between readings divided by duration of run in minutes is average r.p.m. Tachometers may be used only as an approximate check on average speed and to indicate speed variations.

Fuel Consumption should be determined by noting decrease in weight of tank from which fuel is fed. The tank, mounted on sensitive platform scales, is connected to fuel supply pipe by a tube fed by siphoning or pump suction. Difference in weight of tank at beginning and end of run, divided by duration of run in minutes, permits calculation of the consumption per hour. By repeatedly setting the scale counterpoise back a definite small amount and noting the times at which it falls, an indication of steadiness of fuel consumption may be obtained.

Temperatures are given in deg. F. Readings should be made of temperatures of entering air, entering water, outgoing water, fuel; and also, in friction horsepower tests, of mean temperature of jacket water. With pump-circulated jacket water, mean temperature may be taken as average of inlet and outlet temperatures. With thermosyphon circulation, thermometers should be inserted in the jacket, and average of readings taken. At least three readings should be taken during each run, one each being at beginning and end of run. Outlet water temperature should be kept within ±5° of that recommended by engine builder.

Friction Horsepower may be determined approximately by using an electric dynamometer, preferably of the cradle type, to drive the engine and measure the torque reaction. As reaction is in opposite direction to that obtaining when engine drives the dynamometer, provision must be made to measure torque on both sides of dynamometer, or direction of pull must be changed by linkage. Friction horsepower test should immediately follow brake horsepower test, before engine has cooled. Throttle remains in same position as for corresponding brake horsepower test. Compression relief cocks should remain closed, and all accessories used during brake horsepower test should remain in operation.

If an electric dynamometer is not available, friction horsepower can be determined approximately by testing at various speeds throughout load range, plotting a fuel consumption-brake horsepower curve, and then repeating tests with 1, 2, 3, etc. cylinders cut out. By replotting the curve, friction horsepower can be calculated by interpolation.

Indicated Horsepower can be determined approximately by adding friction horsepower at a given speed to brake horsepower at same speed. Results can be corrected to standard barometric pressure of 29.92 in. Hg and standard temperature of 60° F. (520° abs.) by formula

$$\text{B.Hp.}_c = \text{B.Hp.}_o \times (P_S / P_O) \times \sqrt{T_O / T_S}$$

where B.Hp._c and B.Hp._o = corrected and observed brake horsepower, respectively; P_S and P_O = standard and observed barometric pressures; T_S and T_O = standard and observed absolute temperatures, deg. F.

Dimensions and Engine Data.—The code includes a specification sheet for reporting dimensions and other details concerning the engine and its accessories, including the fuel injection system.

COMPLETE TEST OF LARGE MARINE DIESEL ENGINES.—Unusually complete tests of the twin-screw motor-ship *Polyphemus* are given in *Proc.* Inst. M.E. vol. 121, p. 183, 1931. The ship was driven by two 6-cylinder, 4-stroke cycle, air-injection engines rated at 2750 B.Hp. at 138 r.p.m., supercharged on the Buchi system (see p. 12–10). Particulars of the engines follow:

Bore, 24.41 in.; stroke, 51.18 in.; clearance volume, 2115 cu. in; compression ratio, 12.32; inlet valve opens 70° before top center, closes 35° after bottom center; exhaust valve opens 42.5° before bottom center, closes 60° after top center; fuel valve opens 11° before top center; fuel pump capacity per cylinder, 1.125 cu. in.; fuel pump pressure, 1000 lb. per sq. in.; starting air valve opens at top center, closes 135° after top center; starting air pressure, 450 lb. per sq. in., maximum. The total running weight of engine room machinery was 1098.4 tons (2240 lb.) divided as follows: Main engines, without flywheels, but including all pipes, fittings, thrust block and shafts, 492.2 tons; flywheels, 5.5 tons; shafting, stern gear and propellers, 101.2 tons; auxiliaries, pipes and fittings, 197.7 tons; boiler, steam and exhaust pipes, 12.5 tons; air reservoirs, 33.2 tons; miscellaneous fittings, tools, spare parts, etc., 151.9 tons; water in system and lubricating oil, 104.2 tons.

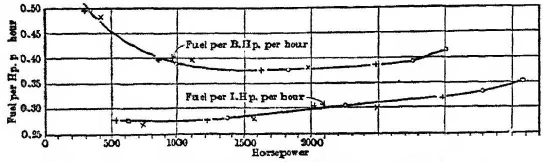

Fig. 25. Fuel Consumption of Motorship *Polyphemus*

A typical analysis of the fuel oil used is: C, 86.24; H, 13.24; S, 0.34; N, nil; ash, 0.0022; carbon residue and free carbon, 0.03; soft asphaltum, 0.08; water, trace; calorific value, 19,500 B.t.u. per lb.; sp. gr., 0.863; flash point, closed, 177° F., open, 162° F.; viscosity (Redwood No. 1) at 70° F., 39 sec.; at 150° F., 30 sec.; at 200° F., 27.8 sec.

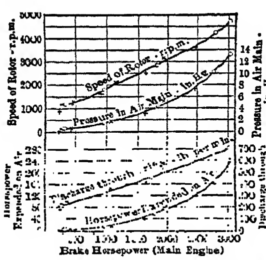

Fig. 26. Performance of Scavenger Air Blower

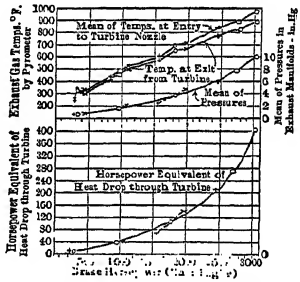

Fig. 27. Temperature, Pressure and Equivalent Horsepower of Exhaust Gases Passing through Exhaust Gas Turbine

Table 8 gives analyses of the exhaust gases at different loads. Hydrogen in the gases was 0.04%, and CO ranged from 0.02 to 0.07%. Engine performance is given in Table 9.

Table 8.—Analysis of Exhaust Gases of Motorship *Polyphemus*

Mean indicated pressure, lb. per sq. in.	131	132	102	71	49
Oxygen, percent	13.0	12.9	13.9	16.0	16.6
Carbon dioxide, percent	5.7	5.3	4.5	2.3	2.2

Table 9.—Performance of Engines of Motorship *Polyphemus*

	Test No.				
	12	13

Brake M.E.P., lb. per sq. in.	117	110	82.4	55.1	27.6
Average speed, r.p.m.	142.3	138.4	121.2	98.0	68.6
Friction horsepower	414	368	295	275	192
Friction M.E.P., lb. per sq. in.	16.0	14.7	13.4	15.5	15.5
Mechanical efficiency (B.Hp./I.Hp.), percent	84.2	83.9	80.8	71.5	55.8
Fuel per hr., lb.	1264	1094	683	384	169
Fuel per B.Hp. per hr., lb.	0.419	0.397	0.377	0.39[illegible]	0.497
Fuel per I.Hp. per hr., lb.	0.35	0.33	0.31	0.28	0.28
Thermal efficiency, B.Hp. basis	0.312	0.328	0.346	0.32[illegible]	0.262
Thermal efficiency, I.Hp. basis	0.37	0.39	0.43	0.47	0.47

Table 10.—Heat Balance at Various Loads of Engine of Motorship *Polyphemus*

All quantities are in 1000 B.t.u. per min.

	Test No.				
	12	13			
Heat in fuel	411.0	357.0	222.0	125.0	55.0
Distribution of heat					
Thermal equivalent of B.Hp.	128.0	117.0	76.8	41.5	14.4
Air-compressor Hp.	6.62	6.87	5.73	4.88	3.31
Rejected through jackets and heads.	56.10	46.20	32.50	20.90	12.94
Rejected through pistons	13.60	11.40	8.40	4.83	2.46
Heat drop through turbine	17.11	11.61	4.54	1.67	0.30
Rejected in exhaust gases	157.85	137.53	74.90	36.45	15.63
Radiation, etc.	31.72	25.39	19.13	14.77	5.96
Total Heat	411.00	357.00	222.00	125.00	55.00

Fuel consumption is plotted in Fig. 25, which illustrates the Diesel engine characteristic that while fuel consumption per B.Hp.-hr. is at a minimum between 3/4 load and full load, fuel consumption per I.Hp.-hr. decreases with decrease of load. Fig. 26 shows performance of the scavenger air blower. Fig. 27 gives data of exhaust gases. Table 10 gives the heat balance at various speeds and loads. A summary of the maneuvering trials is: 1. Number of engine starts possible with an available initial pressure of 455 lb. per sq. in., 65. 2. Average time, *a*, for all cylinders to fire, 11.5 sec.; *b*, to attain prescribed speed, 1.2 sec.; *c*, to stop turning, 7.5 sec. 3. Lowest pressure at which engine started was 120 lb. per sq. in. Engine refused to start with a pressure of 115 lb. per sq. in., on the 66th attempt. 4. Average volume of free air used per start, 249 cu. ft.

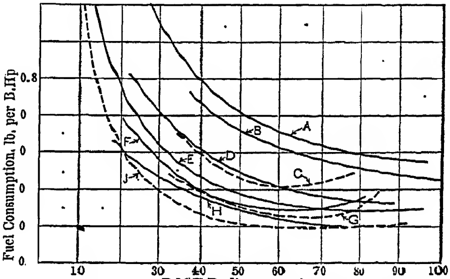

FIG. 28. Fuel Consumption of Truck and Bus Engines. *A*—6-cyl., 4.33 × 6 in.; *B*—4-cyl., 5.90 × 7.09 in.; *C*—4-cyl., 4.33 × 7.09 in.; *D*—4-cyl., 5.31 × 7.87 in.; *E*—2-cyl., 3.15 × 11.00 in.; *F*—6-cyl., 4.33 × 5.59 in.; *G*—4-cyl., 4.72 × 7.09 in.; *H*—2-cyl., 7.5 × 12.0 in.; *J*—4-cyl., 4.5 × 5.5 in.

TEST OF HIGH-SPEED OIL ENGINE.—Table 11 gives results of a test of a Paxman-Ricardo 4-cylinder heavy oil engine rated at 40 Hp. at 1000 r.p.m. and 60 Hp. at 1500 r.p.m., made by W. A. Tookey (*Engg.*, April 5, 1935). The cylinders were 4 5/8 × 5 7/8 in. (394 cu. in. total displacement). Rating is based on a B.M.E.P. of 80 lb. per sq. in. At 1500 r.p.m. the engine developed 125% of its rated power with clear exhaust and 135.8% of its rated power with black exhaust.

FUEL CONSUMPTION OF HIGH-SPEED DIESEL ENGINES.—S. J. Davies (*Jour.* Royal Aeronautical Soc., April, 1931) gives the curves of Fig. 28 showing fuel consumption per B.Hp.-hr. on a base of B.M.E.P. of different types of truck and bus engines, all about 1200 r.p.m. and developing about 50 B.Hp. Maximum values given of B.M.E.P. are the highest consistent with a clear exhaust.

DATA ON HIGH-SPEED DIESEL ENGINES.—Tables 12 to 14 (E. F. Ruehl, *Jour.* S.A.E., 1931) compare weight, speed and power of typical commercial Diesel and

gasoline engines. The Diesel engines all are of the 4-cycle, solid injection type. In later designs, particularly of the larger engines, specific weight has been greatly reduced.

12. DIESEL ENGINE MAINTENANCE

Inspection and maintenance should cover both engines and auxiliary plant. Table 15 (Diesel Engineering Handbook, 7th ed., L. H. Morrison and T. A. Burdick) is a typical schedule form. Opposite each item in the schedule should be entered maximum interval that may elapse between inspections. These intervals will vary in different plants and must be determined individually. Frequency of maintenance operations is controlled by: 1. Cost. 2. Loss of efficiency due to condition of equipment. 3. Necessity of maintaining equipment in service.

A monthly maintenance log on which are listed operations to be performed is advisable. Table 16 (*Power Plant Engg.*, April 15, 1930) is typical. A specific instruction sheet, showing desired clearances and settings, will enable definite standards, initially determined by the manufacturer, and modified by experience, to be maintained. Table 17 (Diesel Engineering Handbook, 7th ed.) is a typical form.

MAINTENANCE EQUIPMENT.—The principal work involved in maintenance is disassembling and replacing parts. Maintenance processes may be classed as: 1. Cleaning. 2. Adjusting. 3. Reconditioning. 4. Renewal of parts. The nature and amount of equipment required to carry out these processes depends on whether the system of maintenance is that of renewal or of reconditioning. In general, renewal is most economical in small plants and with small engines. With larger equipment, reconditioning usually saves time and money. Certain machine tools and precision gages then are essential, as well as one or more skilled mechanics.

COMPRESSION AND COMBUSTION PRESSURES.—Compression pressure should be maintained within 20 lb. of recommended pressure. Probable causes for variation in compression are leaky valves, leaky piston rings, low scavenging pressure, obstructions in suction lines, and increased piston end clearance.

Combustion pressure, *i.e.*, maximum pressure at full load, should be within 50 lb. of manufacturer's recommendation. It is affected by compression pressure, fuel or spray valve conditions, injection timing, injection air pressure, and fuel oil characteristics. The quality of combustion should be good at all times. Incomplete combustion is a direct fuel loss, and causes wear. A poor exhaust shows smoke and high temperature; a good exhaust is clear and the temperature is low.

ROCKER ARM ROLLER CLEARANCE.—Too much rocker arm roller clearance is better than too little. Inadequate clearance may cause blocking of valves when engine is at operating temperature, resulting in loss of compression, overheating, and cutting of

Table 15.—Inspection and Maintenance Schedule for Diesel Engines

Make................Hp..................Type.................Date..............

Enter in this schedule the maximum allowable operating hours between inspections of the listed parts. At the time of inspection all cleaning and adjusting consistent with good engine maintenance is to be done.

valve seats. Excessive clearance will change the timing and cause an undesirable increase in impact, leading to breakage or wear.

VALVES AND VALVE TIMING.—It is poor practice to allow valves so to wear that reseating is difficult. Leaking valves wear rapidly, reconditioning soon is impossible and replacement is necessary. No corrections for exhaust and inlet valve timing should be made for variations of less than 5 deg. Fuel or spray valve timing is extremely important. Much care should be used in its adjustment. Recommended settings must be followed exactly.

FUEL PUMP.—Fuel pump settings and adjustments on air-injection engines determine individual cylinder loads, and have a direct effect on engine steadiness. Adjustments should be checked, and pumps made to deliver equal quantities of fuel to each cylinder. Fuel pumps on airless-injection engines measure quantity and also time delivery of fuel to the individual cylinders. It is important that they be accurately adjusted and timed.

PISTON.—The condition of piston and liner is a good indication of the quantity and quality of lubricating oil used. A bright surface on piston rings and liner, with rings free, indicates good oil supplied in proper quantities. Dull, grayish wearing surfaces, with rings stuck, indicates inferior oil. Too much oil, even of good quality, will cause a gummy deposit on rings and piston. If an engine operates with poor combustion, evidenced by smoky exhaust, a gummy residue will be found on the rings, even if a proper amount of good quality lubricating oil has been used.

PISTON END CLEARANCE determines final compression pressure of a power cylinder. Maximum allowable variation for this adjustment is 0.035 in.

PISTON DIAMETRAL CLEARANCE should be checked whenever a piston or liner is replaced, to insure that it compares closely with that recommended by the manufacturer. Aluminum pistons require greater clearance than cast-iron pistons.

PISTON RINGS must be kept in first-class condition. If they remain in the engine after blow-by has started, power will be lost, and piston and cylinder will be scored, as a result of hot gases destroying the lubrication. Ring condition should be investigated at the first sign of blow-by.

RING AND LINER WEAR.—Piston and cylinder parts receive the greatest wear, and require the most frequent renewal. Greatest wear in the liner invariably occurs near upper end of piston travel. Wear in other parts of the liner is inconsequential, even after several years. Wear at upper end of the liner usually necessitates renewal of the part, and also replacement of piston rings. Replacement of liners is necessary when wear at top exceeds 0.005 in. per in. of cylinder diameter.

Ring and liner wear can be reduced by: 1. Using cylinder lubricant of suitable body, applied at the right points, and in correct amounts. 2. Filtering, or otherwise purifying, air and fuel. 3. Maintaining a tight seal between rings and liner. If considerable wear has occurred, this may require the use of two or more two-piece rings. 4. Keeping rings free in their grooves. 5. Keeping water-jackets free of scale, and water supply adequate.

BEARINGS.—Working clearance and lubrication determine the service that can be obtained from a bearing and its pin. A bearing loosely-fitted will flatten the pin and crack the bearing babbitt. If bearing lacks clearance, it will burn out due to excessive friction.

CRANK-SHAFT AND BEARINGS.—Crank-shaft alignment should be checked annually. Difference in quality of individual bearing lubrication, variation in quality of bearing metal, and the different bearing pressures all tend to destroy crank-shaft alignment. Bearing wear should be closely checked. If the change in clearance is not uniform on all bearings, shaft alignment should be checked.

SAFETY.—The oil vapor present in the engine crank-case, particularly at the time of stopping, is explosive. Cigarettes and lights should be kept away.

Poisonous gases collect above fuel oil in storage. These gases at times have such instant effect that they may overcome a man in a few seconds. When inspecting or cleaning fuel oil tanks all possibility of contact with such gases should be eliminated.

MANUFACTURER'S INSTRUCTION BOOKS.—Most engine manufacturers publish comprehensive instruction books giving specific information on their own engines. These books should be available to members of the operating staff who are responsible for maintenance.

13. HAZARDS AND RELIABILITY

HAZARDS.—Diesel engines are comparatively free from hazards to life and property. When accidents, however, do occur, their effects generally are confined to damage to the engine itself. The most common major accidents are seizure of pistons and breaking of connecting-rod bolts. When a piston seizes, generally as a result of faulty lubrication or of overload, piston and cylinder are scored. This may require replacement of parts, depending on depth and location of scores. Fly-wheel explosions on Diesel engines are rare, because governors seldom fail, and fly-wheels are designed for high peripheral speeds. Crank-shaft breakages, which may be caused by misalignment of main bearings, always start with a crack that gradually spreads and gives warning before any other parts are damaged. Oil vapors accumulating in the crank-case and becoming ignited have caused a few accidents resulting in blowing out of crank-case doors. Such accidents can be prevented by a crank-case ventilating system.

DIESEL ENGINE RELIABILITY.—The A.S.M.E. report for 1933 on oil-engine power cost shows 111 plants reporting fully on enforced engine shut-downs. These plants contained 285 engines with a total operating time exceeding 814,000 hours. No enforced shut-downs occurred in 1933 on 221 engines. On 74 engines, 187 enforced shut-downs aggregated 6,825 hours. The enforced shut-down time was about 0.8 of 1% of operating time. Table 18 summarizes a study of Diesel engine outages made by the Prime-movers Committee of the Edison Elect. Inst. (Publication B-87, July, 1934).

14. SPECIFICATIONS FOR DIESEL FUEL OILS

While different types of Diesel engines require different fuel characteristics, no final standards as yet (1935) have been adopted. The early Diesel engines were of slow speed and had large cylinders. Ample time was available for fuel injection and combustion, and the engines could burn any ordinary grade of commercial crude or fuel oil. The advent of high-speed engines and cracked fuels led to fuel troubles, and the setting-up by engine builders of fuel specifications. These varied among different builders, and difficulty was encountered in meeting them. A tentative specification drawn up by an A.S.M.E.

committee in 1929 failed of general acceptance, as some oils that met the specifications did not operate satisfactorily. In 1934, the A.S.T.M. subcommittee on fuels formulated the tentative classification given in Table 19.

Heating Value of Fuel Oil.—See formula p. 4–47, and table p. 4–48.

Table 19.—Tentative A.S.T.M. Classification of Diesel Engine Fuel Oils (1934)

Method of Test	Grade No.[a] 1–D	3–D	4–D	5–D	6–D
1. Flash point, min., deg. F.	115[b]	150[b]	150[b]	150[b]	150[b]
2. Water and sediment, max. percent by volume	0.05	0.2	0.6	Note [c]	Note [c]
3. Viscosity					
Saybolt Universal sec. at 100° F. min.	30	30			
Saybolt Universal sec. at 100° F. max.	50	70	500		
Saybolt Furol sec. at 120° F., max.				100	200
4. Carbon residue, max., percent	0.2	0.5	3.0	6.0	10.0
5. Ash, percent by weight, max.	0.01	0.02	0.04	0.08	0.12
6. Pour point, deg. F., max.	35[d]	[d]	35[d]	40[d]	[d]
7. Tentative ignition quality

B. Cetene number, min.	50	40	30	Note [e]	Note [e]
C. C.C.R., max.	8.1	8.8	9.8	Note [e]	Note [e]

NOTES.—[a] Grade 1–D is a distillate oil for use in engines requiring a low viscosity fuel; recommended for mechanical (solid) injection, high-speed engines; in general, for engine speeds over 1000 r.p.m.

Grade 3–D is a distillate oil for use in engines requiring medium-low viscosity fuel; recommended for mechanical (solid) injection, medium-speed engines; in general, for engine speeds from 360 to 1000 r.p.m.

Grade 4–D is an oil for use in engines requiring a medium viscosity fuel; recommended for air-injection engines, both 2- and 4-stroke cycle, with speeds not over 400 r.p.m. It can be used in solid injection engines with cylinder diameters over 16 in., and speeds under 240 r.p.m., but engine manufacturers should recommend approved heating equipment.

Grade 5–D is an oil for use in engines permitting a medium-high viscosity fuel; recommended for slow speed (under 240 r.p.m.) air-injection engines. Engine manufacturers should recommend approved heating equipment.

Grade 6–D is an oil for use in engines of special design for high viscosity fuels, and after engine manufacturer's recommendations only. It is not used regularly for Diesel engines and is not recommended unless tested and approved by engine manufacturer. Purchaser should be advised of high cost of engine maintenance and operating problems involved in its use.

[b] Minimum flash point as stated, or as required by local fire regulations, Fire Underwriters' rules, or state laws.

[c] Not determined (1935).

[d] Lower pour points may be specified whenever required by local temperature conditions, to facilitate storage and use, although it should not be necessary to specify a pour point of less than 0° F.

[e] Ignition quality not specified, but burning quality should be determined by actual engine test.

Sulphur apparently need not be considered as regards combustion characteristics. A maximum of 2% is suggested for engines operating intermittently.

COMBUSTION KNOCK AND IGNITABILITY.—Combustion knock, in a rough running engine, is attributed to accumulation of fuel in its cylinders, prior to ignition. Even under conditions that insure ignition, fuel does not ignite instantaneously, but only after a definite delay. The longer the delay, the greater the accumulation of fuel, which then burns more or less simultaneously, accompanied by an audible knock. If the delay is extreme the engine will fail to operate. Practically every factor which tends to aggravate knocking in a spark-ignition engine tends to suppress it in Diesel engines. Fuels of paraffin base, consisting chiefly of saturated, straight-chain hydrocarbons give the smoothest combustion in Diesel engines, while naphthenes and aromatics burn more roughly.

The characteristic of a fuel that determines its speed of ignition under conditions prevailing in an engine cylinder is called ignitability or ignition quality. Crucible and bomb methods of measuring ignition temperatures are not trustworthy methods of determining ignitability. The time lag in bombs is many times the permissible time lag in an engine, and has a pronounced effect on ignition temperature. This effect varies for different fuels. Unfortunately tentative ignition quality in the specifications is diminished in value, for the time being, by three different methods of specifying it being offered without a standardization of test methods.

DIESEL INDEX NUMBER is one of the three methods of specifying ignition quality proposed by the A.S.T.M. It is based on tests that indicate ignitability of an oil to vary in accordance with its aniline point and its gravity. The A.S.T.M. tentative specification uses the formula of Dr. Becker as follows:

Diesel Index Number = (A.P.I. Gravity at 60° F.) × (Aniline Point in deg. F.)/100

Aniline Point is the lowest temperature at which equal parts by volume of freshly distilled aniline and oil are completely miscible. It is determined by heating the mixture in a jacketed test tube to a clear solution and noting temperature at which turbidity appears as mixture is cooled. Although this is a convenient method, the correlation between Diesel index number and ignition quality has been found good only for certain types of oil. It, therefore, is recommended for quick and rough evaluation only.

ENGINE TESTS.—Most investigators have concluded that a compression-ignition engine itself is the best apparatus to test ignition quality of fuels. A variety of methods have been used by Le Mesurier and Stansfield, Boerlage and Broeze, and Pope and Murdock; in principle, however, all agreed. Ignitability, as such, is not measured by any engine test, but is determined indirectly on the basis of the behavior of the fuel in the test engine, as regards such characteristics as combustion knock, ignition lag, rate of pressure rise, or ease of starting.

SCALE FOR EXPRESSING IGNITABILITY.—Whatever testing method is used to measure ignitability, it is essential to determine the manner of rating of the fuel. One way is to use a measured factor or quantity to express rating, as maximum injection advance angle, ignition lag in degrees, or critical compression ratio. The last-named factor is one of the choices set forth in the A.S.T.M. tentative classification.

CRITICAL COMPRESSION RATIO is determined on a C.F.R. Waukesha engine, modified to run as a Diesel by replacing the ignition system with a fuel pump and fuel injection valve, and also replacing the regular piston with one of special design. The operating conditions are: Speed, 600 r.p.m.; fuel feed, 9 c.c. per min.; injection advance angle, 12 deg. before top dead center; injection pressure, 1500 lb. per sq. in.; jacket temperature, 212° F.; air inlet temperature, 100° F.

The critical compression ratio is obtained by motoring the engine at the selected speed. The compression ratio at which firing occurs, as judged by the sound of the exhaust, within three seconds after the fuel is injected, is noted. Although the critical compression ratio so determined for any fuel in the test engine differs from what an actual engine might require to fire that fuel, it nevertheless is of practical value. The engine builder can run tests on his engine with several fuels of known critical compression ratio. He then is able to specify the maximum ratio that will give satisfactory performance.

CETENE NUMBER is not a method of testing ignition quality, but of expressing the rating after the fuel has been tested. The method is derived from that used for testing the knock rating of gasoline. (See p. 14–68.) It is based on the use of two standard reference fuels, cetene ($C_{16}H_{32}$) and alpha methylnaphthalene ($C_{11}H_{10}$), the former having a high, the latter a low, ignitability. The test fuel is matched with a fuel consisting of the two reference fuels mixed in such a proportion that its ignition quality, in the arbitrary scale of the test, is equal to that of the test fuels. The rating of the fuel is then stated as percentage concentration of the high-rate reference fuel, *i.e.*, Cetene Number.

Table 20.—Cetene Number Corresponding to Given Viscosities and Gravities of Diesel Engine Fuel Oil

Viscosities in Saybolt Universal seconds at 100° F.

Viscosity	Gravity, deg. A.P.I., at 60° F.

44	26	31	35	40	44	46	48	50	52	54	56	58	60	62	64	65	67
46	27	32	36	41	45	47	49	51	53	55	57	59	61	63	65	66	68
48	27	32	36	41	45	47	49	51	53	55	57	59	61	63	65	67	68
50	28	33	37	42	46	48	50	52	54	56	58	60	62	64	66	68	69
60	29	34	39	43	47	50	52	54	56	58	60	62	64	66	68	69	70
80	31	35	40	45	50	52	54	56	58	60	63	65	67	69	71	72	...
100	32	37	42	47	52	54	56	58	60	62	65	67	69	71	...	...	...
150	34	39	44	49	54	56	58	60	63	65	67	69	72	...	...	...	...
200	35	40	45	50	55	58	60	62	65	67	69	71	...	...	...	...	...
300	36	41	47	52	57	60	62	65	67	69	72	...	...	...	...	...	...
400	37	42	48	53	59	61	64	66	68	71	...	...	...	...	...	...	...
500	38	43	49	55	60	63	65	67	70					...	...	...	...

The test method used to find the cetene number may be: 1. A starting test with a motored C.F.R. engine, as in the determination of critical compression ratio. 2. Ignition lag method by direct reading the ignition lag with a neon light protractor. 3. Knockmeter method using a bouncing pin. (See p. 14-68.)

Relation of Cetene Number to Viscosity and Gravity.—After using the ignition lag method on a modified C.F.R. engine to determine the cetene numbers of a large number of fuel oils ranging from 34 to 72 cetene number, C. C. Moore, Jr. and G. R. Kaye found a close correlation between the cetene number and the viscosity and gravity of the oil, as shown in Table 20.

SOUR OIL.—Another oil characteristic has (1935) become prominent with the increasing use of high-speed Diesel engines in the sour oil fields of West Kansas and Texas. These crude oils contain hydrogen sulphide in solution which causes considerable corrosion of the finely fitted parts of injection nozzles and fuel pumps. In addition, the oil contains finely-divided abrasives, as sand and ferrous sulphide. To protect engine parts from attack, Behn, at an A.S.M.E. meeting at Tulsa, Okla. (*Diesel Power*, May, 1935), recommended thorough cooling of the injection nozzle, minimum heating of the fuel oil, adequate filtering of the fuel, settling tanks to remove water and vents to discharge gas as emitted.

GAS ENGINES

By H. A. Gehres

1. GAS ENGINE FUELS

A gas engine is a prime mover whose piston is actuated by the combustion of gaseous fuels in air.

GASES AVAILABLE FOR USE IN GAS ENGINE.—**Natural Gas** (dry), is an ideal fuel, of an average heating value of about 1000 B.t.u. per cu. ft., consisting of a mixture of several light hydrocarbons, but mostly methane, CH_4. It is obtained from deposits in the earth, but not connected with the production of oil. It is piped under pressure from the fields to the consuming center. Natural gas pipe lines now serve a considerable portion of the United States. See p. 4–64 for analyses and heating value of natural gas from various fields.

Casinghead Gas is excellent fuel, whose heating value ranges from 1200 to 2000 B.t.u. per cu. ft. It comes from oil wells, and is trapped off at the casinghead as the oil is produced. The wide variation in heating value is caused by the varying quantities of condensible vapors, such as butane contained in it. A considerable quantity of this gas is used in the oil fields for well pumping and other lease uses. Some of it, after being treated for gasoline recovery, is used in pipe lines. Much of it is used to make carbon black, and great quantities are blown to the air.

Refinery Gas is a by-product from the distilling and cracking of oil for making gasoline in oil refineries. The heating value varies from 1200 to 2000 B.t.u. per cu. ft. It is used mostly for heating stills, making steam, and in gas engines for making power in the refineries. In some cases there is enough excess to sell to outside consumers.

Coke-oven Gas is a good gas for engines when properly cleaned. It has a heating value of from 500 to 600 B.t.u. per cu. ft. It is procured from by-product coke ovens. The excess above that required for the firing of the stills is available for distribution. Large quantities are used in steel mills. See p. 4–64.

Producer Gas can be used in gas engines if properly cleaned. It is artificially made in gas producers, and the main combustible constituent is CO. If made from bituminous coal it also contains some of the distilled hydrocarbons. The heating value is from 130 to 150 B.t.u. See p. 13–03.

Illuminating Gas (City manufactured gas) is a good gas for engines but very restricted in its use because of high cost. Its heating value is from 500 to 600 B.t.u. per cu. ft.

Blast Furnace Gas is an excellent fuel for gas engines when properly cleaned, although low in heating value (90 to 100 B.t.u. per cu. ft.). It is a by-product from making iron in blast furnaces. In most cases it is all used in the plant where it is made. See p. 4–64.

Relative Power Value of Gas Engine Fuels.—The value of a gas from an engine rating standpoint is not in proportion to its heating value but is in proportion to the heating value of the combustible mixture. Table 1 gives the approximate heating value of the various gases used in gas engines, and also the heat available from the explosive mixture. From

Table 1, the heating value of coke-oven gas is only about two-thirds that of natural gases, yet their B.t.u. value per cu. ft. of explosive mixture is the same. Therefore, an engine can be rated the same using either one of these two gases.

Table 1.—Approximate Heating Value of Commercial Gases

Taken at 60° F. and at Pressure of 30 in. of Mercury

Gas	Lower Heating Value, B.t.u. per cu. ft.	Average Air required for Combustion, cu. ft. per cu. ft. of Gas	Average B.t.u. per cu. ft. of Explosive Mixture
Natural Gas, Dry	970–1000	9.73	91.0
Refinery and Casinghead Gas	1200–2000	11.5–19	
Oil Gas	820–850	8.07	93.0
Coke-oven Gas	500–603	5.60	91.0
Carbureted Water Gas	550–575	5.25	92.0
Producer Gas from Hard Coal	140–153	1.12	68.0
Producer Gas from Soft Coal .	144–150	1.20	65.5
Producer Gas from Coke. . . .	120–140	0.98	63.0
Blast-furnace Gas.	90–95	0.72	53.0

2. TYPES OF GAS ENGINES

CLASSIFICATION.—Gas engines may be classified in the following various ways:

1. **By Combustion Cycle:** *a.* Four cycle. *b.* Two cycle.
2. **By Power Impulses:** *a.* Single acting. *b.* Double acting.
3. **By Arrangement:** *a.* Vertical. *b.* Horizontal. *c.* V-type. *d.* Opposed. *e.* Radial.
4. **By Speed:** *a.* Low Speed (100 to 250 r.p.m.). *b.* Intermediate Speed (250–600 r.p.m.). *c.* High Speed (600–2000 r.p.m.).

CYCLES OF OPERATION. Four-cycle Principle.—The term 4-cycle is applied to engines in which four complete strokes are required to complete a cycle of events. Fig. 1 shows the various phases of this cycle, in the form of an indicator diagram, in their regular sequence as follows:

1. Suction Stroke, *a–b*. A certain mixture of gas and air is drawn into the cylinder by action of the piston. Pressure in the cylinder drops below atmospheric pressure, due to resistance through passages, valves, etc., but mainly due to the throttling action of the governing or regulating valves.

2. Compression Stroke, *b–c*. After completion of the suction stroke, the inlet valve closes and the returning piston compresses the confined mixture to a predetermined pressure called *compression pressure.*

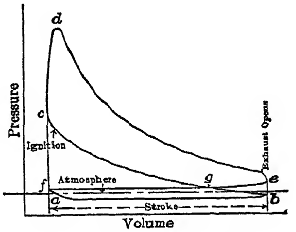

FIG. 1. Four-cycle Indicator Diagram

3. Power Stroke, *c–d–e*. The compressed mixture is ignited shortly before the piston reaches dead center, causing pressure to rise suddenly from *c*, through rapid combustion or explosion, to point *d* or *peak pressure.* Expansion then takes place, pressure gradually falling from *d* to *c*. Just before reaching dead center the exhaust valve opens and the *terminal pressure* suddenly falls to just above atmosphere.

4. Exhaust Stroke, *e–f*. The returning piston expels the remaining burned gases at an *exhaust pressure* slightly above atmosphere. The amount of this pressure depends on the fluid resistance through exhaust valves, piping, mufflers, etc.

Of the four strokes represented only one is a power stroke.

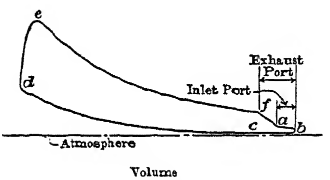
The positive work of this cycle is represented in Fig. 1 by the enclosed area *cdeg*, and the negative work (pumping) by area *abgf*. This negative work varies somewhat with the design of the engine, but mostly with the percentage of load at which the engine is operating. At full load the lost work is very low. As most engines, except some of the smaller sizes, use throttling governing, the lighter the load the lower the suction pressure, and consequently the greater the negative work in proportion to the positive work.

The 2-cycle Principle.—With this principle the complete cycle covers only two strokes of the power piston. To accomplish this the pumping is done by other means than in the power cylinder. The 2-cycle principle lends itself to many variations in design. These variations are mainly concerned with the method of *pumping* and of using the scavenging air. The simplest and most broadly used two cycle is the plain-ported type, which has no valves in the power cylinder. At about the middle of the cylinder are two sets of ports inlet on one side and exhaust on the other. These are so placed that the piston uncovers

both sets of ports at the end of the stroke away from the head. Pumping is done by the under, or crank, side of the piston, using for a pump the crank-case in a trunk piston engine, or a passage sealed from the crank-case, by a partition plate, in a crosshead engine. An automatic suction valve admits the mixture on the crank side on the out stroke of the piston; at the same time a previous charge is being compressed in the opposite end of the cylinder. Near the end of the power stroke first the exhaust port is uncovered, the terminal pressure falling rapidly, and then the inlet port is uncovered. The mixture compressed ahead of the piston flows through, pushing out the remaining burned gases and leaving in the cylinder a fresh charge.

Fig. 2 is a typical diagram of such an engine, admission and scavenging beginning at *a*, continuing to end of stroke and back to *a*, slightly above atmosphere. Compression begins at *c* when exhaust port closes and continues to *d*. Ignition takes place a little before dead center, and pressure rises to peak at *e*. Expansion takes place to *f*, where exhaust port opens and pressure rapidly falls to *a*, where a new charge starts in, all being accomplished in two strokes.

RELATIVE ADVANTAGES AND DISADVANTAGES OF TWO- AND FOUR-CYCLE ENGINES. Advantages, 4-Cycle.—1. Accurate control of fuel-air mixtures. 2. Lower fuel consumption (8000 to 10,000 B.t.u. per Hp.-hr.). 3. Better regulation. 4. Higher speeds obtainable. 5. Lighter weight pistons. 6. Lower lubricating oil consumption.



. 2. Two-cycle Indicator Diagram

Advantages, 2-Cycle.—1. Simple construction. 2. Lower manufacturing cost. 3. Lower maintenance costs.

Disadvantages, 4-Cycle.—1. Less uniform turning effort for equivalent number of cylinders. 2. More costly to build for equivalent horsepower. 3. Necessity of complicated valve gear. 4. More expensive to maintain.

Disadvantages, 2-Cycle.—1. Necessity of using quality-of-mixture regulation, resulting in "missing" at both light and heavy loads. 2. Higher fuel consumption. 3. Inaccurate regulation on variable loads due to missing. 4. Lower rotating speeds due to extremely short time for scavenging. 5. Heavier pistons. 6. Higher oil consumption.

3. COMBUSTION AND REGULATION

CONTROL.—Two methods are used to control the load and speed of a gas engine. The first varies the quantity of a constant mixture of gas and air. The second varies the fuel only.

With gases, a certain ratio of gas to air exists where a perfect mixture will result in perfect combustion when ignited, leaving no unburned fuel and no free oxygen. See Table 1. The range of variation from this perfect mixture, either rich or lean, wherein combustion will take place at all, is limited.

For example, with methane the range is 7% to 13% of gas in the total mixture. As the mixture is varied, either "rich" or "lean" from these limits the engine first will begin to fire irregularly, and finally cease to fire.

Four-cycle engines use the first method of control almost exclusively. The regulating valve controls both gas and air simultaneously, maintaining a constant gas-to-air ratio, but reducing compression at light loads. The 4-cycle engine will, therefore, fire regularly over a wide range of loads.

The 2-cycle engine, of necessity, uses quality regulation, *viz.*, the regulating valve controls gas only. If the air were throttled a corresponding amount of burned gases would be left in the cylinder which would tend to cause prematuring and backfiring. There are two methods of introducing the fuel into 2-cycle engines: 1. Fuel is taken in by suction with the scavenging air; in this way some of the fuel is flushed on through the exhaust ports without burning. 2. Fuel is injected under pressure near, or after, closing of the exhaust ports, but early in the compression stroke.

FUEL CONSUMPTION of gas engines, expressed as heat consumption ranges about as follows: 4-cycle engines, 8,000 to 10,000 B.t.u. per Hp.-hr.; 2-cycle engines (plain), 13,000 to 15,000 B.t.u. per Hp.-hr.; 2-cycle (injection), 10,500 to 12,000 B.t.u. per Hp.-hr.

POWER AND EFFICIENCY FORMULAS.—Power and efficiency formulas are the same for gas engines as for Diesel engines. See page 12–06.

Thermodynamic Analysis.—See page 12–07.

COMPRESSION PRESSURES AND TEMPERATURES.—While the higher the compression pressure the higher will be the thermal efficiency (see Diesel Engines, page 12-07), the gas engine is definitely limited in the compression pressures that can be used, depending on the nature of the gas used as fuel. Since gas engines have the fuel added to the air before or shortly after compression begins, auto-ignition of the charge can occur during compression if compression is too high. This is called preignition. The higher the hydrogen content of the gas used, the lower it is necessary to hold the compression.

The theoretical expressions for temperature-pressure and pressure-volume relations are:

Pressure-temperature relations: $T_2/T_1 = (P_2/P_1)^{(n-1)/n}$;

Pressure-volume relations: $P_1(D + C)^n = P_2 C^n$,

where T_1, T_2 = respectively, absolute temperatures at beginning and end of compression; P_1, P_2 = respectively, initial and final absolute pressures, lb. per sq. in.; D = piston displacement, cu. in.; C = clearance volume, cu. in.; the value of exponent n ranges from 1.32 to 1.35 in water-cooled engines, and is about 1.4 in air-cooled engines.

COMPRESSION PRESSURES USED in gas engines vary with the type of fuel. Usual pressures are as follows:

Refinery and casinghead gas	70–90	lb. per sq. in., gage.
Natural gas (dry)	100–115	" " "
Coke-oven gas	80–100	" " "
Producer gas	120–140	" " "
Blast-furnace gas	150–180	" " "

These values are for dry 4-cycle pistons, not over 19 in. diameter. They should be reduced 5% for dry 2-cycle pistons up to 17 in. diameter, and increased 10% for all water- or oil-cooled pistons of any diameter.

HEAT RECOVERY.— The same principles of heat recovery that apply to Diesel engines (see p. 12–11) can be applied to gas engines, except that due to the lower compression used the cycle is not as efficient and more heat is available from the jackets and exhaust. An approximate heat balance for gas engines is: Brake work, 25%; friction, 7%; jacket water, 30%; exhaust, 35%; radiation, etc., 3%.

4. UTILIZATION OF GAS ENGINES

FOUR-CYCLE ENGINES. Single and Twin Tandem, Double-acting, Crosshead Type.—The largest sizes, 2000 to 7000 Hp., are used mostly in steel plants. They use blast-furnace and coke-oven gas for fuel. They are used to develop electric power, and for direct driving blowers supplying furnace air. Smaller sizes, 800 to 1500 Hp., are used for electric power generation. Many are used for direct driving of compressors for pumping natural gas through pipe lines.

Single-acting, Single-cylinder Trunk-piston Type.—Built in sizes up to 75 Hp. These engines are built for general purposes and for oil well pumping.

Single-acting, Single and Twin Crosshead Type.—Built in sizes from 25 to 250 Hp. These engines are used to generate electric power, and also are used in large numbers for pumping gas for pipe lines, and for gasoline extraction from casinghead gas.

Single-acting, Multi-cylinder Trunk-piston Type.—Built in all sizes up to 1500 Hp. These engines are used for general power generation, direct driving of ammonia compressors, oil line pumps, etc.

TWO CYCLE.—Single and Twin Double-acting Type.—A small number have been built to use blast-furnace gas.

Single and Twin Single-acting Crosshead Type.—Very large numbers of this type of engine are used for oil well pumping and cable tool drilling, casinghead gasoline extraction plants. They are built in sizes of 15 to 250 Hp.

Single and Twin Cylinder Trunk Piston (crank-case scavenging).—Used for oil well pumping, and cable tool drilling.

5. IGNITION SYSTEMS

MAKE-AND-BREAK SYSTEM.—The make-and-break ignition system consists of mechanical igniters, comprising a body, a stationary electrode and a movable electrode. Some types have only one electrode, insulated and connected to the current source, the return current going through the engine structure. Others have complete copper circuits with both electrodes insulated, usually by means of mica, porcelain or lava.

The movable electrode makes contact with the stationary electrode, and at the proper time the contact is broken, either by mechanical or magnetic means, and the resulting spark ignites the charge. A rather heavy induction coil is connected to each igniter

The current usually is supplied by storage batteries, floating on the line, with voltage from 40 to 110, or by a low-tension magneto. When 40-volt current is used on a 110-volt circuit, a resistance with a suitable rheostat for varying the charge is used. This system was used almost universally for many years, but in recent years it rapidly is giving way to the high-tension jump spark system, because of its lower cost and absence of the heavy maintenance expense of the mechanical igniters.

JUMP-SPARK SYSTEM.—The jump-spark system is based on a small plug which has one insulated electrode and one grounded to the engine, with a fixed gap between them. Current is supplied at a sufficiently high voltage to cause a spark to jump the gap. Two systems are in general use: 1. *Battery,* with either high-tension or low-tension distribution. 2. *High-tension Magneto.* With battery ignition, the high-tension distribution is used most generally. It consists of a battery, an interrupter, a breaker, a transformer type of coil, condenser, and the jump-spark plugs in the cylinders. It functions as follows:

The battery is connected in series through the breaker and the primary circuit of the coil. A timing cam allows the breaker points to close at the proper time so that current passes through the primary coil, building up a magnetic flux in the iron core. The cam immediately opens the breaker, causing the collapse of the flux in core, which induces high-voltage current in the secondary winding. A small condenser is bridged across the breaker points to absorb current which would try to flow across the gap as the breaker opens, thus preventing burning of the points. The condenser is discharged the next time the points make contact. Current induced in the secondary is carried to a central terminal of a distributor, which connects to the center of a rotating arm. Arranged around the distributor shell are terminals, each connected through heavily insulated cable to a spark plug. As the outer end of the arm passes each terminal, the breaker closes and opens, inducing a spark at the plug connected to that terminal. Thus one breaker, one condenser and one coil will handle any number of cylinders. The breaker, distributor and condenser usually are built into one unit and the coil into another.

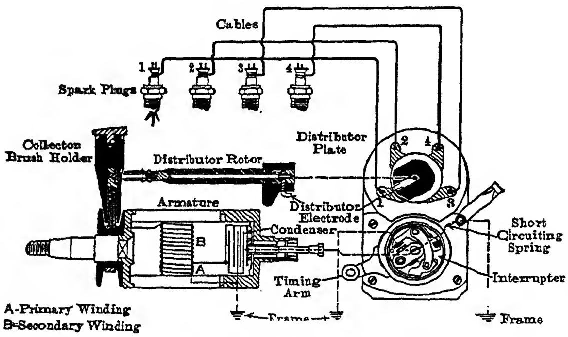


FIG. 3. High-tension Magneto Ignition System

In very large engines, particularly those of the horizontal type, the very long high-tension wires become a disadvantage and low-tension distribution often is used. The principle is the same, except that each spark plug has a separate coil located near it. These separate coils can be operated from a low-tension distributor with a single breaker and condenser. The most reliable, however, have a breaker and condenser for each. In this way, a failure of any of the parts affects only one cylinder.

THE HIGH-TENSION MAGNETO SYSTEM has a basic principle similar to that of the jump-spark system (see above), except that the source of current is one of the various forms of magnetos. The magneto originated as a small electric generator with a rotating armature but with the field flux supplied by permanent magnets. Low-voltage current was supplied to make-and-break and low-tension distributor systems. Later designs produced the high-tension current direct. The armature contains both primary and secondary windings. As the armature rotates, a low-tension current is produced in the primary winding. A pair of breaker points connected to this winding forms a short circuit. At the point of maximum current flow the points are opened, interrupting the current, and thus inducing a high-tension current in the secondary winding, which is connected through a distributor and cable to the plugs. See Fig. 3.

The trend now (1935) is toward the more simple, less costly and more durable inductor type. This type simply reverses the direction of flux through the iron core of a stationary coil, thus inducing current in the winding. The only rotating or oscillating member is the iron pole pieces imbedded in some non-magnetic material. In other types the magnet is rotated and the pole pieces are stationary. In neither type are there windings on the

rotor. As the pole pieces rotate past the magnet or *vice-versa* the magnetic flux through the coil core is reversed, thus inducing current in the primary winding, which when interrupted near the time of greatest current induces the high-tension current in the secondary winding. See Fig. 4.

BATTERY SYSTEMS are used mainly where several engines operate in a group, and the battery up-keep is justified, and also where batteries are necessary for lighting and other purposes. They also are recommended for the very large engines where low-tension distribution is desirable.

ROTARY MAGNETOS require impulse couplings for starting. This is a spring tripping device, which when engaged, either manually or automatically, winds up and trips, giving the rotor a very quick partial rotation, which makes a strong spark at low engine speed. When the speed is increased sufficiently, the impulse device is automatically disengaged and the rotor continues to revolve uniformly.

Rotary magnetos can be converted into an oscillating type by means of a tripping arm fastened to the end of the rotor, and held in position by two strong tension springs. The tripping cam pushes the arm to one side until it slips off. The springs return the rotor to the original position rapidly enough to produce a spark.

Another type of oscillating magneto is made with a bar type magnet extending across the cores of two coils, whose windings are in series. A sliding bar with roller at its outer end, operated alternately with a cam or eccentric, causes the magnet to come in contact with the cores, and close a pair of breaker points, and then breaks the contact between the magnet and cores, at the same time opening the breakers. Current is induced in the primary circuit by the flux collapse when the magnet is pulled away from the coil cores, and in the secondary at the parting of the breaker points, which causes the spark at the plug.

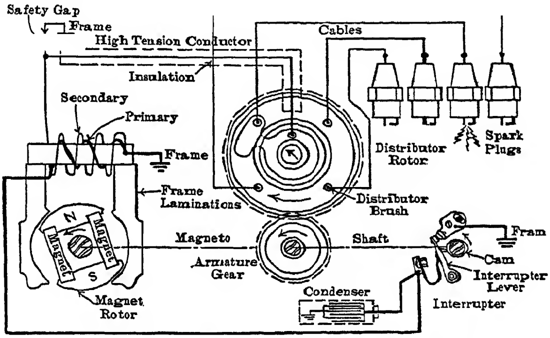

Fig. 4. Rotating-magnet Magneto Ignition System

Oscillating magnetos have the advantage of giving the same degree of spark at all engine speeds, but they are limited to comparatively slow-speed engines.

6. FACTORS AFFECTING ENGINE PERFORMANCE

EFFECT OF AIR INTAKE TEMPERATURE ON ENGINE RATINGS.—As the intake air varies in temperature, the weight of air in each charge varies. The warmer the air the less the weight of the charge, and consequently the lower the maximum rating that can be obtained. Table 2 gives the relative capacity and efficiency, with unity taken at 60° F.

Table 2.—Relative Capacity of Gas Engines at Various Temperatures of Intake Air

Initial Temp., deg.		Relative Capacity Or Intake Efficiency	Initial Temp., deg.		Relative Capacity Or Intake Efficiency
Fahr.	Absolute		Fahr.	Absolute	
−20	441	1.18	70	531	0.980
−10	451	1.155	80	541	.961
0	461	1.13	90	551	.944
10	471	1.104	100	561	.928
20	481	1.083	110	571	.912
30	491	1.061	120	581	.896
32	493	1.058	130	591	.880
40	501	1.040	140	601	.866
50	511	1.020	150	611	.852
60	521	1.000	160	621	.838

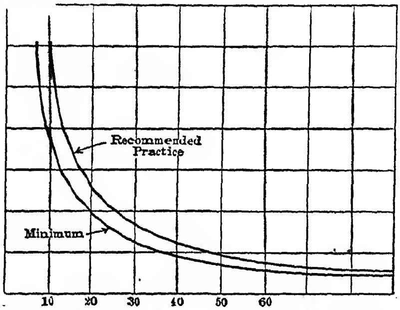
EFFECT OF ALTITUDE ON ENGINE RATING.—See Table 3. The effects of increased air temperature and altitude are similar in their effect on engine rating. It is not

necessary in most cases to reduce the rating under 3000 to 5000 ft. altitude, as an engine may be capable of 100 to 110 lb. mean indicated pressure (M.i.p.) at sea level but for reasons of long life would not be rated over 75 M.i.p. If satisfied with an overload capacity of 12% the top rating could be 84 M.i.p. Therefore, an altitude of 5000 ft., or an inlet temperature of 160° could be used, before a loss in rating would be recognized.

COOLING WATER REQUIRED.—The cooling water required for a gas engine varies with the inlet and outlet temperatures. Table 4 gives the requirements for a medium-speed, single-acting gas engine of 16- to 18-in. bore, with dry pistons, for various inlet temperatures and 140° F. outlet temperature. The recommended amounts are for establishing the capacity of pumps, cooling towers, heat exchangers, etc., in order to provide reserve capacity.

For double-acting engines with water- or oil-cooled pistons and rods multiply the figures of Table 4 by 1.25. For small, high-speed engines multiply them by 0.90. For radiator or tank cooling temperatures up to 180° F. outlet, and 166 to 170° F. inlet are permissible. Where the water supply is 80° F., or below, it is good practice to recirculate part of it to avoid too large a temperature gradient through the engine.

Fig. 5 is a curve giving approximate gallons per B.Hp.-hr., plotted against temperature difference between inlet and discharge.



Temperature Difference between Inlet and Discharge, deg. F.

Fig. 5. Cooling Water Consumption of Gas Engines

Where the water supply tends to deposit scale the outlet temperatures should be kept to 125° F. or below.

7. LUBRICATION

Three methods of general lubrication are in use on gas engines, *viz.*, Splash, Sight Feed and Pressure.

SPLASH SYSTEM.—The crank-case is filled with oil to such a level that some part of the connecting rod, crank, or counterweight dips into it. The resulting splash throws oil into pockets in the various bearings, whence it runs into the bearings. Its main advantage is simplicity, as no pumps and little or no piping are required.

SIGHT FEED SYSTEM.—A low-pressure circulating pump is used with pipes leading to adjustable sight feeds above each bearing. The advantage of this system is that the operator can see and adjust the amount of oil to each bearing and a filter can be used. This system is used mainly on horizontal engines.

THE PRESSURE SYSTEM consists of a pump capable of pumping from 10 to 40 lb. pressure, and a piping system leading directly to the bearings. This system is used mostly on vertical and higher speed engines. Its advantages are: Large quantities of oil flushed through the bearings for both lubrication and cooling; ability to deliver directly to

Table 3.—Influence of Altitude Above Sea Level on Volumetric Efficiency

Table 4.—Cooling Water Requirements of Medium-speed, Single-acting Gas Engines

Outlet Temperature, 140° F.

Inlet Temp., deg. F.	50	60	70	80	90	100	110	120
Gal. per B.Hp.-hr. Minimum	4.06	4.57	5.23	6.10	7.32	9.15	13.40	18.30
Gal. per B.Hp.-hr. Recommended	5.33	6.00	6.86	8.00	9.60	12.00	16	24

a piston-pin or crosshead-pin in vertical engines; it allows the use of much higher bearing pressures than other systems, so that reduced weights and more compact dimensions can be attained. Pressure-type filters are used with this system, and on medium- and large-size trunk-piston engines, oil coolers or heat exchangers usually are furnished.

Cylinders on small- and medium-size trunk-piston engines usually are lubricated by splash. On crosshead and large-size trunk-piston engines, the cylinders are lubricated by one or more feeds to the cylinder bore which are piped through separate lines direct from the force feed pump. The type of pump used for this service consists of a small tank with drive, and a separate pump plunger and barrel for each cylinder feed. A different oil from that used in the crank-case then may be used in the cylinders. For engine-driven compressor work, these pumps can be had with two compartments so that a different oil from that used in the engine cylinders may be used in the compressor cylinders.

OIL CONSUMPTION.—Lubricating oil consumption for high-speed, trunk-piston, 4-cycle engines should be from 1500 to 2500 Hp.-hr. per gallon; for medium-speed 4-cycle engines, 2500 to 3500 Hp.-hr. per gallon; for slow-speed 4-cycle engines, up to 5000 Hp.-hr. per gallon.

For slow-speed crosshead engines, lubricating oil consumption should be from 4000 to 7000 Hp.-hr. per gallon; for trunk-piston, 2-cycle engines, 1500 to 2000 Hp.-hr. per gallon; for crosshead, 2-cycle engines, 3000 to 4000 Hp.-hr. per gallon. These figures are based on full ratings.

FILTRATION.—The life of an engine varies directly with the quality of its lubrication. With an ample oil film and a lubricant absolutely free of all abrasives there should be no wear at all in a bearing. Wear is caused by particles of abrasive that are greater in size than the thickness of the oil film.

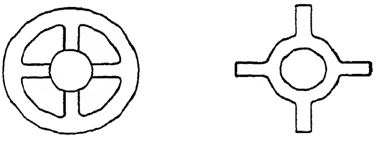

Fig. 6. Elements of Pressure-type Metal-edge Filter

Splash-lubricated engines usually are not provided with filters as a concession to simplicity and economy. A filter can be used with these engines, however, if a pump is provided to pass oil from the crank-case through the filter, whence it returns to the crank-case either by gravity or pressure.

Sight-feed-lubricated engines almost universally are provided with filters capable of continuously handling the entire amount of oil circulated, since this amount is relatively small. Pressure-lubricated engines are furnished with all degrees of filtration from 0 to 100% of the oil circulated.

Because of the large amounts of oil circulated, partial filtration is quite common, particularly on small portable engines. The filter either is installed in a parallel circuit to the main system, filtering what it can and returning it to the crank-case, or is placed in series with the main system where the filtering element takes what it can, the remainder going through a spring-loaded by-pass valve.

Types of Filters.—Filters may be classified as: 1. Gravity type fabric cloth filter. 2. Pressure type fabric cloth or felt filter. 3. Pressure type metal cloth filter. 4. Pressure type metal edge filter.

The first type probably produces the best filtration, as such filters usually are large, with a low rate of flow. They are practical only for large stationary installations.

The second type will produce quality of filtration in inverse proportion to the flow. The slower the flow, the better the quality of filtration. They are used for both full and partial filtration. While the fabric cloth filter produces the best filtration, its capacity is seriously affected by water in the oil, which closes the fabric and reduces the capacity.

The third type is really more of a strainer than a filter. It is more convenient to clean than other types, being built mostly in basket form. When the baskets are lifted out they bring the dirt with them.

The fourth type is used most commonly for portable and marine engines. The filtering elements consist of stacks of thin washers alternating with spacers of from 0.0015 to 0.006 in. thick. The washers have an unbroken outer periphery (see Fig. 6*a*), while the spacers have only radial " spokes " (see Fig. 6*b*). The oil passes from the outside of the stack through the space made by the spacer and passes on through the passage through the center of the stack. Other types have crimped wire wound around a perforated cylinder or a crimped ribbon wound in the form of a disc. The amount of crimping determines the degree of filtration.

These filters can be made for all degrees of filtration. They can be so fine that the collected dirt forms a mat, producing a finer filtration but slower flow until the amount

flowing is so small as to require cleaning of the filter. To be practical, this type requires large surface area. Many of them, as a concession to expense, space and less frequent cleaning, only catch the coarser particles.

Various methods of cleaning are in vogue. The cloth bag filters and some of the edge filters must have the elements removed and washed. Some of the metal edge filters have cleaning discs or scrapers, which can be operated by an outside handle, the sludge dropping to the bottom of the case where it is drained off. Others reverse the circulation of oil for a short time. Still others blow compressed air in a reverse direction through the filter element.

8. OPERATION AND CORRECTION

DEFECTIVE OPERATION AS SHOWN BY INDICATOR CARDS.—Fig. 7 shows a perfect type of indicator card as taken from a horizontal, 4-cycle gas engine. The M.i.p. is 85.5 lb. per sq. in. with only 250 lb. per sq. in. peak and 30 lb. per sq. in. terminal pressure. The line from compression to peak leans away from the vertical, indicating no detonation. The toe of the card is well rounded, indicating proper timing of the exhaust valve. Vertical engines usually do not give such a rounded peak because the combustion space is more compact, and the flame can reach all points in it much more quickly.

Fig. 8 shows two cards superimposed. Both were taken with all adjustments identical, except ignition timing. Both have the same M.i.p., and since the regulating valve adjustment was the same they would show the same power efficiency. Card *B* has the ignition unduly advanced and shows a peak pressure 100 lb. per sq. in. higher than normal card *A*, indicating a corresponding abuse of the engine with no gain in power or efficiency.

Fig. 9 shows two cards, card *A*, normal, and card *B*, with late ignition. The loss of power in this case is shown by the drop in M.i.p. from 83 lb. per sq. in. for *A* to 69.5 lb. per sq. in. for *B*. Bad mixture conditions also are responsible for the decided loss in power.

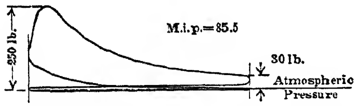

FIG. 7. Perfect Four-cycle Engine Indicator Card

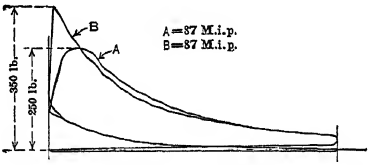

FIG. 8. Effect of Advanced Ignition

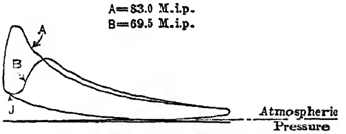

FIG. 9. Effect of Late Ignition

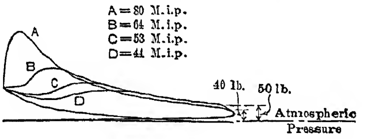

FIG. 10. Effect of Enriching of Mixture

Fig. 10 shows several superimposed cards with all adjustments the same, except mixture. Card *A* is normal, while *B*, *C* and *D*, with their several lowered M.i.p., are the result of too rich a mixture. The engine operation is erratic, and the terminal pressure is 10 lb. per sq. in. higher than normal. High terminal pressures and the corresondingly high temperatures mean abuse of exhaust valves.

Fig. 11 was taken under conditions similar to those of Fig. 10, except that cards *B*, *C* and *D* were taken with mixtures too lean. They also show erratic operation and loss of power, but have lower terminal pressures than normal. Too lean a mixture is a prolific cause of backfires. The mixture burns so slowly that some of it is still burning when the follow-charge starts to enter the cylinder.

Fig. 12 shows the effect of preignition due to an overheated spot in the combustion space. The peak pressure is extremely high, the M.i.p. extremely low. Ignition took place during compression at point *K* instead of near the end of stroke. The upper loop in this card shows negative work. This condition is very detrimental to engines. The effects of early and late ignition are about the same for 2-cycle engines. Mixture conditions are only right in 2-cycle engines for certain ranges in load, since it is necessary to regulate only the gas.

If a 2-cycle engine misses for one stroke, due to the more complete scavenging of the two revolutions, the following power impulse is a very large one, as shown in Fig. 13. *A* is a normal card and *B* was taken following a miss.

Defects in scavenging are very detrimental to 2-cycle operation. Fig. 14 shows the proper shape for a scavenging card for an under-piston scavenging crosshead engine or a trunk-piston engine. The pressure quickly falls while exhaust ports are open from *C* to *D* and the intake starts immediately following the closing of inlet port at *A*. Volumetric efficiency is 89%.

Fig. 15 shows a combination defect of too high an exhaust pressure, as evidenced by the undue distance from end of stroke to point *A*, where suction starts, and too much resistance in the intake pipe or valves as shown by the shaded area below the atmospheric line. The volumetric efficiency is only 67%.

Gas Pressures.—It is extremely important, particularly for 4-cycle engines, where close regulation is required, that the gas pressure be kept at a uniform atmospheric pressure, and checked by a manometer on the gas header. If the gas pressure is different from that of the air a perfect mixture can be had at any one load, but as soon as the load changes the mixture will vary, and the engine becomes erratic. The final regulator should not be required to reduce the pressure from more than 8 oz. per sq. in. If the supply is at a greater pressure an additional high-pressure regulator should be supplied. A tank of

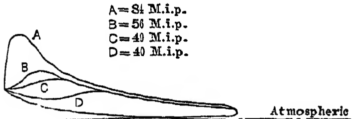

Fig. 11. Effect of Lean Mixture

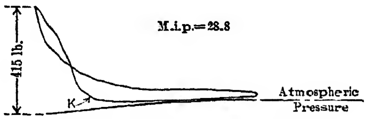

Fig. 12. Effect of Preignition

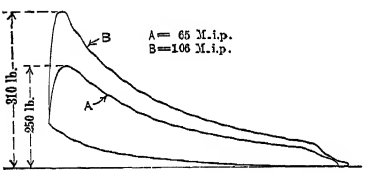

Fig. 13. Effect of Missed Ignition

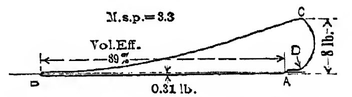

Fig. 14. Proper Shape of Scavenging Card

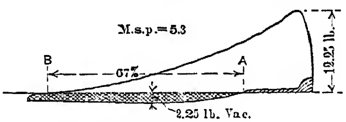

Fig. 15. Effect of Improper Intake

ample volume, say, at least, 5 times the volume of one cylinder should be placed in the fuel line between the final regulator and the engine. For best results there should be a regulator and tank for each engine.

In gasoline plants using 2-cycle engines, where close regulation is not required, it is common practice to run several engines from one fuel header, using one regulator. However, with this arrangement all the engines occasionally "get in step," causing violent pulsations in the header and temporary erratic operation.

EFFECT OF DIFFERENT COMBUSTION CHAMBER SHAPES.—Detonation in a gas engine is caused by too rapid a pressure rise. It can be the result of too early ignition, although the shape of the combustion space and the rate of flame propagation of the mixture have a very decided bearing. The smaller the combustion space, and the more central the spark plug, the quicker the flame started by the plug can reach the most remote part of the combustion space and, therefore, the faster will be the pressure rise. Fig. 16 shows one extreme, the valve-in-head type, with valves in face of the head and the spark plug in the center. This provides the shortest possible path from the plug to the rim of the combustion space. The other extreme is represented by Fig. 17, a horizontal engine with vertical valves. Here the flame has to travel a relatively long distance from the spark plug to the upper edge of the cylinder bore. A design similar to Fig. 16 will produce cards of the form of Fig. 8*B*, while a design like Fig. 17 will produce low peak-pressure cards similar to Fig. 8*A*. In any design the spark plug should be so located as to give the longest possible path for flame propagation without putting it in pockets that would fail to scavenge.

Starting.—Small high-speed gas engines usually are either hand-cranked, or started by means of a battery and starting motor, similar to automotive equipment. The larger engines are started by air, a suitable air compressor and storage capacity being provided. In starting, air at from 150 to 200 lb. per sq. in. pressure is admitted by means of a suitable valve gear, during the power stroke of the engine. When the engine starts to fire, the check valve in the head is held shut by the internal pressure as long as it is higher than the air

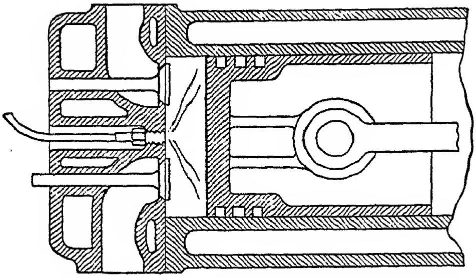

FIG. 16. Compact Combustion Space of Valve-in-head Engine, with Spark Plug in Center

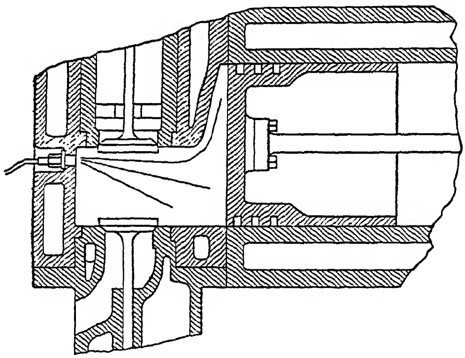

FIG. 17. Attenuated Combustion Space of Horizontal Engine with Vertical Valves

pressure. After the air is shut off this valve remains closed permanently. The air compressors usually are separate from the engine and are driven by either motor, gas or gasoline engine, either belted or direct drive. En-bloc units are available with either one power cylinder and one compressor cylinder or two power cylinders and two compressor cylinders. For larger installations the compressors should be 2-stage.

9. DETAILS

Floor Space.—The figures below give the approximate floor area required for vertical and horizontal gas engines. The horsepower in each case is calculated on a standard basis of 70 lb. per sq. in B.m.e.p., and piston speeds of 900 and 750 ft. per min., respectively, for vertical and horizontal engines.

Vertical engines	4–6 Hp. per sq. ft.
Horizontal engines	0.5–1.0 Hp. per sq. ft.

Air Tank Capacity.—Table 5 gives recommended storage capacities for different classes of engines for single installations, both in proportion to the brake horsepower, and to the engine cylinder displacement on power strokes only.

Where there are many engines in one installation, additional capacity should be added in proportion to the rapidity with which it would be necessary to start engines if they were all down at one time.

Table 5.—Capacity of Air Storage Tanks

Type of Engine	B.Hp. per cu. ft. of Storage Capacity	Cu. ft. of Storage Capacity per cu. ft. of Piston Displacement
Large horizontal, slow-speed double-acting...	13	2.5
Medium size, horizontal single-acting.......	15	4
Medium size, vertical multi-cylinder........	9–12	10–12
Small size, vertical multi-cylinder..........	15	10–12

Exhaust Piping.—The exhaust piping on a 4-cycle engine should be of ample size to prevent undue back pressure, particularly when mufflers are used. This loss of power in a 4-cycle engine is a direct relation to the M.i.p., *viz.*, a 1-lb. per sq. in. back-pressure in an engine operating at 70 lb. per sq. in. M.i.p. shows a loss of $^1/_{70}$ of the indicated horsepower.

Back pressure has much more effect on a 2-cycle engine, as it very seriously affects the volumetric efficiency of the scavenging pump, thereby limiting the rating of the engine and causing it to run hot (see page 12–40, and Fig. 15). The exhaust causes pressure waves which may either help or hinder the scavenging. The frequency of the pressure wave depends on the speed of the engine and the length of the exhaust piping. If possible the length of the exhaust pipe should be varied until the most favorable scavenging conditions are obtained, *viz.*, scavenging to take place while the pressure wave is in the lowest part of its cycle. If mufflers are necessary they should be of large size with very low back-pressure. A large pit makes an excellent exhaust muffler for 2-cycle engines.

Air Filters.—For long life it is just as necessary to filter the air as it is the oil, for most engine locations. Air filters should be of such size that the drop in pressure through them is not over 6 to 8 in. of water. If more than this, it will be difficult to maintain proper mixtures at different loads.

Foundations.—The mass of foundation required varies with the type of engine and the quality of the soil. Small high-speed multi-cylinder engines require little or no foundation, often being mounted on light steel girders or wood sills.

Table 6 gives satisfactory foundations based on both B.Hp. per cubic yard and pounds of engine weight per cubic yard for different classes of larger engines for good soil conditions.

Table 6.—Foundation Volumes for Gas Engines

Type of Engine	B.Hp. per cu. yard	Weight of Engine Per cu. yard of Foundation
Vertical 3-cylinder.....................	8–12	1000–1500 lb.
" 4-cylinder.....................	9–14	1000–1500 "
" 6-and 8-cylinder...............	12–16	1400–2000 "
Horizontal 4-cycle, single or twin, direct-connected compressor engine.........	4–7	800–1300 "
Horizontal 2-cycle, single..............	8–10	1100–1300
Horizontal 2-cycle, twin...............	10–12	1500–1600 "

For bad soil conditions it is good practice to build the foundation with an extended footing at the bottom, extending well outside the main block, thus reducing the bearing pressure on the soil. Where more than one engine is installed this footing should form a solid mat under all of the engines.

GASOLINE ENGINES

The gasoline engine thermodynamically and in construction details is similar to other internal combustion engines. Its most important difference is the addition of a carburetor which volatilizes the liquid gasoline fuel, mixes it with the proper amount of air to form an explosive mixture, which it then delivers to the cylinder. Ignition of the charge is accomplished by an electric spark across the points of a spark plug in the cylinder head. The ignition current is supplied usually from a generator driven by the engine.

Gasoline engines can be operated, with slight alterations, with natural gas, kerosene and other petroleum products as fuel. When operating on natural gas of at least 10,000 B.t.u. heating value, the engine being equipped with high-compression heads, the power developed will be about 15% less than when operating on gasoline.

The effect of altitude on power developed is small up to elevations of 3000 ft. Above 3000 ft. the power developed will decrease about 5% for each 1000 ft. increase in altitude. If the engine is equipped with high-compression heads, the decrease will be about 3% per 1000 ft. increase of altitude. High-compression heads are recommended for high altitudes and also when natural gas is used as fuel.

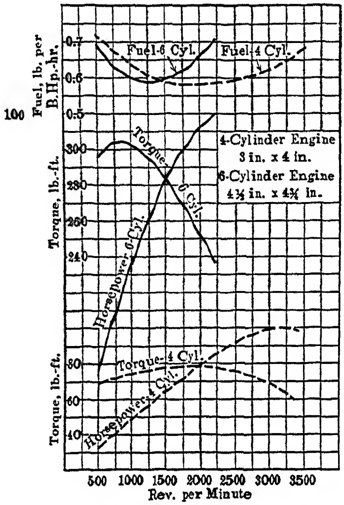

Fig. 1. Typical Performance Curves of Gasoline Engines

Gasoline engines are used mainly for the driving of automobiles, but they also have wide industrial use. Some of the applications of gasoline engines are the driving of agricultural machinery, air compressors, fans and blowers, centrifugal and power pumps, concrete mixers, conveyors, cranes, electric light plants, excavating machinery, tractors, oil field equipment, pile drivers, refrigeration machinery, road building machinery, saw mills, and other wood-working machinery, separators. They also find wide application in the propulsion of small boats.

Fig. 1 shows performance curves of typical 4-cylinder and 6-cylinder gasoline engines. Table 1 gives dimensions and capacities of a range of sizes of gasoline engines made by one manufacturer. The horsepower figures are for stripped engines, corrected to standard temperature and pressure. A deduction of about 15% should be made to determine net horsepower available. This will include an allowance for fan drives and accessories and also variations in temperature and barometric pressure.

For data on proportions and operating characteristics of gasoline engines used in automotive practice see pp. 14-55 to 14-66.

Gasoline engines are built by Allis-Chalmers Mfg. Co., Milwaukee, Wis.; Fairbanks, Morse & Co., Chicago; Hercules Motors Corporations, Canton, O., and others.

GAS PRODUCERS

By John Blizard

TABLE OF CONTENTS

GAS PRODUCERS

GAS PRODUCERS*

By John Blizard

1. THEORY OF GAS PRODUCERS

The object of a gas producer is to convert a solid fuel into a combustible gas, by causing a current of air, or air and steam, to traverse a mass of thick incandescent fuel, and the freshly charged fuel above it. Hydrogen, methane, tars and steam are driven off from the freshly-charged fuel, so that the incandescent fuel bed contains the carbonaceous residue and the ash.

THERMO-CHEMICAL REACTIONS BETWEEN OXYGEN, STEAM AND CARBON.—The heat absorbed or given off when any chemical reaction takes place depends solely on the mass, initial and final states of the reacting system, and is independent of the number of stages in which it takes place (Law of constant heat summation).

When 12 lb. of carbon unite with 32 lb. of oxygen at 64° F. to form 44 lb. of CO_2, 14,544 × 12 B.t.u. are liberated. This may be expressed by a thermochemical equation,

$$C + O_2 = CO_2 + 174{,}500 \text{ B.t.u.} \quad [1]$$

where C = atomic weight of carbon, lb.; O_2 and CO_2 = respectively, molecular weight of oxygen and carbon dioxide, lb.; O_2 and CO_2 also represent 380 cu. ft. at 60° F. and 29.92 in. of mercury; or the volume of a 1-lb. molecule of any gas is 380 cu. ft. at 60° F. and 29.92 in.

When 12 lb. of carbon unite with only 16 lb. of oxygen, only 4325 × 12 B.t.u. are liberated, and

$$C + {}^1/_2\, O_2 = CO + 51{,}900 \text{ B.t.u.} \quad [2]$$

Equations [1] and [2] are termed exothermic, because heat is liberated; but when 44 lb. of CO_2 combine with 12 lb. of carbon, 70,700 B.t.u. are used up; this is an endothermic reaction. It is represented by equation [3], obtained by subtracting 2 × equation [2] from equation [1].

$$CO_2 + C = 2CO - 70{,}700 \text{ B.t.u.} \quad [3]$$

Equation [2] represents the best results to be obtained by blowing air up through a thick incandescent bed of carbon; both CO and CO_2 are formed when the air first meets the incandescent carbon. The CO_2 is reduced later in the upper layers as shown in equation [3].

If the CO formed is delivered to the furnace where required, without loss of heat by cooling, no heat will be lost in the process, since the 51,900 B.t.u. liberated in forming the CO will be present in the hot gas; but if the gas be cooled this heat will be wasted and the theoretical producer efficiency will be (174,500 − 51,900) ÷ 174,500 = 70%.

The quantity and composition of the gas formed by oxidizing 12 lb. of carbon with air to CO will be

	Cu. ft. per 12 lb. C	Cu. ft. per lb. C	Percent by Volume
Carbon monoxide, CO	380	32	34.6
Nitrogen, N, (3.78 × 190)	718	60	65.4
Total	1098	92	100.0

where 3.78 is the ratio of N to O by volume in the air, and 380 cu. ft. is the volume of a 1-lb. molecule. The calorific value of the gas formed will be

$$(174{,}500 - 51{,}900) \text{ B.t.u.} \div 1098 \text{ cu. ft.} = 112 \text{ B.t.u. per cu. ft.}$$

To reduce the temperature in the producer, which interferes with its operation, to use some of the heat liberated in burning the carbon for making hydrogen, and to raise the calorific value of the gas, steam is blown through the fuel bed with the air.

* The assistance of Mr. A. K. Bradley, of the Morgan Construction Co., and Mr. J. F. Rogers, of the Wellman Engineering Co., in the revision of this chapter is acknowledged by the editor.

When 4 lb. of hydrogen burn at constant pressure to steam at 64° F., the thermo-chemical reaction is

$$2H_2 + O_2 = 2H_2O + 209{,}500 \text{ B.t.u.} \qquad [4]$$

By subtracting equation [1] from equation [4], equation [5] is obtained. This represents the main reaction between steam and carbon at temperatures between 900° F. to 1100° F.

$$2H_2O + C = CO_2 + 2H_2 - 35{,}000 \text{ B.t.u.} \qquad [5]$$

Above 1100° F., equation [6], obtained from equations [3] and [5], represents the main reaction, known as the water gas reaction;

$$H_2O + C = CO + H_2 - 52{,}850 \text{ B.t.u.} \qquad [6]$$

By adding equation [2] to equation [6], we obtain

$$2C + {}^1/_2\, O_2 + H_2O = 2CO + H_2 - 950 \text{ B.t.u.} \qquad [7]$$

from which it will be seen that comparatively little heat will be required for the reaction to take place; neglecting this small quantity, we have a theoretical efficiency of 100%. The gas formed by the combination of 16 lb. oxygen, 18 lb. steam, and 24 lb. carbon, and mixed with the nitrogen accompanying the oxygen in the air, will consist of

	Cu. ft. per 24 lb. C	Cu. ft. per lb. C	Percent by Volume
Carbon monoxide, CO.	760	32	41.0
Hydrogen, H.........	380	16	20.5
Nitrogen, N..........	718	29	38.5
Total.........	1858	77	100.0

The net calorific value of the gas will be 188 B.t.u. per cu. ft., or of 70% greater calorific value than when no steam is used. But equation [7] is unapproachable in gas producers, as additional heat must be generated to maintain the producer at the required high temperature, less steam per pound of carbon is decomposed and some carbon is burned to CO_2.

Formula [8] represents more closely what actually happens:

$$3C + O_2 + 2H_2O = CO_2 + 2CO + 2H_2 + 68{,}800 \qquad [8]$$

The gas formed will be	Cu. ft. per 36 lb. C	Cu. ft. per lb. C	Percent by Volume
CO_2..................................	380	10.6	11.4
CO..................................	760	21.1	22.8
H..................................	760	21.1	22.8
N..................................	1440	39.9	43.0
Total.	3340	92.7	100.0

The ratio of the net calorific value of the gas formed to the calorific value of the carbon burned is about 87%. The net calorific value of the gas is 137 B.t.u. per cu. ft., and one pound of steam is decomposed per pound of carbon converted into gas.

VOLATILE MATTER FROM COAL.—When coal is heated, gases, tars and steam are driven off. These products react among themselves and with the gases rising from the incandescent fuel bed. Among these gases are hydrogen, methane (CH_4), and ethylene (C_2H_4). The methane and ethylene have a considerably higher calorific value per unit volume than hydrogen or carbon monoxide, and so enrich the gas. The thermo-chemical equations of their combustion at constant pressure to water and CO_2 at 64° F. are

$$CH_4 + 2O_2 = CO_2 + 2H_2O_2 + 382{,}000 \text{ B.t.u.}$$

$$C_2H_4 + 3O_2 = 2CO_2 + 2H_2O + 600{,}000 \text{ B.t.u.}$$

The methane reacts with steam to form either CO or CO_2, and breaks up into C and H_2. Thus

$$CH_4 = C + 2H_2 - 40{,}000 \text{ B.t.u.}$$

$$CH_4 + H_2O = CO + 3H_2 - 92{,}800 \text{ B.t.u.}$$

$$CH_4 + 2H_2O = CO_2 + 4H_2 - 75{,}000 \text{ B.t.u.}$$

CH_4 reacts with CO_2, thus

$$CH_4 + CO_2 = 2CO + 2H_2 - 110{,}700 \text{ B.t.u.}$$

LIMIT OF REACTIONS.—All simple gas reactions are incomplete, though as a rule this can be observed only at high temperatures. Every chemical reaction will continue only until the reacting substances have each attained a definite relative concentration, corresponding to their temperature and total pressure. Thus, CO_2 and CO always will

have the same concentration if left long enough together in the presence of carbon at the same temperature and pressure. When this equilibrium is disturbed by raising the temperature, some CO_2 will react with carbon to form CO with the absorption of heat, which tends to diminish the temperature. In all chemical equilibria, when the temperature increases, the system will change so as to absorb heat and tend to annul the temperature change (principle of Le Chatelier). Thus at high temperatures, since CO_2 combining with C to form CO absorbs heat, less CO_2 and more CO exist at high temperatures when the mixture is in equilibrium.

These equilibria are of great importance in gas producer practice. Messrs. Rhead and Wheeler (*Trans.* Chem. Soc., 1910, 97–2178 and 1911, 99–141) found by experiment that the relative percentages of CO_2 and CO in equilibrium with carbon at one atmosphere pressure were as follows:

Temperature, deg F	1562	1652	1742	1832	2192
CO_2, percent	6.23	2.22	1.32	0.59	0.06
CO, percent	93.77	97.78	98.68	99.41	99.94

Another important reaction in a gas producer is that obtained by subtracting equation [6] from equation [5].

$$CO_2 + H_2 = CO + H_2O - 17{,}850 \text{ B.t.u.} \qquad [9]$$

This reaction also is reversible, and since heat is absorbed, when written as above, the ratio of the product of the concentrations of CO and H_2O to that of the CO_2 and H_2 will be greater as the temperature rises, when the reacting substances are in equilibrium.

The "equilibrium constant" $K = (CO \times H_2O)/(CO_2 \times H_2)$, expressed in terms of the relative concentrations of CO, H_2O, CO_2 and H_2, has been determined by Hahn (*Zeit. für Physikal. Chemie*, 1903, 43, p. 705, and 44, p. 513), as follows:

Temp. deg. F	1447	1627	1807	1987	2201	2561
K	0.81	1.19	1.54	1.95	2.10	2.49

At 1526° F., K is equal to unity; that is, the carbon monoxide and hydrogen are equally strong reducing agents. At higher temperatures, hydrogen, and at lower temperatures, carbon monoxide is the stronger reducing agent (Haber, Technical Thermodynamics of Gas Reactions, p. 145).

EXPERIMENTS ON ACTUAL FUEL BEDS.—Technical Papers 137, 139, U. S. Bureau of Mines, give results of tests by Messrs. Kreisinger, Augustine, Katz and Ovitz on combustion in a fuel bed. The compositions of the gas, and the temperature in different layers are given when burning various coals and coke. They show the oxygen to be practically used up after passing through 4 in. of the fuel bed. Table 1 gives the results of one test when Pittsburgh bituminous coal was burned at the rate of 20 lb. per hour, in a fuel bed 6 in. thick and of 1 sq. ft. area.

It is interesting to note that the sample of gas taken 6 in. from the grate had a gross calorific value of 115 B.t.u. per cu. ft., and that this thin bed of fuel acted as a gas producer with a fairly good efficiency.

Table 1.—Gasification of Pittsburgh Coal

2. PERFORMANCE OF GAS PRODUCERS

TESTS OF GAS PRODUCERS.—Tests of Morgan producers at the Youngstown Sheet and Tube Co. in 1930 showed an average rate of gasification of 6108 lb. of coal per hr., equivalent to 77.76 lb. per sq. ft. of producer area per hr. The average thickness of fire was 9 in.; of ash 33 in. The average weight of steam used per lb. of coal was 0.228 lb. at a pressure of 74 lb. per sq. in. Average gas temperature and pressure were 1370° F. and 1.43 in. of water, respectively. Average gas analysis was as follows: CO_2, 5.78%; illuminants, 0.16%; O_2, 0.26%; H_2, 12.85%; CO, 22.19%; CH_4, 3.19%; N, 55.57%. B.t.u. per cu. ft. was, maximum, 152; minimum, 128; average, 139. The proximate

analysis of the coal used was: Volatile matter, 36.30%; fixed carbon, 53.22%; sulphur, 2.10%; ash, 10.48%; moisture, 1.93%.

Table 2 is the log of a test of $61^1/_2$ hr. duration, in regular operation, of a Wellman type L producer, 10 ft. diameter, in a steel plant in the Pittsburgh district. The analysis of the coal was: Moisture, 0.93; C, 76.74; H, 4.66; O, 5.50; N, 1.58; S, 1.97; ash, 9.55; ash fusion temperature, 2190° F.

ESTIMATED HEAT LOSSES.—(Campbell, Manufacture and Properties of Iron and Steel, Ed. 2, 1903, p. 229.)—H. H. Campbell estimated the actual losses from actual practice at Steelton, Pa., as follows:

Lost as carbon in ash	2.1 percent
Sensible heat of dry gas	13.7 "
Sensible heat of steam in gas	0.7 "
Radiation and conduction (by difference)	5.1 "
Total loss	21.6 percent

Dr. C. S. Palmer (*Proc.* Engrs. Soc., West. Penna., vol. xxxiv, p. 338) says that this loss is perhaps about the average.

ECONOMICS OF PRODUCER GAS. (Abstracted from paper by Victor Windett, *Trans.* A.S.M.E., IS-51-8, 1929).—The rate of gasification materially affects the quality of the gas. In the decade 1920–30 advances in producer construction, together with complete mechanical operation, have permitted gasification at rates 8 to 10 times those recorded in experiments in the previous decade, with an improvement in the quality of the gas. See Table 3.

The heating value of producer gas comprises three elements: 1. The heat of combustion or calorific value, as determined by chemical analysis of the gas, amounting to about 80% of the heat. 2. The sensible heat, corresponding to the temperature at which the hot gas enters the furnace, amounting to about 12% of the heat of the coal. 3. The

Cost of 1,000,000 B.t.u. calorific value of gas and tar vapor.	0.2881

* Foreman's time prorated from furnace foreman's part time.

calorific value and sensible heat of the tar vapor contained in the gas. Table 4 shows the relative value of each of these factors. The figures are based on routine operation of a large producer plant using Pennsylvania bituminous coal. If the hot raw gas is burned in the furnace practically all of this heat is recovered.

Table 6 gives an analysis of the cost of gas produced in a battery of three mechanically operated gas producers, gasifying 4000 lb. per hr. continuously over a period of one month. The cost per 1,000,000 B.t.u. with a battery of 10 producers, one of which was a stand-by, was practically the same. An analysis of the relative cost of gas, for a steel plant, as produced in 30 small hand-poked producers, and in 6 mechanically operated producers, showed that the cost of gas per ton of ingots was $1.48 with the hand poked producers and $0.98 with the mechanically operated producers.

Tests on some Western coals, of relatively low B.t.u. content, showed a production of 12 gal. of tar per ton of coal, 11.25 gal. being delivered to the furnace, and the balance condensed in the flues. The incandescent tar particles contribute to the luminosity of the gas, and the radiant heat therefrom adds materially to the effectiveness of the gas. Von Helmholtz has established the relative effectiveness of luminous and non-luminous flames as being in the ratio of 1.8 to 1.0.

The relative value of producer gas and other fuels is shown in Table 5. The comparisons are based on mechanically-operated producers, operated at high rates, and include the heat content of the gas, preheating of gas and air, and 20% excess air. Calculations for oil and tar include a 2 1/2% charge for atomization, heating in cold weather, and charge for burners, piping and containers. Producer gas cost is based on a cost of $5.06 per ton of coal gasified, or $4.00 per ton delivered.

If clean gas is required instead of raw hot gas, modifications in producer practice may be necessary. In general, gas temperatures in the producer should not exceed 1200° F.

Table 7 gives the cost of clean gas in one plant. The coal is screened for the producers, the dust being used elsewhere. Tar removed from the gas is burned under boilers. The thermochemical efficiency of the process, based on the original energy of the coal is 72%; by crediting the tar burned under the boilers, it becomes 78%.

3. FUEL FOR GAS PRODUCERS

Wood, peat, lignite, bituminous coal, anthracite and coke have been used in gas producers. When the gas is to be burned in a nearby furnace, a highly volatile fuel is suitable. If it has to be transported long distances or used in a gas engine, either elaborate scrubbers and tar extractors must be installed or the tars must be destroyed in the producer. For small power plants, anthracite or coke is preferred because the gas, when made in a simple up-draft producer, contains little tar.

A bituminous coal that cakes very little is desirable, since caked coal must be broken up to give the air blast access to the whole fuel bed. On the other hand, it may be advantageous for some of the fine particles of coal to cake together into larger pieces, since they are less likely to restrict the gas passages.

The Wellman Engineering Co., which builds large, mechanically-operated producers for supplying gas for furnaces says: "The most desirable coals for use in the producer are those running from 30% to 40%, volatile, 52% to 65% fixed carbon, with ash content under 15%. When a mechanical feeder is used, the coal should be crushed so as to pass through a 4-in. ring and may contain 35% of fines."

Ash that fuses at a comparatively low temperature will form clinkers, which oppose the passage of air, occupy space in the producer which should be occupied by fuel, and cling to the sides of the producer, reducing its effective area, and sometimes arching over. The fusibility of coal ash has been studied by Messrs. W. A. Selvig and A. C. Fieldner, and the softening temperatures of the ash of the United States coals are found to range from 1900° F. to 3100° F. (See *Coal Age*, Jan. 2, April 17 and June 12, 1919; Jan. 22, Sept. 30 and Oct. 21, 1920. See also p. 4–26.)

Coal having an ash fusion temperature of over 2200° F. is very satisfactory.

4. GENERAL DESIGN AND OPERATION OF GAS PRODUCERS

The essential features of an efficient gas producer are given as: 1. Ability to continuously feed fuel. 2. Maintenance of a uniform fuel and ash level. 3. Maintenance of uniform density of fire. 4. Ability to free the incandescent carbon from ash. 5. Uniform distribution of blast throughout the fuel bed. Other factors to be considered in producer design are: 6. Rate of gasification per square foot of fuel bed. 7. Depth of fuel bed. 8. Method of charging fuel, its rate of descent through the producer, and method of removing ash. 9. Means to control quantity of steam in the blast. 10. Construction and shape of shell.

THE RATE OF GASIFICATION per unit area depends upon the size of fuel, caking properties of fuel, fusibility of ash, size of producer, depth of fuel bed and the steam saturation of the air blast. About 10 lb. of fuel per sq. ft. per hour appears to be the amount allowed in hand poked producers, designed to give off uniform gas over long periods. When the fuel bed of the producer is agitated mechanically, as much as 92 lb. per sq. ft. per hr. may be burned.

THE DEPTH OF FUEL BED depends on the rate of gasification, and will be greater when the rate of gasification is greater. A homogeneous fuel bed 10 in. deep would be sufficient to give a good gas, and small producers have been used successfully with pea size anthracite, with provision for a maximum effective depth of fuel bed of only 18 in. The deep fuel bed requires a stronger blast, and is more difficult to poke, but it enables the ascending gas to give up more of its heat to the descending fuel.

The Wellman Engineering Co. recommends examining the producer fire bed by pushing a rod through it, removing the rod, and observing the temperatures from its color. This company also says that to make a rich gas, the combustion zone should be 6 to 8 in. deep, and below it, the ash zone should never be less than 6 in. nor more than 15 in. above the blast cover; the green coal zone should be from 12 to 18 in. thick. It also points out that if the upper green coal zone is but 6 to 8 in. thick, the gas will leave the producer at 1200° F., and have about 150 B.t.u. per cu. ft., but if maintained 8 to 15 in. deep, the gas will leave at 700° F. and contain 170 to 180 B.t.u. per cubic foot.

C. D. Smith, fuel engineer, in a private communication states: The most suitable thickness depends upon the kind of coal, the rate of burning, and amount of poking. In hand poked producers the fuel bed is invariably thicker than in mechanical producers, due to irregular poking.

CHARGING OF THE FUEL.—The fuel may be charged intermittently into a hopper or hoppers on the producer cover, from which the fuel may be fed to the fire bed, by opening a lower valve, after closing the hopper cover. Or, the fuel may be fed mechanically at rates depending on the required rate of gasification. Preferably, the fuel should be charged as continuously as possible, and distributed uniformly over the fire. In all producers the hoppers are placed with the view of evenly distributing the fuel over the fuel bed. In some mechanically operated producers the fuel bed is fed from a hopper, situated between the central axis and wall, to a rotating fuel bed; in others the cover and hopper are rotated, in order to distribute the falling coal from the hopper evenly over the fuel bed.

DESCENT OF THE FUEL.—Bituminous coal, if properly agitated, will descend through a producer, so as to leave all parts of the fuel bed exposed to the blast. If it is not agitated, the blast will pass through channels, reducing the effective area of the fuel bed, the gas will be poor, the temperature will rise in the gas channels, and troublesome clinkers will form.

Means are provided for poking either by hand or mechanically. With hand poking, the producer, at regular intervals, is carefully searched round the sides for clinkers, which are detached when found; the fuel bed is explored for any channels or hollows which may have formed; the surface of the fuel bed is broken up as it cakes together, and the fuel bed levelled.

The fuel bed of some producers is agitated continuously by mechanical means. This tends to reduce the uneven temperatures, the formation of clinker and the caking of the coal. The shell or base of these mechanical producers may be rotated, the entire depth of the fuel bed may be agitated by pokers, the upper level of the fuel bed may be levelled only, or it may be levelled and agitated for a few inches below the surface to prevent the fuel caking.

The best type of mechanical producer to use depends on the size of coal, its tendency to cake and the fusibility of its ash. The fuel bed of mechanical producers is poked by laborers from time to time, but the actual labor of poking will be less than in producers with no mechanical agitation.

REMOVAL OF ASH.—The ash may be raked through the water lutes or ashpit by hand labor. When a dry ashpit is used, doors are provided for removing the ash. Sometimes the bottom is an inverted cone with a door at the bottom, through which the ash falls on opening it.

When removing ash by hand labor, the intervals between removals are farther apart than when removing ash mechanically, and the fuel bed has to descend further by vigorous poking when the larger quantity of ash is removed. The perfect ash remover would remove the ash as formed. The mechanical ash remover consists usually of a plow which is held against the rotating ash bed, and forces the ashes out through the water lute.

When grates are used, doors are provided through which clinker may be drawn periodically from above the grates.

CONTROL OF STEAM IN BLAST.—The most convenient means of controlling the steam saturation of the air blast lies in observing the saturation temperature; the effect of the steam saturation has been already referred to. The steam for saturation may be supplied from a separate boiler, the exhaust of a steam engine, or it may be generated by waste heat from the gas producer itself, or by the waste heat from a gas engine.

DISTRIBUTION OF AIR BLAST.—The air blast in most producers is admitted through a central tuyere or blast hood. Large producers generally are kept under pressure. Blast is supplied by a constant volume blower, a centrifugal blower or a steam injector blower. Small gas-engine producer plants generally rely on the engine itself to draw air through the fuel bed, and scrubber resistance must be small to permit the gas engine to draw in its full charge.

CONSTRUCTION AND SHAPE.—The producer usually consists of an outside shell of steel plate, open at the bottom if a water lute is used, into which it extends. The top usually is water-cooled, though occasionally it is crowned inside with brick. The shell is lined with good firebrick, which must be well laid. A water jacket sometimes is provided to assist in cooling the brick-work.

Horizontal sections through the producer usually are circular, though sometimes square. The walls are shaped either to keep the sectional area of the fuel bed constant, or to decrease it as fuel descends. Producers have been built with water-cooled walls, and in the Mond producer air and steam blast passes around the shell before entering the producer, being thus preheated.

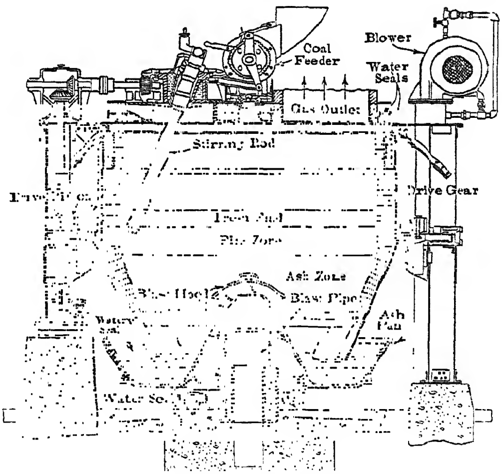

Fig. 1. R. D. Wood Gas Producer

TYPICAL PRODUCERS.—Fig. 1 shows a mechanical producer built by R. D. Wood & Co., Philadelphia. The upper part of the shell is cylindrical. The lower part is conical, terminating in a bosh. Both shell and ash-pan rotate. The feeder is a ratchet-driven drum, with three pockets, rotating in a housing, the escape of gas being prevented by a water-seal. An adjustable deflector plate controls the discharge of coal to the center or wall of the producer. The fuel bed is stirred by a forged steel, water-cooled bar, set at an angle and revolved in a circle of diameter approximately half that of the producer. The shell is rotated by a spur gear meshing into a gear ring on the shell, driven by a motor through a speed reducer. Blast is supplied by a turbo-blower. The blast pipe is in the center of the ash-pan, and terminates in a hood. Ashes are removed by an adjustable steel plow. All joints between stationary and rotating parts, through which gas could escape, are water-sealed. The producer rotates once in every 6 min., and the stirrer rod once every 1.83 min.

The Morgan producer (Morgan Construction Co., Worcester, Mass.) is shown in

Fig. 2. The essential features of this machine are a rotating shell, levelers which continuously level the fuel bed and agitate the fire, continuous coal feeding, and water-cooled walls. A gear ring drives the bottom of the producer, and also a central hub. Three arms on the hub carry the water-cooled shell. The top of the producer is stationary, and is carried by three columns. The top is water-cooled, and supports the continuous feeders and the levelers. Its lower edge extends down into the water-jacket of the shell thus effectually sealing the producer. Ashes are removed by a stationary plow on the rotating bottom. Blast is furnished through a central tuyere by means of a steam ejector, which delivers air through a nest of Venturi tubes underneath a hood. The additional steam necessary for gas making is introduced into the central tuyere through a by-pass. The quantity of steam is readily controlled to coincide with the gas-making requirements. This type of machine has continuously gasified as much as 8000 lb. of coal per hr.

In the Wellman mechanical producer, Fig. 3 (Wellman Engineering Co., Cleveland), the ash pan and shell revolve and the top is stationary. The coal feed comprises two bells so timed that one bell always is closed gas tight. The rate of feed is controlled by a variable speed vane wheel operated by ratchet wheel and adjustable stroke crank. The water-cooled poker is set at an angle, with the point in advance, and swings in an arc from the center to the side wall. This causes a gentle lifting of the semi-plastic coal mass, making it porous for the free exit of the gas and closing holes and pipes. The blast hood is mounted on the ash pan and gives a uniform blast over the entire area of the producer. The ash-pan is stopped three times in each revolution of the shell for approximately 21° total, to loosen up the ash bed. Scrapers and ejectors force the ashes to the outside of the pan where they are removed continuously by the stationary ash plow.

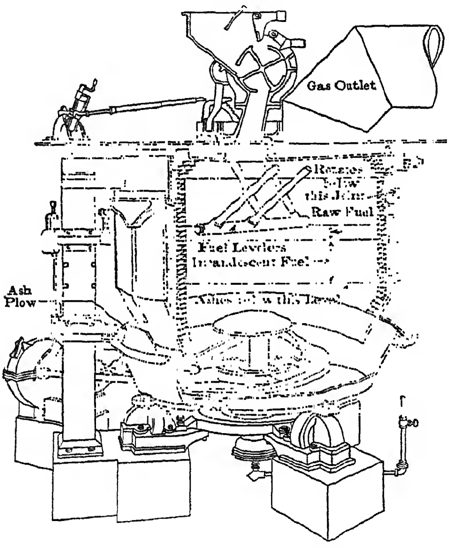

FIG. 2. Morgan Gas Producer

Fig. 4 is a simple suction producer. Coal is charged to the hopper N at the top, thence after closing the cover it is passed through a valve to the fuel bed.

The air enters at the left through A, passes into a saturator B, where it becomes saturated with steam evaporated from water which has been heated by the gas engine. This water enters the scrubber at the top, trickles down over the coke, and passes to the water seal R. The saturated air passes through C to the producer ashpit, up through shaking grates D to the body of the producer E. Gas leaves through F and G to H, where it may be either discharged to the atmosphere when starting, or passed down through K, up through a water scrubber L, and to a moisture trap M. This producer is intended for use with any good, clean Pennsylvania anthracite, with a calorific value of 12,500 B.t.u. per pound or over, less than 15% ash, and less than 1 1/2% sulphur. Either pea or No. 1 Buckwheat sizes may be used.

PRODUCER OPERATION.—The following notes on producer operation are abstracted from the operating instructions issued by R. D. Wood & Co.

Starting.—Ash-pan should be filled level with hard dry ashes free from coal and coke, using only those that will not pass a 1/2-in. screen. If coal-free ash is not available, clinker or firebrick broken to 2-in. cubes, may be used. Freedom from coal and coke is highly important, as combustible in the ash will form clinker, clogging the blast hood. When the ash is in place, porosity of the bed should be ascertained by operating the blower.

Cover ash bed with small dry wood to depth of 18 in., and sprinkle wood with kerosene. Turn water into the water-cooling system, and close fuel entrance from feeder. Light the wood by dropping lighted oil-soaked waste through poke-holes. Gradually increase water supply to cooling

system as heat increases in producer. The wood should be burned as slowly as possible, to heat the brickwork thoroughly and uniformly.

When the wood has burned to a charred mass, purge the producer of smoke, and close poke holes on top plate. Begin feeding coal through the feeder, and start the blower. The pressure at the bottom of the producer should be about 1 1/2 in. of water or less. Exhaust steam from the turbo-blower should be turned into the blast pipe. The fire should not be forced, but burned slowly for several hours to form a heavy coat of tar and soot on the underside of the top plate. When the bed has been built to a gas-making condition, the coal feed should be increased to the amount necessary to produce the desired quantity of gas.

Operation.—Blast pressure should be increased to a point where coal will be burned at the rate it is fed. Moisture in the blast should be kept sufficiently high to prevent formation of clinker. Blast saturation is indicated by the temperature in the blast pipe, which should be from 130° to 150° F. The proper temperature is determined by the amount of coal burned to produce the required quantity of gas. Excess steam will cool the fire, and cause the bed to become tarry. A cool bed causes clinker and hot gas. Excess pressure at the bottom of the producer may cause ignition of gas in the producer. Gas temperature should be between 1,300° and 1,400° F., and bottom pressure about 4 1/2 in. of water when burning 30 tons of coal per 24 hr. Bottom pressure usually must be increased for higher fuel consumption or when the bed becomes packed.

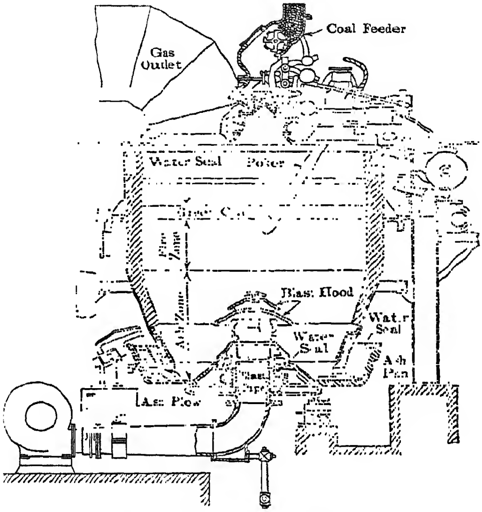

Fig. 3. Wellman Gas Producer

Ash level should be kept at a depth of 21 to 25 in. over the blast hood. Depth of ash should be ascertained every hour by insertion of a measuring rod for a period of 75 sec. in the poke-holes, the holes at the center being used to determine depth over the hood. The heated portion of the rod will show the location of the fire, and the black portion below it the depth of ashes. The producer should be stopped while measurements are being taken. The level of the top of fuel bed is found by a rod inserted in the poke-holes, and resting on top of the coal. The distance below top of producer should be approximately 54 in.

Shutting-down.—To burn out producer, shut off the coal supply and allow feeder to operate until empty. When gas has left producer, insert slide in blast pipe and shut down the blower. Open the poke-holes, open feeder slides and doors on gas exit flue to burn out soot. The producer should continue to rotate until it is time to open the doors. During burning out, the fuel bed should be examined for clinker or fire ring on the walls. Clinker should be broken up with a hand poker, and fire ring cut from the walls.

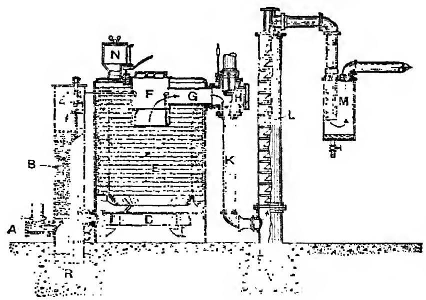

Fig. 4. Suction Gas Producer

CLEANING AND COOLING GAS.—Gas leaving a producer contains tar in the form of vapor, dust and soot produced by the decomposition of hydrocarbons. Weill (Manchester Assoc. Engrs., 1912), referring to up-draft bituminous producers, states that the gas contains 10 to 12 grams of tar per cubic meter, 3 to 5 grams of heavy dust per cubic meter, and 9 to 11 grams of soot per cubic meter. The tar, soot and dust content may remain in the gas if the furnace is near the producer; in fact the tar both adds to the calorific value of the fuel and renders the flame luminous. But if the gas has

to be transported long distances or used in a gas engine, it is cleaned to prevent the deposition of tar, and cooled to raise its calorific value per unit volume.

Gas made from low volatile fuels can be cleaned usually by first passing it up through a simple form of water scrubber, and then through a scrubber filled with sawdust. Special tar extractors are required to remove the tar from gas made from bituminous fuels in up-draft producers.

REMOVAL OF TAR.—There are several methods of removing the tar. A common method is to pass it through a centrifugal cleaner, which really is a badly-designed fan. Weill (Manchester Assoc. Engrs., 1912) gives the following particulars of a cooling and purification plant for a 1000-H.p. producer, gasifying 930 lb. of fuel per hour.

The Mond washer referred to is a water spraying device in which revolves a dasher; the cleaners are the centrifugal cleaners referred to above. Temperatures, deg. F., entering Mond washer, over 752; entering No. 1 cleaner, 120; entering No. 2 cleaner, 90; entering sawdust scrubber, 57; cooling water, 46; atmosphere, 50.

	Grams Tar per cu. meter	Percent Extracted
Leaving producer.........	11.68	0.0
" Mond washer.....	4.30	62.9
" No. 1 cleaner.....	1.55	22.8
" No. 2 cleaner.....	0.30	10.8
" sawdust scrubber..	0.04	2.2

The Smith Tar Extractor. (*Trans.* A.S.M.E., xxxv, p. 837).—The Smith tar extractor consists of a mat of glass wool, through which the gas is forced by a blower under a pressure of several lb. per sq. in. The fall in pressure in passing through the mat is from 2 to 4 lb. per sq. in. The tar particles, in passing through the mat, collect to form larger drops which fall out of the gas into a trap.

Flinn and Dreffein Tar Extractor consists of a tapered plug, heavily threaded, fitted into a female similarly threaded. The plug is mounted upon a vertical shaft, which has a thread the same pitch as the plug. The threaded part of the shaft passes through an outside yoke. Accordingly, the plug may be screwed up or down and remain in mesh with the female thread, but not in contact with it. The width of passage or channel between the threads is varied through changing the position of the plug. The dirty gas enters the tar extractor above the plug and is drawn through by means of the suction produced by the gas exhauster. In the upper chamber of the extractor, above the plug, are water sprays. Water is used to further cool the gas and also to act as a vehicle for maintaining the flow of tar and soot removed from the gas. Only a small volume of water is used for this purpose.

The position of the plug is determined by the drop in pressure necessary to overcome the resistance resulting from the restricted passages, which resistance is indicated by a differential gage. An average drop in pressure of approximately 1 lb. is carried, thereby setting up a gas velocity greater than two miles per minute. At this exceedingly high velocity, the small particles of tar strike against the threads, causing a thin film of liquor, which results in a stream of tar that is drained off from the bottom of the extractors into a settling tank. Wherever there is a thread, the gas must change its direction and the tar particles strike the metal surfaces with great force. At each thread, the gas changes its direction twice, so that in a tar extractor having a plug of ten threads, there are twenty impacts, being more than can be obtained in any mechanical device. This tar extractor can be adjusted for varying rates of gas flow. At light loads, the plug is screwed up to give small width of channel for the gas.

GAS PRODUCERS WITH RECOVERY OF AMMONIA.—About 60 to 75% of the nitrogen of a fuel gasified in a producer will pass off as ammonia, if sufficient steam is used in the blast to prevent the temperature rising. The ammonia formed is brought into contact with sulphuric acid and combines with it to form ammonium sulphate, thus:

$$2NH_3 + H_2SO_4 = (NH_4)_2SO_4,$$

$$34 \text{ lb.} + 98 \text{ lb.} = 132 \text{ lb.}$$

Since 132 lb. of ammonium sulphate contains 28 lb. of nitrogen, the greatest quantity of ammonium sulphate which may be recovered from 2000 lb. of fuel containing 1% nitrogen is 94 lb. The ammonium sulphate formed is in a weak solution, from which the water must be driven off by evaporation. In the Mond ammonia-recovery producer plant about 2 tons of steam are used per ton of coal, one-half of which steam comes from recuperation towers. The air blast is saturated with steam at about 185° F.

Tests by Bone and Wheeler (*Jour.* Iron and Steel Inst., 1907, No. 1, p. 154) on a Mond producer, show the effects of the steam saturation of the blast on the ammonia recovery. The coal contained 1.39% N, which, if all recovered, would correspond to 147 lb. of ammonium sulphate per 2240 lb. of coal; the ton used below is the ton of 2240 lb.

Lb. of steam per lb. of coal gasified.............	0.45	0.55	0.80	1.10	1.55
Cu. ft. of air (32° F. and 29.92 in.) per lb. of coal	37	35	37	37	37
Lb. of NH_3 in gas as $(NH_4)_2SO_4$ per ton of coal...	39	45	51	65	72

A large plant, working continuously, is necessary for economical by-product recovery, in order to make the capital investment on the ammonia-recovery plant pay. By-product recovery producer plants are working on coal and peat. With peat, the gases leaving the incandescent zone rise up through the raw peat and dry it, thus permitting peat of a fairly high moisture content to be used.

Tests by Denny and Krubbs (*Engg.*, Jan. 27, 1922) on a Mond producer plant showed the by-product recovery per ton (2240 lb.) of coal with 1.4% N, to be ammonium sulphate 60.4 lb., pitch 35.4 lb., washer dust 100 lb., washer liquor as (NH_3) 0.76 lb. The thermal efficiency, on net coal gas value and gross heat used on plant, was only 42.7%. Mean composition of gas, CO, 10%; CO_2, 14.9%; H_2, 24.2%; N_2, 47.8%; CH_4, 3.1%.

SPACE REQUIRED FOR PRODUCER PLANTS will depend on the rate of gasification per unit area of fuel bed, on the size and number of scrubbers and other factors. See Tables 8 and 9.

Table 8.—Space Required for Anthracite Producer Plant

Rating, 1,000 B.t.u. per hour........	250	500	750	1,000	1,250	1,500	2,000	3,000
Diameter of producer, in............	42	54	60	66	72	78	90	108
Foundation (suction), feet square....	4.5	5.5	6	6.5	7	7.5	8.5	10
Foundation (pressure), width above by	8.5	9.5	10	10.5	11	11.5	12.5	14
Height of producer, ft...............	10	10	10	10	12	12	12	12
Minimum head room, ft.............	19.5	19.5	19.5	20	22	22	22	22
Minimum length of building, inside, ft.	14	14.75	15.25	16.5	16.75	17.75	20.5	22
Minimum width of building, inside, ft.	13.5	14.25	14.75	16	16	17	17.5	19

Producer plants for semi-anthracite would be installed in buildings of about the same size as above for the same output.

Table 9.—Space Required for Mechanically Operated Producer Plants for Bituminous Coal

Rating, 1,000 B.t.u. per hour..................	6,000	20,000 to 25,000	30,000 to 35,000
Size, outside diameter of generator, ft..........	9	14	16
Floor space, approximately, ft................	21 × 33	29 × 46	36 × 55

A modern (1935) mechanical producer, 10 ft. internal diameter requires a building space about 18 ft. square.

5. TESTING GAS PRODUCERS

The usual primary object of a gas-producer test is to determine the ratio of the chemical heat energy of the gas to the energy in the fuel. Other objects may be to determine the calorific value of the gas, its tar and soot contents, the difficulties encountered in operating the producer, the ammonia in the gas, the steam used in the air blast, and the resistance of the fuel bed to the blast. See Test Code for Gas Producers, p. 16–50.

6. PROPERTIES OF PRODUCER GAS

THE CALORIFIC VALUE OF THE GAS may be determined directly by a continuous-flow, constant-pressure gas calorimeter or from the analysis of the gas. Tables 10 to 13, inclusive (prepared by G. W. Jones of the U. S. Bureau of Mines) enable the calorific value to be rapidly determined from the analysis; Table 14 (also prepared by Mr. Jones) enables the cubic feet of gas per pound of carbon in the gas to be determined.

USE OF TABLES. *Example.*—The gross calorific value of a gas containing CO_2, 10.8; C_2H_4, 0.5; CO, 17.7; CH_4, 2.4; H_2, 10.2%, will be $7.9 + 57.2 + 24.2 + 33.1 = 122.4$ B.t.u. per cu. ft. at 60° F. and 29.92 in. of mercury.

The cubic feet of gas at 60° F. and 29.92 in. of mercury per lb. C in the gas is read from the tables by observing the total of the percentage of CO_2, CO, CH_4 and twice the percentage of C_2H_4; this will be $10.8 + (0.5 \times 2) + 17.7 + 2.4 = 31.9$, and the cubic feet of gas per pound of carbon corresponding to 31.9 (Table 14) is 98.7. Supposing the fuel to contain 70% carbon, of which 2% goes to the ash and 1% to tar and soot, the cubic feet of gas per pound of fuel will be $98.7 \times 0.67 = 66.1$ cu. ft. The chemical energy in the gas per pound of fuel will be $66.1 \times 122.4 = 8100$ B.t.u.; so that if the calorific value of the fuel be 10,000 B.t.u. per lb., the efficiency, based on the gross calorific value, will be 81%. To obtain the net calorific value from the gross calorific value, it is necessary to subtract the latent heat of steam, at some arbitrary temperature, formed by burning H_2, CH_4, and C_2H_4, from the gross calorific value. If the latent heat of steam at 60° F.

be chosen (1058.2 B.t.u. per lb.), the net calorific value may be obtained by deducting $0.5H_2\% + CH_4\% + C_2H_4\%$ from the gross calorific value. Thus, the net calorific value of the above gas will be

$$(122.4 - 5.1 - 2.4 - 0.5) = 114.4 \text{ B.t.u. per cu. ft.}$$

THEORETICAL FLAME TEMPERATURE.—Calorific intensity, or theoretical flame temperature, is the highest temperature that can be reached when a gas burns at constant pressure in air so that the sole gases present after combustion are the oxidized gas and nitrogen. It is higher than the maximum temperature in an actual flame, because when gas burns, it does not burn completely, instantaneously, and it loses heat by radiation. The calorific intensity is calculated by dividing the net calorific value of the gas by the mean thermal capacity of the products of combustion over the temperature range.

The calculated values for the same gases vary with the values chosen for the mean

B.t.u. per pound-molecule per deg. F. difference, or in calories per gram-molecule per deg. C. difference. To obtain the specific heat (B.t.u. per lb. per deg. F.), the values given must be divided by the molecular weight of the gas.

Thus, $8.02 \times (4500 - 32)$ = B.t.u. required at constant pressure to raise 28 lb. of CO or N_2 or 32 lb. of O_2 from 32° F. to 4500° F., and $8.02 \div 28 = 0.286$, is the mean specific heat of N_2 or CO over this range.

CALCULATION OF CALORIFIC INTENSITIES.—The net calorific value of a pound-molecule of hydrogen is 104,750 B.t.u. and the mean thermal capacity per degree of the products of combustion in air (1.89 vol. N_2 and 1 vol. H_2O per vol. H_2) over the approximate temperature range = $(1.89 \times 7.9) + 11.34 = 11.34 + 14.93 = 26.27$, and the rise in temperature above 32° F. = $104{,}750 \div 26.27$ = 3985° F.

Similarly for CO, the thermal capacity per degree of 1.89 molecule of N_2 and one molecule CO_2 = $(1.89 \times 8) + 12.65 = 15.12 + 12.65 = 27.77$, and rise in temperature = $122{,}600 \div 27.77$ = 4420° F.

For methane, the theoretical flame temperature = 3720° F., which is lower than that of either H_2 or CO, although the calorific value of methane is about three times that of hydrogen and carbon monoxide.

The actual maximum flame temperature measured by Fery (*Comptes Rendu*, 137, 1903, p. 909) for a free hydrogen flame in air was 3452° F., or about 600° F. less than the calculated flame temperature for hydrogen.

The maximum temperature measured in a Bunsen flame, burning CO, when 29.5 volumes of CO were present in 100 volumes of the air-CO mixture, is given in the *Gas World*, April 10, 1915, p. 413, as 3220° F., or about 1270° F. below the calculated temperature; a maximum temperature of 3330° F. was obtained with 34% CO in the mixture. The maximum speed mixture of CO and air contains 45 to 50% CO, and evidently the higher temperature above the complete combustion mixture (29.5% CO) is due to a smaller, more intense flame with 34% CO.

THEORETICAL FLAME TEMPERATURE OF PRODUCER GAS.—The temperature of a producer gas flame is less than that of either of the component combustible gases, because it contains inert gases.

Tables 17 and 18 and the subjoined calculations show the flame temperatures and other calculations of the combustion of producer gas. From these tables, the maximum rise in temperature is (2940 − 60) = 2880° F., since the sensible heat content of the gas

4,500	8.02	12.37	12.66	2,482

formed by burning 100 lb.-molecules of gas for this range is 4,530,000 B.t.u., which is shown in Table 17 to be the net calorific value of 100 lb.-molecules. If the air be raised 1000° F. before mixing with the gas, then, since 100.4 lb.-molecules of air are required to burn 100 lb.-molecules of gas, and the mean specific heat per pound-molecule per deg. F. of the air equals 7.15 B.t.u., the sensible heat of the gas after burning will be greater by 7.15 × 100.4 × 1000, or 718,000 B.t.u., and the total sensible heat after combustion will be 4,530,000 + 718,000, or 5,248,000 B.t.u. This (line 2, Table 18) corresponds to a maximum temperature a little over 3300° F. If the gas be preheated as well as the air, the sensible heat will be increased by 7.48 × 100 × 1000 B.t.u. per 100 lb.-molecules, and the total sensible heat of the gases after combustion will be 5,248,000 + 748,000 = 5,996,000 B.t.u. Since Table 18 shows that 5,860,000 B.t.u., corresponds to a flame temperature of 3660° F., the flame temperature when preheating air and gas is a little above this.

Table 17.—Calorific Values, Volumes of Products of Combustion and Air Required to Burn Constituents of Producer Gas

Composition by Volume		Net Calorific Value (29.92 in. and 60° F.)		Volume of Products of Combustion per 100 Volumes of Gas Burned			Volume Total Products of Combustion	Volumes of Air to Burn 100 Volumes

Total per cu. ft. gas burned, B.t.u.	119	137	154
Actual mean specific heat (B.t.u. per lb. per deg. F.)	0.289	0.294	0.299

The theoretical flame temperatures of the above producer gas are tabulated as follows: cold gas and air, 2940° F.; cold gas, air heated 1000° F., 3340° F.; gas and air heated 1000° F., 3710° F.

The theoretical flame temperature varies considerably with the composition of the producer gas. Thus a gas richer than the above, containing 2% CO_2, 30% CO, 12% H_2, 3% CH_4, and 53% N_2, requires 1.28 volumes of air to burn one volume of gas, and has a theoretical flame temperature of about 3400° F., or about equal to that of the leaner gas with preheated air.

RADIATION FROM FLAMES.—Helmholtz (Die Licht und Warmestrahlung verbrennender Gase, Berlin 1890) found that in non-luminous flames, hydrogen radiated 3.61% and carbon monoxide 8.74% of the total heat of combustion. This accounts partially for the actual CO flame temperature being so much lower than the calculated flame temperature, and shows that for most heating purposes carbon monoxide is to be preferred to hydrogen, since it radiates twice as much heat per unit volume burned. The presence of tar in a producer gas flame enables it to radiate more heat.

IGNITION TEMPERATURES.—The ignition temperature must be reached at some point in an explosive mixture before the whole mixture will burn. Dixon and Coward (*Jour.* Chemical Society, 1909, 95, p. 514) give the following:

	Ignition range °F. in air
Hydrogen	1076–1094
Carbon monoxide (moist)	1191–1216
Methane	1202–1382

LIMITS OF INFLAMMABILITY.—Gaseous mixtures are inflammable only between two extreme limits, which are given by Thomas (*Engg.*, July 8, 1921, p. 78), as follows:

Hydrogen, 4.2 to 75.0%; carbon monoxide, 12.3 to 75.0%; methane, 5.5 to 13.3%. The figures refer to the proportion of combustible gas in the mixture.

The limits of inflammability of mixtures of combustible gas may be calculated from the proportions of the gases present and the limits of inflammability of the individual gases, but when considerable quantities of inert gases, as CO_2 and N_2 are present in producer gas, it is difficult to estimate the limit of inflammability. Payman (*Chem. Soc. Jour.*, 1919, part II, p. 1461) shows that from 24.7% to 61.6% of producer gas is inflammable in air-gas mixture.

SPEED OF MIXTURES OF COMBUSTIBLE GASES.—The rates of uniform flame speed in a 25 cm. tube over the range of inflammability have been found by Payman (*Chem. Soc. Jour.*, 1919, part II, p. 1461) for various gases. Table 19 shows some of Payman's values:

Table 19.—Rates of Uniform Flame Speed in Various Gases

Coal Gas, percent	Speed, cm. per sec.	Producer Gas, percent	Speed, cm. per sec.	CH_4, percent	Speed, cm. per sec.	$CO + H_2$, percent	Speed, cm. per sec.
7.2	21.5	24.7	20.0	5.80	23.3	9.25	18.2
11.9	87.1	46.0	62.7	7.47	42.0	41.50	309.7
16.8	153.9	49.0	72.2	9.52	66.6	45.92	315.2
20.4	115.6	54.3	69.7	10.64	63.5	51.23	280.0
21.8	74.3	58.8	43.5	12.25	35.0	58.55	178.5
24.3	22.0	61.6	24.0	13.35	19.1	71.34	44.4

The producer gas shown in Table 19, contained by volume, 5% CO_2, 21.3% CO, 12.6% H_2, 3.1% methane and higher paraffins and 58% N_2 (by difference). CH_4 is the principal constituent of natural gas; and CO and H_2 of water gas. The coal gas contained 1.1% benzine and higher olefines, 0.3% CO_2, 2.6% C_2H_4, 9.6% CO, 33.9% methane and higher paraffins, 49.2% H_2 and 3.3% N_2 (by difference). Payman also states that the mixture of air and producer gas with the fastest speed of uniform movement of flame contains slightly more inflammable gases than are required for complete combustion. Usually the mixture with the fastest movement of flame contains more inflammable gas than that corresponding to the mixture in combining proportions. Thus a hydrogen-air mixture in combining proportions contains 29.5% hydrogen, but a mixture containing 40% hydrogen has the fastest speed of uniform movement.

Mason and Wheeler (*Trans.* Chem. Soc., 1920, p. 1238) show the important part that convection currents play in the transmission of flame. They found that a mixture of 6.35% methane in air, when passed along a tube at the rate of 23 cm. per second, had double the flame speed the same mixture had when stationary.

7. DESIGN OF FURNACES FOR PRODUCER GAS

General rules for furnace design cannot be given. The character of the work, the temperatures to be maintained in the furnace, the character of atmosphere (oxidizing or reducing) in the furnace, the method of burning the gas, the method of handling the work in the furnace, and many other variables influence the design. A slight change in one variable may cause a wide variation in operating conditions, and render a given design unsuitable. For a complete discussion of the subject of industrial furnace design, see Trinks, Industrial Furnaces (John Wiley & Sons). See also Industrial Furnaces in Vol. 3 of this series.

In general, producer gas is a suitable fuel only in large installations. The initial cost of gas making equipment makes the cost of producer gas prohibitive when only a few furnaces are to be fired. If, however, a sufficient number of large furnaces or a large number of small furnaces are in use, producer gas will be an economical fuel. The gas may be used raw and hot, that is, as it comes from the producer, or it may be clean and cold. In the first form it must be burned in furnaces as close to the producer as practicable. In the second form it may be distributed to furnaces located at considerable distances from the producer.

Trinks, in Industrial Furnaces, Vol. 2, Chap. vi, compares the relative advantages of the several kind of fuel available for furnaces. The following is a summary of his statements relative to producer gas.

RAW PRODUCER GAS generally is used in large furnaces in which close regulation of furnace temperature and furnace atmosphere is not necessary. Its advantages include a low cost per B.t.u., simplicity of operation, low installation cost, and availability, since gas can be made wherever bituminous coal is available. Also, the gas burns with a lumin-

ous flame. Among the disadvantages are the necessity of locating the furnace close to the producer to avoid condensation of tarry vapors and the loss of sensible heat in long pipes. Further, the mains become choked with soot and tar and require cleaning at regular intervals. Uniformity of composition and quality of gas is difficult of maintenance, and the flow cannot be measured because of the dirt in the gas. Among the operating disadvantages are the necessity of delivering coal to, and removing ashes and clinker from the producer, the maintenance of a steam plant to supply steam to the producer, and the difficulty of maintaining an intelligent labor force in the gas house, because of the unfavorable working conditions.

COLD CLEAN PRODUCER GAS is limited generally to large installations, and to maximum furnace temperatures of about 2000° F., unless regenerative or recuperative furnaces are used. Among the advantages of this fuel are the low temperature of combustion, making it desirable for furnaces where temperatures should not exceed 1600° F., and the efficiency with which it can be burned. Depending on correct furnace operation, accurate temperature and furnace atmosphere control is possible, quality of heated product can be kept uniform, damage to it minimized, and scaling kept low. The gas burns without smoke, even if the atmosphere is reducing, and it can be distributed to a large number of small furnaces. The fuel cost is relatively low. Among the disadvantages are the high initial cost of gas making plant, the necessity of handling coal and ashes, the low heat content of the gas, and the necessity of disposing of the tar made in the producers. Also, the cost of operating labor at the producer is high, and good furnace operation depends largely on the quality of labor in the producer plant.

1. TRAIN RESISTANCE

RESISTANCE DUE TO SPEED.—(*Bull.* No. 1001, Am. Locomotive Co., Feb., 1910.) The best data available show resistance to vary from 2.5 to 3 lb. per ton (2000 lb.) for 72-ton freight cars, including weight of car, to 6 to 8 lb. for 20-ton cars. At speeds between 5 to 10 and 30 to 35 mi. per hr. resistance of freight cars is practically constant. Resistance R_E of engine and tender is figured separately. $R_E = F + H + W + G + R$, where F = engine friction = 1.11% of weight on drivers, H = head-on air resistance = $0.002\,AV^2$, W = resistance due to weight on engine trucks and trailing wheels, and to tender, being the same per ton as for cars, G = grade resistance = 20 lb. per ton for each one percent of grade, R = curve resistance = $0.4 + cD$, A = frontal area, taken as 120 sq. ft., V = speed, m.p.h., D = degree of curve. Values of c are:

Wheel base of engine, ft.	5	6	7	8	9	12	13	15	16	20
c =	0.380	.415	.460	.485	.520	.625	.660	.730	.765	.905

If T_E = tractive force of locomotive and T_C = tractive force to overcome resistance of cars, T_B = tractive force of locomotive due to boiler pressure, $T_C = T_E - R_E$. At low speeds a maximum value of $T_E = 0.85\,T_B$. For piston speed over 250 ft. per min., $T_E = 0.85\,T_B \times F$, where F = speed factor given below.

Piston speed, ft. per min...	250	300	350	400	450	500	550	600	650	700	750
Speed factor, F..........	1.00	0.954	.908	.863	.817	.772	.727	.680	.636	.592	.550

Fig. 1 (Univ. of Illinois *Bull.* 43, 1910) shows the results of tests of resistance of freight

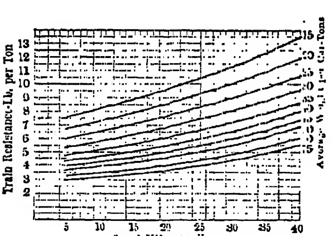

FIG. 1. Freight Train Resistance

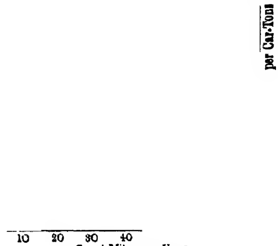

FIG. 2. Passenger Train Resistance

trains of average American box, gondola and tank cars, on straight level track of good construction, with temperatures above 30° F. and wind velocity not more than 20 mi. per hr. Fig. 2 (Univ. of Illinois *Bull.* 110, Dec., 1918) shows the resistance of passenger trains under the same conditions as in the freight train tests. Weight of cars ranged from 30 to 75 tons. The American Locomotive Co. gives (1917) the resistance of freight cars on straight level track, at speeds from 5 to 25 mi. per hr., as

Total weight of car, tons..	20	25	30	40	50	60	70	80
Resistance, lb. per ton....	7.00	5.89	5.13	4.20	3.64	3.27	3.00	2.80

The resistance of an empty freight car weighing 30 tons, carried on 6-wheel trucks, has been found to be 7.27 lb. per ton, and 3.17 lb. per ton for the loaded car weighing 121 tons. Tables 1 and 2 give data on the resistance of both passenger and freight cars.

Table 1.—Resistance of Loaded and Empty Freight Cars

Weight, tons		Resistance, lb. per ton		Weight, tons		Resistance, lb. per ton	
Loaded	Empty	Loaded	Empty	Loaded	Empty	Loaded	Empty
75	21	2.90	5.63	40	14.0	4.40	7.65
70	20.3	3.07	5.82	35	12.6	4.74	8.05
65	19.5	3.24	6.00	30	11.1	5.07	8.45
60	18.6	3.43	6.26	25	9.5	5.44	9.05
55	17.6	3.65	6.50	20	7.8	5.91	9.60
50	16.5	3.90	6.85	15	6.0	6.40	10.3
45	15.3	4.18	7.26				

Table 2.—Resistance of Passenger Cars

Computed from formula $R = 5.4 + 0.002\ (V - 15)^2 + 100/(V + 2)^3$

Speed, mi. per hr. V	Resistance, lb. per ton R	Hp. per ton	Speed, mi. per hr. V	Resistance, lb. per ton R	Hp. per ton	Speed, mi. per hr. V	Resistance, lb. per ton R	Hp. per ton
5	5.89	0.079	30	5.85	0.468	60	9.45	1.52
10	5.51	.147	35	6.20	.579	70	11.45	2.37
15	5.42	.217	40	6.65	.709	80	13.85	2.95
20	5.46	.291	45	7.20	.864	90	16.65	4.00
25	5.60	.374	50	7.85	1.047	100	19.85	5.29

RESISTANCE DUE TO GRADES may be taken as 20 lb. per ton per 1% of grade. The length of grade compared to the length of train should be taken into consideration. (Am. R. R. Assoc., 1916.)

RESISTANCE DUE TO CURVES, R_c ranges for cars, from $0.7c$ to $1.0\ c$, per ton of train on the curve; c = degree of curvature. The lower figure is for large capacity cars, and the higher for low capacity cars. For locomotives R_c may be taken as 1.4. For mine cars, with short wheel-bases, and wheels loose on axles, Baldwin Locomotive Works gives the formula: Resistance, lb. $= 0.20\ lW/r$, where l = wheel-base, ft.; W = weight, lb.; r = radius of curve, ft.

Tests of five freight trains, on track of fair construction laid with 70-lb. rail, to determine the excess of their resistance on curved track over that on straight track are reported in Univ. of Illinois *Bull.* 167, July, 1927. Average gross weights of cars ranged from 15.1 to 48.6 tons. Tests were run in warm weather, and tests at speeds of 10, 20 and 30 mi. per hr. were made with each train on each curve. Results are summarized in Table 3.

Table 3.—Resistance of Curves

Train Numbers	Curve Resistance—Pounds per Ton per Degree					
	On One-degree Curve			On Three-degree Curve		
	10 m.p.h.	20 m.p.h.	30 m.p.h.	10 m.p.h.	20 m.p.h.	30 m.p.h.
1	0.35	0.47	1.00	0.70	0.67	0.61
2	0.54	0.46	0.25	0.57	0.47	0.27
3	0.57	0.50	0.60	0.55	0.45	0.48
4	0.46	0.12	0.52	0.69	0.54	0.29
5	0.66	0.75	0.39	0.70	0.75	0.41
Average (all trains)	0.52	0.46	0.55	0.64	0.58	0.41
Average, disregarding speed		0.51			0.54	

RESISTANCE DUE TO ACCELERATION, R_A, lb. per ton, may be calculated from

$$R_A = 70\ V^2/S = 96.5\ V/t = 70\ (V_2^2 - V_1^2)/S,$$

where V = velocity, mi. per hr.; S = distance, ft.; and t = time, sec., during which acceleration or retardation occurs; V_1 and V_2 = respectively, initial and final velocities, mi. per hr. Am. Ry. M. M. Assoc. (*Proc.*, 1914) formula for correction in drawbar pull for acceleration is $F = 31.1\{1 + (0.6w/W)\} \times \{(V_2 + V_1)(V_2 - V_1)/S\}$, where F = correction factor, lb. per ton; W = weight of car, tons; w = weight of wheels, tons; other notation as above. Constants are based on 33-in. wheels. Positive values of F are subtracted from drawbar pull; negative values are added.

TOTAL RESISTANCE, $R_T =$ $+ R_G + R_C + R_A$ as calculated above. Wm. Elmer (*Trans.* A.S.M.E., 1921) gives the Kiesel train resistance formula as

$$R_T = 100\,N + 1.5W + 0.01\ (V + 16)\ V\sqrt{WN} + (C + 20\ G)W,$$

where R_T = total train resistance lb.; N = number of cars + 3; W = weight of entire

train, tons; V = speed, mi. per hr.; C = curvature of track, deg.; G = grade, percent. Locomotive friction and head-on wind resistance are not considered, and the resistance of the locomotive is taken as equal to that of 3 cars.

RESISTANCE DUE TO FRICTION of locomotive machinery, R_F, lb. per ton, is given by W. F. M. Goss as results of tests at Purdue locomotive testing laboratory as $R_F = 3.8\,d^2\,s/D$, where d and D = diameter of cylinder and drivers, respectively, in.; s = stroke of piston, in. The Am. Ry. Eng. Assoc., 1915, for freight equipment under normal conditions on straight level tangent in warm weather, at 7 to 35 mi. per hr., gives $R_F = 2.2\,T + 121.6\,N$, where T = total weight of cars and contents, tons; N = number of cars. R_F ranges from 4 to 8 lb., depending on whether cars are loaded or empty. In extreme cold, R_F may be as high as 30 lb. with empty cars. American Locomotive Co. (1917) states that R_F is constant at all speeds, and is equal to 25 lb. per ton of weight on drivers.

WIND RESISTANCE OF A TRAIN.—The resistance of air to a plane moving normally to itself is represented by the expression KAV^2, where A = frontal exposed area, sq. ft.; V = speed, mi. per hr.; K = a constant = 0.0033. K includes the suction on the back of the moving body, which is $^1/_3$ the total resistance. Frontal pressure then may be taken as $0.0022\,AV^2$, and Hp. = $(0.0022\,V^3/375)$, where Hp. = horsepower required per sq. ft. of exposed surface. Wind resistance is greatly diminished by streamlining, removing all exposed projecting surfaces, and enclosing all openings between cars and engine. The Union Pacific Ry. (1934) has placed in service a streamlined train, capable of speeds up to 110 mi. per hr. with a total expenditure of 600 Hp. The weight of the train was 85 tons.

WATER SCOOPING RESISTANCE (H. C. Webster, *Ry. Engr.*, Jan., 1918).—If R_s = resistance due to water scooping, lb., a = area of delivery pipe, sq. in., g = 32.2, $R_s = (88.246\,aV)/(144g\sqrt{V^2/2})$. For speeds of 25 to 60 mi. per hr., with a = 50 sq. in., values of R_s are

Speed, mi. per hr.	25	30	35	40	45	50	55	60
Resistance, R_s, lb.	901	1310	1779	2330	2940	3610	4320	5220

At speeds of 40 mi. per hr., the relation of a and R_s is

Area, a, sq. in.	35	40	45	50	55	60	65	70
Resistance, R_s, lb.	1631	1860	2100	2320	2560	2800	3040	3260

ADJUSTED TONNAGE RATING (*Proc.* Am. Ry. M. M. Assoc., 1914).—As the resistance per ton of light cars is greater than that of heavy cars a locomotive can pull more tons of heavy cars at the same speed over the same track. To compile tonnage ratings the cars that a locomotive can haul over a division are determined by test or calculation for both heavy and light cars. Then $C = (W-w)/(n-N)$, where C = car allowance or adjustment factor, W and N = respectively total weight and number of loaded or heavy cars of first train, and w and n = weight and number of empty or light cars of second train. Then $T_L = W + N \times C$, and $T_E = w + n \times C$, where T_L and T_E = respectively adjusted tonnage for loaded and empty cars. In general, C will be lower the steeper the grades; it may be as low as 2 or as high as 80.

2. TRACTIVE FORCE OF LOCOMOTIVES

Notation. T = tractive force, lb.; C, c = respectively, diam. of high-pressure and low-pressure cylinders, in., of compound engines; D = diam. of drivers, in.; D_b = diam. of drivers of booster engines, in.; d, d_1 = respectively, diam. of outside and inside cylinders of simple engines; H = total area of heating surface, sq. ft.; K = evaporation per sq. ft. of heating surface, sq. ft. (assumed = 10 lb.); k, M, m = constants; n = No. of pairs of drivers; P = boiler pressure, lb. per sq. in.; Q = weight on drivers, tons (2000 lb.); R = ratio of m.e.p. in booster cylinder to boiler pressure = 0.80 for 75% cut-off, 0.774 for 70% cut-off, 0.73 for 50% cut-off; r = gear ratio of boosters; S = stroke, in.; s = stroke of inside cylinders of simple engines, in.; V = speed, mi. per hr.; w = wt. of 1 cu. ft. of steam, lb. (taken as 0.39 lb. corresponding to 100° F. superheat).

TRACTIVE FORCE OF SIMPLE LOCOMOTIVE.—The fundamental formula (Kiesel), which takes into account engine friction and head-on wind resistance is

$$\frac{2\,(P -}{[\{110\,wV}$$

The Am. Ry. Eng. and Maint. of Way Assoc. (*Bull.* 112) recommends

$$T = d^2P(S/D)\,\{0.95 - (392\,S/11{,}000\,D)\,V\}.$$

For 3-cylinder simple locomotives ... d practice of the Am. Ry. Assoc. (1926) is $T = mPd^2\,S/D + mPd_1^2\,s/2\,D$. Values of m are given as follows:

Main valve cut-off, maximum, %	90	80	70	60	50
m, without auxiliary ports	0.85	0.80	0.74	0.68	0.60
m, with aux. ports, 80% min. cut-off	....	0.80	0.78	0.77	0.75

locomotives, ... Assoc. (1924) is
max. cut-off;

OF COMPOUND
ocomotive is given b
ds the standard of

$T = (1.7\,Pc^2S)/\{(c^2/C^2) + 1\}\,D$, for 90%

$T = (1.5\,Pc^2S)/\{(c^2/C^2) + 1\}\,D$, for 50% max. cut-off.

V OF MALLET ARTICULATED LOCOMOTIVES.—The Baldwin Works s the formula: $T = 1.7\,Pc^2S/\{(c^2/C^2) + 1\}D$ for varying cylinder a cylinder ratio of 2.4 this becomes $T = 1.2\,Pc^2S/D$. The American Loco- rmula is $T = C^2SMP/D$. Values of M are given in Table 4. This formula i.e.p. equal to 91% of boiler pressure.

Table 4.—Values of Constant M

Percent Cut- High-pres- e Cylinder	Ratio of Low-pressure to High-pressure Cylinder Volume

TRACTIVE FORCE OF LOCOMOTIVE BOOSTER.—Recommended practice of the Am. Ry. Assoc. (1930) gives the formula $T = RPd^2Sr/D_b$.

HORSEPOWER OF A LOCOMOTIVE is determined fundamentally from the formula for horsepower of a steam engine Hp. $= P\,L\,A\,N/33{,}000$ (see p. 7-05). If M = speed of train, mi. per hr., d = diam. of cylinders, in., p = mean effective pressure, lb. per sq. in., S = length of stroke, in., D = diam. of driving wheel, in., then for two cylinders, Hp. $= p\,d^2\,S\,M/375\,D$.

3. TYPES OF STEAM LOCOMOTIVES

CLASSIFICATION.—Table 7 gives a generally-used classification of steam locomotives, with the names in common use. The type symbol was suggested by F. M. Whyte.

DIMENSIONS OF TYPICAL AMERICAN LOCOMOTIVES in service (1935) are listed in Table 8, together with details of the service in which they are used.

MALLET ARTICULATED LOCOMOTIVES have exceptionally high tractive force, combined with ability to traverse sharp curves. This type was developed by Anatole Mallet and first introduced in Europe in 1889. It is extensively used on American railways, especially in mountain service. The Mallet locomotive has a single boiler, fitted with a mechanical stoker, set over two groups of driving wheels, each with its own frame, cylinders and other equipment. The rear frames are aligned rigidly with the boiler.

NOTATION.—W_d = weight on drivers, lb.; W_t = total weight of locomotive, lb.; $T.F.$ = tractive force, lb.; $H.S._E$ = evaporative heating surface, sq. ft.; $H.S._S$ = superheater heating surface, sq. ft.; G = grate area, sq. ft.; D = diam. of drivers, in.

1. *Boston and Albany* (B. & A.).—A suburban type operating out of Boston, Mass.

2. *Pennsylvania Railroad* (P. R. R.).—Over 400 of these locomotives are used to haul the "Broadway" 16 1/2-hr. trains between New York and Chicago, the "American" 23-hr. train between New York and St. Louis, the "Congressional" between New York and Washington, and main-line expresses.

3. *New York Central* (N. Y. C.).—About 200 of these engines are used on the "20th Century Limited" 16 1/2-hr. train between New York and Chicago, the "Southwestern Limited" 23-hr. train between New York and St. Louis, the "Empire State Express" 8 1/2-hr. train between New York and Buffalo, and other main-line expresses.

4. *Chicago and Northwestern* (C. & N. W.).—35 of these locomotives haul the "San Francisco Limited" out of Chicago and also fast freights between Chicago and Omaha.

5. *Great Northern Railway* (G. N. R.).—Used to haul the "Empire Builder" and the "Oriental Limited."

6. *Indiana Harbor Belt* (I. H. B.).—A typical switching engine in hump yard and transfer service between trunk lines.

7. *Pennsylvania R. R.* (P. R. R.).—A mountain-type engine for heavy passenger trains and scheduled fast freights with running speeds approaching those of passenger service. About 100 are in use, with 200 more quite similar.

8. *Wabash R. R.* (Wab.).—Used to haul fast freights between St. Louis and Buffalo.

9. *Chesapeake and Ohio* (C. & O.).—Said to be most powerful 2-cylinder locomotives ever built. Forty are used to haul coal trains of 12,250 tons over 237 miles of line between Russel, Ky., and Toledo, O., with maximum grades of 0.7%, maximum curves of 7°.

10. *Union Pacific* (U. P.).—A 3-cylinder freight locomotive. Eighty have been built.

11. *Northern Pacific* (N. P.).—Designed to use a semi-bituminous (Rosebud) coal of low heating value; are said to have the largest boiler ever used on a locomotive. They weigh, with tender, over 1,000,000 lb., and can develop over 6000 Hp. Twelve are in use.

The front frames are hinged to the rear frames by a pin on the center line of the locomotive, and support the front end of the boiler on sliding bearings, or waist bearers. The lower section of the waist bearer is a lubricated brass plate, on which the upper section slides, and which takes the wear. Clamps on the front waist bearer prevent the frames from dropping in case of derailment. On entering a curve the front frames swing on the hinge pin as center. Controlling springs on the front boiler bearing tend to hold the front and rear frames in line, and assist the rear unit to follow into a curve.

The cylinders are compounded. High-pressure cylinders drive the rear set of wheels, and take steam direct from the boiler. They exhaust to the low-pressure front cylinders, whose exhaust is up the stack. Cylinder ratios range from 2.35 to 2.50. A ball joint, located on the hinge pin center, is fitted to the back end of the receiver pipe from high- to low-pressure cylinders, to permit it to swing with the frames. The exhaust pipe from low-pressure cylinders to stack also has flexible joints. Both pipes have packed glands and slip joints for expansion and contraction.

Superheated steam is used almost universally in Mallet locomotives, the superheater being arranged as in a single expansion locomotive. Reheaters between high- and low-pressure cylinders are unnecessary. The high-pressure steam pipes extend back from the superheater in the smoke box to the high-pressure cylinders, where steam distribution is by piston valves. Either piston or balanced slide-valves, the latter preferably double ported, may be used on low-pressure cylinders. Lubrication is satisfactory if one lubricator connection is run to each high-pressure cylinder and one to the receiver pipe. The two sets of valve motion are controlled simultaneously by a power reverse mechanism, usually operated by compressed air.

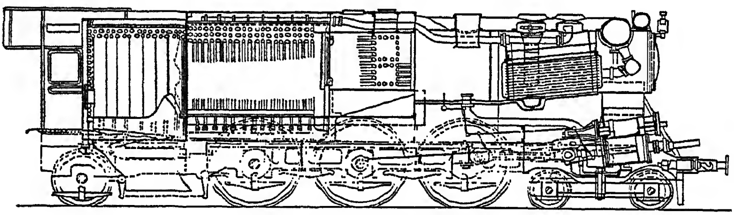

Fig. 3. Loeffler Locomotive

BALANCED COMPOUND LOCOMOTIVES have two high-pressure cylinders between the frames and two low-pressure cylinders outside. The inside cranks are 90° apart, and the outside crank pins are 180° from the inside crank on the same side. High-pressure steam can be admitted to the low-pressure cylinders for starting.

LIMITED CUT-OFF LOCOMOTIVES (*Engg.* Oct. 22, 29, 1920). The Penna. R. R. in 1920 replaced with 2–10–0 locomotives, a large number of engines that, in the service to which they were assigned, were required to work with little or no expansion of steam. In the new engines, the cylinders were enlarged and the cut-off arranged to be maximum at 50% of stroke. At this cut-off the engine gives a turning moment diagram similar to that of the earlier engines in full gear. The engines have piston valves 12 in. diam., operated by Walschaerts gear, and have inside admission. Steam lap is 2 in.; lead is $^3/_{16}$ in.; exhaust lap is $^1/_8$ in. To obtain sufficient starting effort, auxiliary ports $^1/_8 \times 1\,^1/_2$ in. admit steam to the cylinders before the main ports are uncovered. Cylinders are $30\,^1/_2 \times 32$ in., and the boiler pressure is 250 lb. per sq. in. The locomotives weigh 371,800 lb. in working order, have a tractive force of 90,000 lb., and a drawbar pull of 76,200 lb. at 7.4 mi. per hr. At 14.5 mi. per hr., in full gear (50% cut-off) drawbar pull is 65,000 lb. They develop 1 Hp. on 3 lb. of coal, and use 17.3 lb. of steam per I.Hp.-hr.

HIGH-PRESSURE LOCOMOTIVES.—A committee of the Am. Ry. Assoc., 1932, gives the advantages of high steam pressure as: The energy that can be stored in a given quantity of steam is increased by increasing the pressure and temperature, hence requiring less water to develop a given amount of power; the increased power is obtained by greater expansion of the steam in the cylinders; engines of greater capacity can be designed for the same weight, and more efficient use of the steam is had by use of smaller cylinders, valve chambers, and steam pipes, with reduced area for loss of heat by radiation. Disadvantages include: difficulty with cylinder and valve lubrication; increasing maintenance costs; piston valves probably must be replaced by a poppet valve which does not require lubrication; stronger pipes, globe valves and cab fittings are necessary.

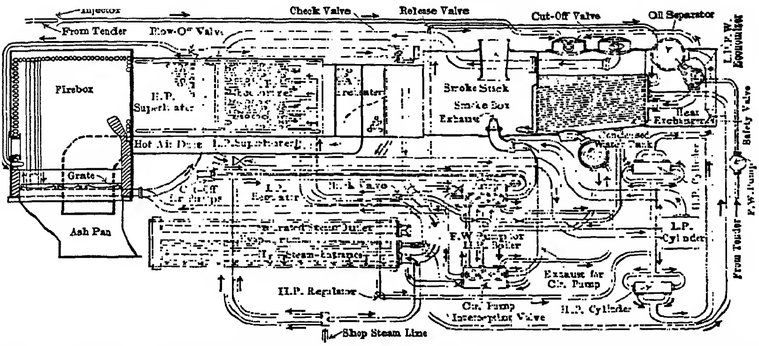

Fig. 4. Diagram of Loeffler Principle of Steam Generation Applied to German State Ry. 4-6-2 Locomotive

The German State Railways placed in service, in 1927, high-pressure locomotives of the Schmidt-Henschel and the Schwartzkopf-Loeffler types. The Schmidt 4–6–0 locomotive has a water-tube firebox with a fire-tube boiler barrel. A pressure between 1300 and 1700 lb. per sq. in. is developed in a closed tube system, filled with distilled water, which transfers heat from the firebox to water in a drum carrying 850 lb. per sq. in. steam pressure. The fire-tube part of the boiler carries a pressure of 200 lb. per sq. in. Feedwater enters the steam space of the low-pressure boiler, and is pumped into the high-pressure boiler. Steam at 850 lb. is used in an inside high-pressure cylinder. The exhaust, mixed with 200 lb. steam, is used in two outside low-pressure cylinders. Cylinder diameters are: high-pressure 11 7/16 in.; low-pressure 19 5/8. Stroke of all cylinders is 23 3/4 in. Driving wheel diameter is 79 in.

The Loeffler 4–6–2 locomotive, Figs. 3 and 4, is a 3-cylinder compound, with a rated tractive force of 37,000 lb. Its steam generator is a cylindrical drum, partly filled with water from which steam is forced at high velocity by two pumps through a grating of steel tubes forming the firebox. The steam is superheated in the firebox tubes. From the firebox tubes, a part of the superheated steam, at 1470 to 1760 lb. per sq. in. pressure and 840° F. goes to the two high-pressure outside cylinders, but the greater part returns to the drum. It is discharged into the water in the bottom of the drum, and gives up heat absorbed from the firebox. The exhaust from the high-pressure cylinders, at a pressure of about 265 lb. per sq. in., flows through an oil separator, and then into the tubes of a heat exchanger where it generates steam at 214 lb. per sq. in. pressure. This steam,

after superheating, enters the single low-pressure cylinder. Cylinder diameters are: high-pressure 8 5/8 in.; low-pressure 23 5/8 in. Stroke is 26 in. Driving wheel diameter is 79 in. Total wheel-base is 63 ft. 2 in., and the overall length is 75 ft. 7 1/2 in.

A 2–6–2 tank locomotive carrying a pressure of 850 lb. per sq. in. was built in 1927 by the Swiss Locomotive and Machine Works, Winterthur. The water-tube boiler has one large drum at the top and two smaller ones at the bottom, all connected by water chambers and tubes. A superheater, feed-water heater, economizer and air preheater are provided. The 3-cylinder uniflow engine is mounted in front of the boiler. It is geared to a jack shaft, the ratio being 2 : 5. Engine and valve gear are enclosed in an oil tight casing. Cylinders: diameter, 8.5 in.; stroke, 13.5 in. Driving wheel diameter is 60 in. Fig. 5 is a diagram of the operation of this engine. Tests made on two divisions of the Swiss Federal Railway provide a comparison with a conventional steam locomotive of approximately equal capacity. These show a coal economy of 35 to 40% and a water economy of 47 to 55%.

Since 1924 the Delaware and Hudson R. R. has placed in service three high-pressure locomotives with water-tube firebox and fire-tube boiler barrel, and a cross compound two-cylinder engine. The boiler pressure of the first locomotive was 350 lb. per sq. in.; of the second 400 lb.; and of the one built in 1930, 500 lb. The 1930 locomotive is of the 2–8–0 type. It exerts a maximum tractive effort of 70,300 lb., working compound. Cylinder diameters are: high-pressure, 20 1/2 in.; low-pressure, 35 1/2 in. Driving wheel diameter is 63 in. Grate area is 82 sq. ft.

Two high-pressure locomotives were built in 1931, one by the American Locomotive Co. for the New York Central and one by the Canadian Pacific Ry. at its Angus shops. Both are of the Schmidt type. Their general dimensions follow:

	N. Y. C.	C. P. R.
Type	4–8–4	2–10–4
Steam pressure (low), lb. per sq. in.	250	250
" " (high), lb. per sq. in.	850	850
" " (closed circuit)	1350	1350

" " (low-pressure), in.	23	24
Stroke (high-pressure), in.	30	28
" (low-pressure), in.	30	30
Driving wheel diam., in.	69	63
Tractive force, lb	66,000	90,000

English Locomotive for Coal Traffic.—(*Ry. Mech. Engr.*, Aug., 1920).—A typical 0–8–0 engine tested with a train of total weight of 1402 tons (2240 lb.) developed over 1100 drawbar horsepower on a 60-mile section. The ruling grade was 0.57% for a short distance. On the test in the opposite direction, a ruling grade of 0.93% for 4 miles was encountered. The train load was 787 tons and a drawbar pull of 28,000 lb. was developed in starting on the ruling grade. Speed reached 16 mi. per hr. 7 min. after starting. The engine was of the 3-cylinder, piston-valve type, with cylinders and valve chests in one casting. The principal dimensions were: Cylinders, 18 1/2 in. diam. × 26 in. stroke; piston valves, 8 3/4 in. diam.; wheel base, 18 ft. 6 in.; driving wheels 55 1/4 in. diam.; weight on drivers, 160,380 lb.; weight of engine and tender, working order, 259,200 lb.; tractive effort, 36,960 lb. The boiler was of the straight type, outside diam. 66 in., with a firebox 9 ft. × 3 ft. 11 in. It contained 102 2-in. tubes, 24 5 1/4-in. flues and 7 2-in. stay tubes, all 16 ft. 2 5/8 in. long. Heating surface, sq. ft., was: tubes, 1407; firebox, 166; total, 1573; superheater surface, 530 sq. ft. Grate area was 27 sq. ft., and working pressure 180 lb. per sq. in. The 6-wheel tender weighed 98,800 lb. and carried 4125 gal. of water and 5 1/2 tons of coal. A Schmidt superheater was used.

TURBO-LOCOMOTIVES—CONDENSING.—The steam turbine-driven condensing locomotive has had limited application in Europe and Argentina. V. P. Dolen-go Kozerovsky (*Mech. Engg.*, Feb., 1929) states its principal advantages to be: Overall efficiency, 14 to 22%, or 1.5 to 2.5 times that of the piston locomotive; continuous driving torque; smooth initial starting torque; elimination of boiler washing; reduction in weight of feedwater and fuel to be carried. It costs more than the piston locomotive and its condenser is somewhat dependent on atmospheric conditions.

The brothers Ljungstrom (Aktiebolaget Ljungstrom Angturbin), Stockholm, designed and built the first turbo-locomotive, which was placed in service on the Swedish State Railways during the winter of 1921–22. The usual reciprocating engines were replaced by a turbine on the tender, exhausting into an air-cooled condenser. Air for combustion was preheated by the waste gases, feedwater was heated by exhaust steam from the auxiliaries. Draft was created by a turbine-driven fan. A maximum of 1500 Hp. and a maximum drawbar pull of 30,000 lb. was developed. Weight efficiency was 157 lb. per Hp.

Almost at the same time Henry Zoelly, of Escher, Wyss & Co., Zurich, converted an ordinary piston locomotive into a turbo-locomotive, using, however, ideas and principles entirely different from those of Ljungstrom. Both types were successful, and most of defects observed in actual service were eliminated in later designs. Several large con-

cerns in Europe then designed and constructed nine turbo-locomotives, four under the Ljungstrom patents, three embodying Zoelly principles, and two of independent designs; one of the latter had an electrical transmission. Table 9 gives details of these locomotives.

Ljungstrom Locomotive.—The distinctive features of the Ljungstrom locomotives are a single turbine, good distribution of weight, and a good weight efficiency. The impulse-reaction turbine has an unusually large number of rows of blades, giving it almost constant efficiency over a wide speed range. This feature enables the engine to work economically under variable service conditions, whether hauling freight or passenger trains. See curves of the coal consumption of turbine and reciprocating locomotives at different speeds in *Ry. Mech. Eng.*, Nov., 1922. Usually the turbine is uneconomical at slow speeds, and the economy of the Ljungstrom locomotive is below that of a reciprocating locomotive of the same power at speeds below 4 mi. per hr. Another important feature of the Ljungstrom turbine is a rapid rise of the horsepower curve or decline of the tractive-effort curve as speed increases.

The condenser (old type) is unusual in that the plant requires no surplus water, apart from the make-up required for boiler leakage, heating, whistle steam, etc. Test data show the average water requirements to be 170 gal. per 100 mi., a saving of 95%.

The last three locomotives in Table 9 embody improvements and refinements over the first one, among them two whirling blasts of highly preheated air over the fire and provision for heating feedwater. The first locomotive smoked badly, but the latest ones are practically smokeless, cinderless and noiseless.

The last engine has the best combined weight efficiency known for a steam locomotive. Average fuel consumed is 22 lb. of oil per 1000 ton-miles; average vacuum is 16 in. Hg at 100° F. air temperature, and 22 in. at 88° F. The large quantity of distilled water in the condenser acts as a cold reservoir for relatively short overloads.

Disadvantages of the Ljungstrom system are: Location of fuel (not so pronounced with liquid fuels); high power required for driving condenser fans to supply 4500 cu. ft. of cooling air per sec.; flexible live-steam connection between boiler and tender units.

Krupp-Zoelly Locomotives.—All the German locomotives use a water-cooled surface condenser, with the disadvantage of having both a condenser and a recooler for the condenser cooling water. The condenser is small as compared with the air-cooled surface type. The heat transmission from steam to water is about 500 B.t.u. per deg. F. per sq. ft. per hr., whereas for an air-cooled condenser of the Ljungstrom type it is about 25 B.t.u. at an air velocity of 4000 ft. per min.

The principal items of performance of the Krupp-Zoelly type are: 1. Part of the water passing through the sprinklers evaporates, with resulting water consumption approximately one-half that of a piston locomotive of equal capacity; 2. As heat transfer is effected almost exclusively through this evaporation, the recooling plant is practically independent of outside temperature; 3. For the same reason, the air consumption in, and hence power required to move it through, the sprinkler-cooler is small.

Descriptions of the turbine locomotives in Table 9 will be found in the following: Ljungstrom—*Engg.* July 21, Aug. 4, 11 & 18, 1922; *Ry. Mech. Engr.*, Oct. and Nov., 1922. Zoelly—*Trans.* A.S.M.E., 1924. Maffei—*Ry. Mech. Engr.*, Feb., 1927. Ramsay—*Ry. Mech. Engr.*, Jan., 1925.

Turbo-Locomotive—Non-Condensing.—A non-condensing 2-8-0 turbo-locomotive was built by Ljungstrom for a Swedish railway. (See *Ry. Age*, Oct. 29, 1932.) The tractive force is 47,400 lb.; boiler pressure is 185 lb. Total weight is 259,044 lb., with 158,760 lb. on drivers. Drivers are 53 1/8 in. diam.

In spite of the many advantages of the condensing turbine-driven locomotive, the manufacturing cost and complicated arrangement has prevented its general adoption. Experiences with turbo-locomotives have proved the turbine to be a satisfactory prime mover for locomotives. The complications of the condensing type have been avoided in the non-condensing turbo-locomotive. The combined reaction-impulse turbine, in front of the smoke-box, is connected to the side rods through a gear and jack-shaft. The turbine exhausts to the exhaust nozzle as in reciprocating locomotives. Road tests in 1932, comparing the turbine locomotive with a 3-cylinder piston locomotive show an average fuel saving per drawbar Hp.-hr. of approximately 10%.

UNIFLOW LOCOMOTIVES.—The Prussian State Rys. have experimented with locomotives having cylinders working on the Stumpf or uniflow principle, where the flow of steam is always in one direction through the cylinder. (See p. 7–39.) The North Eastern Ry. in England also has a locomotive of this type. The long cylinder (twice the usual length) and the heavy piston which must be used, are disadvantages, difficult to overcome in applying the uniflow principle to locomotives.

GEARED LOCOMOTIVES frequently are used on private railroads in rough country. The entire weight of engine and tender is utilized for adhesion and the locomotives can climb steep grades at low speeds. A 3-cylinder vertical engine, attached to the side of

the boiler, drives a shaft extending the whole length of engine and tender. The shaft has flexible joints and is coupled to the axles by bevel gearing. The wheels are arranged in three 4-wheel swiveling trucks, giving a highly flexible wheel-base. See *Ry. Age*, Dec. 17, 1921. A Shay locomotive of this type, used on the Greenbrier, Cheat and Elk R. R., weighs 150 tons. The gear ratio is 1 to 2.45. Total weight, including tender, is 308,000 lb., all on driving wheels. The U. S. Ry. Administration heavy Mikado locomotive has practically the same hauling capacity on level track. Comparative dimensions of the two locomotives are:

	U. S. R. A., Mikado	Shay, Geared	Shay in % of Mikado
Tractive effort (85%), lb.	60,000	59,740

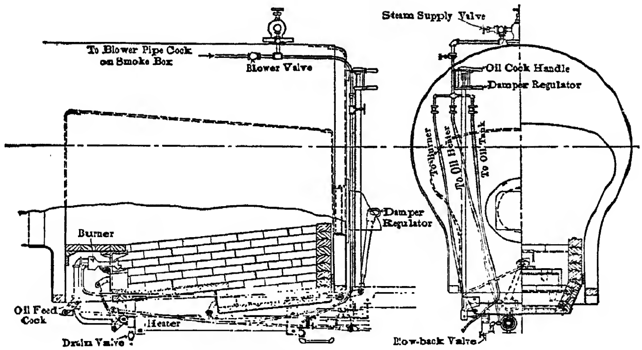

Fig. 6. Firebox Construction for Oil Burning

OIL BURNING LOCOMOTIVES.—The oil fuel tank holds approximately 3000 gal., equivalent to about 17 tons of coal. Oil expands 1% per 25° F. increase in temperature, and 2 in. space over the oil in a square tank, and 6 in. in a semi-cylindrical tank is necessary.

J. N. Clark (*Ry. Mech. Engr.*, Dec., 1921) states that 50 to 175 gal. of oil are required to fire up engines at terminals, requiring from 30 to 110 min. A 2–8–2 locomotive, 207,000 lb. on drivers, was fired up with 1/3 glass of water at 120° to 200 lb. steam pressure in 108 min., using 119 gal. of oil. On the So. Pacific R. R. a train weighing 1000 tons, hauled by a 2–10–2 superheater locomotive, showed fuel consumption per 1000 ton-miles of

Speed, miles per hr.	5	10	15	20	25	30	35	40	45	50
Oil consumed, gal.	0.3	1.1	2.5	4.5	7.0	10.0	13.7	18.0	22.7	28.0

The stand-by fuel consumption was 45 gal. of oil per hr. to hold the train and operate the air pump. A light engine standing under steam burned 37 gal. per hr.

Firebox Construction for Oil-Burning.—The required equipment consists essentially of an injector or atomizer through which the oil is fed into the furnace, a suitable fire-pan replacing the regular ash-pan, and an arrangement of firebrick to protect the lower parts of the furnace sheets from direct action of the flame. Flow of oil is controlled by a plug cock in the feed line. A heater may be placed in this line as it is essential to have the oil warm enough to insure a steady flow to the burner. Figs. 6 and 7 show the general

arrangement. To secure complete combustion and fill the firebox with flame, it is necessary to spray the oil into the furnace. This is done with a steam jet. The burner used by the Baldwin Locomotive Works, Fig. 8, is rectangular in cross-section with two separate ports or chambers (one above the other) running its entire length, with a free outlet for oil at the nose of the burner. The steam outlet, is contracted at this point by an adjustable plate to give a thin wide aperture. The burner is of brass, as an iron casting is sufficiently porous to permit steam to penetrate the oil passage.

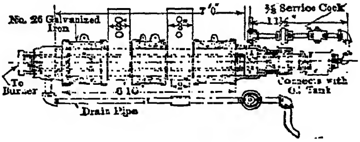

FIG. 7. Oil Heater

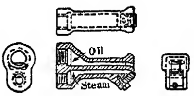

FIG. 8. Baldwin Locomotive Works Oil Burner

Miscellaneous Locomotives

INTERNAL COMBUSTION LOCOMOTIVES are fitted especially for work in contracting operations, plantations, quarries, brickyards, etc., including light switching in railroad yards. Their radius of operation is limited only by the capacity of the fuel tank. The locomotives weigh 5, 7 1/2, 10, 15 and 25 tons. The vertical engine drives through a friction clutch, change gear, jack shaft and the usual locomotive connecting-rods. The gear ratios are: A low gear for starting and accelerating; second gear for exceptionally heavy hauling; third gear, giving a speed of approximately 6 mi. per hr. for light hauling; fourth, high-speed gear for running light, giving a speed of approximately 12 mi. per hr. At rated loads, gasoline consumption will be about 0.1 gal. per Hp.-hr.

COMPRESSED-AIR LOCOMOTIVES.—A compressed-air locomotive comprises essentially a storage tank mounted on driving wheels and two engines similar to those of a steam locomotive. The locomotive tank is charged from storage tanks along the line. These usually are riveted steel cylinders designed for about 1000 lb. per sq. in. working pressure; sometimes small-diameter seamless steel cylinders designed for a working pressure of 2000 lb. or more are used.

COMPOUND AIR LOCOMOTIVES WITH ATMOSPHERIC INTERHEATERS.—Air enters the high-pressure cylinders at 250 lb. gage pressure and is expanded down to 50 lb., while the temperature drops about 140° F. Practically all the lost heat is restored in the atmospheric interheater, which is a cylindrical reservoir filled with brass tubes, placed between the high- and low-pressure cylinders. The air enters the low-pressure cylinder at 50 lb. gage pressure and a temperature within 10 or 20° F. of that of the surrounding atmosphere. The exhaust induces a draft of atmospheric air through the tubes of the interheater. This combination permits air to expand from 250 lb. down to atmosphere without unmanageable refrigeration.

Relative Economy of Simple and Compound Locomotives.—Assume 11.2 cu. ft. of free air to be compressed to 150 lb. gage pressure. Its volume will be 1 cu. ft. Compressed

to 250 lb. gage pressure, its volume will be 0.623 cu. ft. Allow these volumes to expand by moving pistons of 1 sq. ft. and 0.623 sq. ft. area, respectively, a distance of 1 ft. The energy developed will be: At 150 lb., 21,600 ft.-lb.; at 250 lb., 22,425 ft.-lb. Now assume the 11.2 cu. ft. of free air compressed to 250 lb. gage to be expanded in two cylinders of 4 : 1 ratio. The energy developed will be 35,880 ft.-lb. if the heat be restored between the two cylinders. The gain due to compounding from 250 lb. pressure, with interheating, as compared to simple expansion from 150 lb. pressure is 35,880/21,600 = 166%.

These results are about as good as can be obtained with either simple or compound locomotives. Any improvement due to expansive working just about balances losses due to clearance and initial refrigeration. The work done per cu. ft. of free air in the two systems is: Simple cylinders, 21,600/11.2 = 1840 ft.-lb.; compound cylinders and atmospheric interheater, 35,880/11.2 = 3205 ft.-lb. Actual tests show 1900 ft.-lb. of work per cu. ft. of free air with the simple locomotive, and 3000 ft.-lb. with the compound, the gain due to expansive working and the losses due to internal friction being somewhat greater in the compound than in the simple engine.

In the operation of compressed air locomotives the air compressor generally delivers compressed air at a pressure ranging from 800 to 1000 lb. per sq. in. to the storage reservoir. An average of about 12,000 ft.-lb. per cu. ft. of free air is required to compress and deliver it at these pressures. The efficiency of the two systems then is: 1900/12,000 = 16% for the simple locomotive; 3000/12,000 = 25% for the compound locomotive with atmospheric interheater.

OIL-ELECTRIC LOCOMOTIVES.—A report of a committee of the Amer. Ry. Assoc. shows that there were about 125 oil-electric locomotives in service on U. S. railroads at the beginning of 1932. The rated horsepower ranges from 300 to 800. Compared with steam locomotives on a horsepower basis, their first cost is considerably higher. The total operating costs per hour, including fixed charges and depreciation, show wide fluctuation, but are somewhat less than for steam operation. From the standpoint of smoke and noise prevention, the oil-electric locomotives have an advantage for terminal and city yard operations, tunnel runs and operations in yards adjacent to residential sections.

In 1928 the Canadian National Rys. placed in service a 2660-Hp. oil-electric locomotive of the 4–8–2–2–8–4 type. Each of the two units of the locomotive is driven by a Beardmore 12-cylinder, solid injection type engine, 12-in. bore and 12-in. stroke, rated at 1330 Hp. at 800 r.p.m. The engines are coupled to generators; four Westinghouse traction motors geared to the driving axles, are used in each unit. The locomotive develops a tractive force of 100,000 lb. during accelerating periods, and 42,000 lb. continuously. The engines develop their rated horsepower on a fuel rate of 0.43 lb. of oil per B. Hp.-hr.

GASOLINE-ELECTRIC RAIL CAR.—(*Ry. Mech. Engr.*, Aug., 1932). An unusual arrangement of rail car, in service on the A., T. & S.F.R.R., consists of a power unit 30 ft. long, and a baggage and express unit 60 ft. long, the two being joined by a center

articulated truck. Under the car are three 4-wheel trucks of the drop-equalizer type; one is at the junction between the two parts. The V-type Winton engine has 12 cylinders, 9 in. bore and 12 in. stroke. It is rated at 900 Hp. at 900 r.p.m. The electrical equipment comprises a General Electric direct-current generator on the engine shaft, and four traction motors geared to the axles of the two forward trucks. A twin-cylinder 2-stage air compressor displacing 70 cu. ft. per min. is built into the engine. The engine has a carburetor for each cylinder, to use either gasoline or distillate. Throttling is by control of the intake valves. The individual carburetors shorten the travel of fuel and air mixture, permit the use of cheap non-volatile fuels and insure even distribution to all cylinders. Air for combustion enters through felt air cleaners under the roof. Picking up of fuel at the intake valve eliminates all handling of fuel and air mixtures outside of the cylinders and overcomes back-fire hazards. Each cylinder has two exhaust valves. The single-bearing generator has a built-in exciter and differential field control of the voltage. Total weight of the car is 245,000 lb. It can haul four heavy passenger cars as trailers at speeds up to 80 m.p.h.

LIGHT-WEIGHT STREAMLINED TRAINS (*Ry. Age*, Feb. 2, 1934).—Gasoline-electric trains, designed for normal speeds of 90 m.p.h. on level tangent, and maximum speed of 110 m.p.h. have been built for the Union Pacific Ry. To reduce weight, the trains were built throughout of aluminum alloy, except that truck wheels and axles were alloy-steel castings of 50,000 lb. per sq. in. tensile strength. The cars are of tubular shape, streamlined to reduce air resistance, and form a deep stiff beam. Four 4-wheel trucks carry the three articulated car bodies comprising the first train. The first car, 72 ft. 8 in. long, contains the power plant, a mail compartment and baggage room; the second car, 59 ft. 10 in. long, seats 60 passengers; the third car, 71 ft. 11 in. long, seats 56 passengers and contains a buffet. Total overall length is 204 ft. 5 in., and total weight is 170,000 lb., of which 85,000 lb. is carried on the first truck. The center of gravity is kept low to insure safety and easy riding, being 38 in. above rails, or 20 in. lower than in the usual car. The car bottoms are 9 1/2 in., and the car tops 11 ft., above the rails. Trucks are shrouded, reducing air resistance 20%. Windows and doors are set flush for the same purpose. The streamlining was based on wind-tunnel tests with a model built on a scale 3/8 in. per ft.

The power plant comprises a 12-cylinder V-type distillate-burning engine, developing 600 Hp. at 1200 r.p.m., driving a 425-kw. generator with built-in exciter. The engine cylinders are 7 1/2 in. diam., 8 1/2 in. stroke. Pistons are aluminum alloy, and connecting-rods drop-forged alloy steel. The 7 main high-lead-bronze bearings are 5 1/2 in. diam. The 12 babbitted connecting-rod bearings are 4 3/4 × 3 in. Forced feed lubrication is used, with crank-case supply. The engine block and crank-case are fabricated steel. Generator voltage is regulated by traction demand to give a constant load on the engine at any speed. Two 300-Hp. motors, with forced ventilation, on the front truck are geared to the wheels. The braking system is designed to give uniform retardation by controlling brake shoe pressure in proportion to speed by means of a decelerometer control.

4. ELECTRIC LOCOMOTIVES

CLASSIFICATION (Recommended by Committee of Am. Ry. Assoc.).—Idle or guiding axles are designated by numbers, driving axles by letters, an articulated joint by a plus sign, and swivel type trucks, not articulated, by a minus sign. Table 12 gives examples. This classification is recommended also for internal combustion locomotives with electric transmission.

STANDARD METHOD OF RATING ELECTRIC LOCOMOTIVES (From *Recommended Practice*, Am. Ry. Assoc., 1930).—Ratings are taken as at rims of drivers, with locomotive at constant speed on tangent, level track, and are: *a*, Maximum start; *b*, One-hour; *c*, Continuous. At each rating: *a*. Speed (V), mi. per hr.; *b*. Tractive effort (T), lb.; and horsepower (Hp.) are given. Hp. $= VT/375$.

Locomotive ratings are based on motor shaft ratings for maximum start (except as noted below) for 1 hr. and continuously, with motors operating at rated voltage. The 1-hr. motor ratings are with motors starting cold. Motor torque is reduced 3% when determining tractive effort, to compensate for mechanical losses, unless test data are available. Motor shaft ratings are determined by stand tests, and under agreed conditions of temperature rise, ventilation, etc., except with respect to 1-hr. rating.

If test data are not available, tractive effort and speed are determined by $T = 0.97\ (24\,tG/dP)$; $V = SPd/336.1\,G$; where t = motor shaft torque, lb.-ft.; G = number of gear teeth; P = number of pinion teeth; d = driver diameter, in.; S = r.p.m. of motor.

The maximum start rating of locomotive is at the maximum torque exerted by motors

Table 12.—Classification of Electric Locomotives

with any combination of connections, and at maximum speed attainable with this combination at maximum torque. If tractive effort so derived exceeds 25% of total weight on drivers, tractive effort is taken as 25% of total weight on drivers, and the speed is the maximum attainable at such tractive effort, with any combination of motor connections. The 1-hr. and continuous ratings of locomotive are determined from the 1-hr. and continuous ratings of motors.

TRACTIVE RESISTANCE OF ELECTRIC LOCOMOTIVES AND CARS (W. J. Davis, Jr., *Gen. Elec. Rev.*, Oct., 1926).—Table 13 summarizes formulas derived from an analytical study of various tests and investigations of train resistance. The first two terms of the equations, derived from dynamometer and coasting tests on standard freight and passenger cars and electric locomotives, represent journal friction almost entirely, and are based on oil lubrication at average temperatures. Journal friction may increase 20 to 40% at temperatures below 32° F. The third term comprises resistances due to flange friction, concussion, swaying and other frictions proportional to speed. The factor of this term decreases with increase of truck wheel-base, and increases with poor roadbed conditions and inferior riding qualities of motor cars. The last term gives air resistance, lb. per ton, for average weight of car or locomotive for standard types of equipment. No allowance is made for head or strong side winds. Locomotive resistance represents tractive effort delivered to driving axles, excluding friction losses in gears,

Table 13.—Train Resistance Formulas for Electric Locomotive and Motor Car Service

Notation.—R = tractive resistance, lb. per ton (2000 lb.) on tangent, level track; A = area, sq. ft., of cross-section of locomotive or car body and trucks; V = speed, mi. per hr.; n = No. of axles per car; w = average weight per axle, tons; wn = average weight of locomotive or car, tons.

Values of A: *Locomotives.*—50-ton, 105; 70-ton, 110; 100-ton and over, 120. *Freight cars,* 85–90; *Passenger cars,* 120. *Multiple-unit cars,* 100–110. *Motor cars:* 2-truck, 80–100; 1-truck, 70–75.

Where Used	Usual Formula Recommended for convenience in calculation. Approved for axle weights over 5 tons.	General Formula Applicable to all axle weights. To be used when axle weights are less than 5 tons.
Locomotives	$R = 1.3+\frac{29}{w}+0.03V+\frac{0.0024AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.03V+\frac{0.0024AV^2}{wn}$
Freight Cars	$R = 1.3+\frac{29}{w}+0.045V+\frac{0.0005AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.0005AV^2}{wn}$
Passenger Cars (Vestibuled)	$R = 1.3+\frac{29}{w}+0.03V+\frac{0.00034AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.03V+\frac{0.00034AV^2}{wn}$
Multiple Unit Trains: Leading Car (Vestibuled)	$R = 1.3+\frac{29}{w}+0.045V+\frac{0.0024AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.0024AV^2}{wn}$
Trailing Cars	$R = 1.3+\frac{29}{w}+0.045V+\frac{0.00034AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.00034AV^2}{wn}$
Motor Cars	$R = 1.3+\frac{29}{w}+0.09V+\frac{0.0024AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.09V+\frac{0.0024AV^2}{wn}$

motor bearings and other parts of driving equipment. These usually are covered in motive power efficiency. The formulas are based on tests in mild weather conditions. Values obtained from them may be used in calculations of electric distributing systems, substations, energy consumption, and power demand. In determining electric motor charactristics and gear reductions to meet particular speed requirements, it may be desirable to add a small percentage to the required speed, as insurance against unusual conditions.

ELECTRIC LOCOMOTIVE DATA.—Table 14 gives data of typical electric locomotives in service in 1934. In general, single units which may be coupled in service to form operating locomotives of one, two or three units, are listed.

TYPICAL ELECTRIC LOCOMOTIVES.—N. Y. N. H. and H. R. R.—General data of these locomotives are given in Table 14. J. C. Hassett and W. M. Guynes describe them in detail in *Ry. Age*, Sept. 19, 1931–June 11, 1932. They operate over maximum grades of 1.5% between New Haven and Grand Central Terminal, New York, and between Penna. Terminal, New York, and the Sunnyside yards, with 11,000-volt, 25-cycle, single-phase alternating current, and also with 600-volt direct current. Two twin-arrangement motors, mounted on each axle, are geared to a quill surrounding the axle. Spiders on the quill engage the driving wheel spokes through soring cups. A twin motor complete with quill gear, pinions, gear case and quill linings weighs 14,000 lb., or 25.5 lb. per continuous Hp., and requires 4300 cu. ft. of cooling air per min. To supply a total of 30,000 cu. ft. of air per min. for motors, grids, etc., requires 34 Hp. Tests show 550 Hp. per axle to be a safe continuous rating of the motors; the estimated rating was 457 Hp. Troubles due to poor commutation at starting and at high speeds, evident in former A. C. traction motors, have been overcome by a low flux per pole and the use of 12 poles, and by varying commutating field strength, and by providing brush holders of low inertia in their moving parts. The contract ratings of the motors are

A. C. continuous,	18,000 lb.	tractive effort at	57	mi. per hr., or	2740 Hp.
A. C. hourly,	25,200 "	" " "	51.2	" " " "	3440 "
D. C. continuous,	22,500 "	" " "	43.5	" " " "	2610 "
D. C. hourly,	31,200 "	" " "	37.4	" " " "	3140 "

The train capacity on tangent level track at full voltage in express service is 15 80-ton cars at 65 m.p.h. in the A. C. zone, and at 58 m.p.h. in the D. C. zone.

Penna. R. R. (J. V. B. Duer, *Ry. Age*, May 21, 1932).—The 11,000-volt, 25-cycle, electrified section between New York and Washington, 227 miles, uses locomotives of four types, viz.:

Type	Class	Service	Hp. at driver rims	Rating speed, m.p.h.	Rated tractive force, lb.	Max. operating speed, m.p.h.
2-C-2	P5	Heavy-duty Passenger	3750	63	22,300	90
2-B-2	O1	Light-duty Passenger	2500	63	14,900	90
1-D-1	L6	Freight	2500	37.8	24,800	54
0-C-0	B1	Shifting	570	15.9	13,500	25

The weight on a pair of drivers does not exceed 75,000 lb.; largest single locomotive unit weighs 375,000 lb. The main motors are single-phase commutator type, with a continuous rating of 625 Hp. per armature at driver rims. The motors of passenger locomotives are twin-armature, frame-supported, geared to the driving wheels through a quill drive. The freight locomotive has single, axle-mounted motors geared to each driving axle. Driving and truck axles and motor armatures are mounted in anti-friction bearings. These locomotives can be used singly or in combination to meet traffic de-

Notes to Table 14

[1] **Cleveland Union Terminal** (C. U. T.).—A 3000-volt direct-current installation with overhead catenary, of 22 locomotives to operate a terminal electrification, 17 miles long at Cleveland, Ohio.

[2] **New York Central** (N.Y.C.).—A 600-volt direct-current installation of 42 locomotives to handle freight trains between Harmon, N. Y., and New York City, 31 miles. While rated as freight locomotives, they sometimes are used on passenger trains into Grand Central Terminal.

[3] **New Haven** (N.Y.N.H. & H.).—Designed to operate on either alternating or direct current and used in passenger service between New Haven, Conn., and New York City. See above.

[4] **Virginian** (Va.).—A split-phase, constant-speed locomotive. Single-phase 11,000-volt, 25-cycle current is taken from an overhead catenary. A phase-converter on the locomotive supplies 3-phase induction motors. Regenerative braking is used. The running speeds are 14 and 28 m.p.h. These locomotives operate coal trains between Mullens, W. Va., and Roanoke, Va., 133 route miles. The data cover a 3-cab locomotive operated as a complete articulated locomotive. The momentary maximum tractive force is 277,000 lb.

[5] **Great Northern** (G.N.).—A motor-generator locomotive receiving 11,000-volt alternating current from an overhead catenary, converted to direct current on the locomotive. Regenerative braking is used on descending grades. The electrified line extends from Wenatchie, Wash., to Skykomish, Wash., 80 miles.

[6] **Pennsylvania** (P.R.R.).—Locomotives used on the New York-Washington electrification. See above.

mands. Thus, 2500 nominal B.Hp. is available in the single O1 locomotive; two O1 units coupled have 5000 Hp.; and an O1 and a P5, 6250 Hp.; two P5 units, 7500 Hp.

Each locomotive assembly consists of: 1. A chassis, made up of main frame, drivers, trucks, spring and brake rigging, motors, flexible drives, main transformer, and train heating boiler, together with the necessary storage reservoirs for air, oil and water. The foundation is a single steel casting in which are cast the air reservoirs and the oil and water reservoirs for the train heating boiler. 2. The deck unit, carrying the main control groups, air compressor, main wiring and most of the control wiring. The foundation is a structural aluminum framework, mounted on the chassis unit. 3. The cab unit.

Instead of a current-rupturing device between the pantograph and the primary of the main transformer, a pantograph lowering relay is used. This is so connected as to use the substation circuit breakers to open high-tension short-circuits, grounds, or overloads, on the locomotive. The P5, L6 and O1 locomotives also have a grounding device which functions automatically under transformer short-circuit or overload conditions to ground the pantograph. This opens the substation circuit breakers, after which the pantograph automatically lowers and locks.

Relay devices protect against motor overload, thus permitting maximum use to be made of tractive force available from driving wheel adhesion. At the same time they protect the motors should adhesion exceed normal values due to the application of sand or mis-handling of equipment. This relay protection is interlinked with anti-wheel-slip protection to direct the engineman's attention to driving wheel slippage.

Swiss (*Ry. Age*, Feb. 20, 1932).—A 1—B—1—B—1+1—B—1—B—1 electric locomotive for the St. Gothard line of the Swiss Federal Railroads was designed for heavy grades between Ertzfeld and Bellinzona. The locomotive is 111 1/2 ft. long and comprises two symmetrical sections with a joint between to permit their separation. Each section is complete in itself and has four motors and four driving axles. The locomotive, designed for both freight and passenger service, weighs 245 tons and develops 8500 maximum Hp. and maximum speed of 62 m.p.h. It will haul 1500-ton trains of 37 40-ton cars, on level track, and 750-ton trains over the 2.7% grades. The mechanical parts were built by the Locomotive and Machinery Wks., Winterthur, and the electrical parts by Brown-Boveri and Co., Baden, Switzerland.

5. LOCOMOTIVE DESIGN AND CONSTRUCTION

FACTORS IN LOCOMOTIVE DESIGN.—The general dimensions of a locomotive for any given conditions of service can be determined most conveniently, with sufficient accuracy for a preliminary estimate, by means of design factors. Let T = rated tractive force, lb.; W_a = adhesive weight, or weight on drivers, lb.; W_t = total weight of locomotive, lb.; S_h = evaporative heating-surface, sq. ft.; S_s = superheater surface, sq. ft.; G = grate area, sq. ft.; D = diameter of drivers, in.; d = diameter of cylinders, in.; s = stroke, in.; P = boiler pressure, lb. per sq. in.; A = adhesion factor; B = boiler factor; C = combustion factor; B_d = boiler demand factor; E = efficiency of design factor; F = superheater factor. Then according to Lawford H. Fry (*Ry. Mech. Engr.*, April, 1921), the most important factors in common use are:

$A = W_a/T$	$C = S_h/G$	$E = W_t/S_h$
$B = T/S_h$	$B_d = TD/S_h$	$F = S_s/S_h$

The rated tractive force is computed from $T = (0.85\,d^2\,sP)/D$, and is the tractive force deliverable by the cylinders at the driver rims, if cut-off is long enough to give 92% of boiler pressure as mean effective pressure in the cylinders, and if machine friction absorbs about 8% of the indicated cylinder power. Table 15 gives values of factors for different types of locomotives.

Adhesion factor A shows the weight holding the driving wheels to the rail per pound of average force tending to rotate them. $A \geqq 4.0$ probably will prevent slipping of wheels when starting.

Boiler factor B measures the pounds of rated tractive effort to be developed per sq. ft. of boiler heating-surface with the engine working in full gear. Two locomotives at the same speed V will develop horsepowers directly proportional to the tractive effort, according to formula Hp. = $TV/375$.

Boiler demand factor B_d is proportional in full gear to the foot-pounds of work per revolution done by each square foot of heating surface. This factor is used to determine rated tractive effort T.

Combustion factor C depends on quality of fuel. With anthracite C = 35 to 40;

with bituminous coal, $C = 55$ to 60, for superheater locomotives. With saturated steam these figures should be increased by from 10% to 20%.

Efficiency of design factor E shows relation between weight and total area of heating-surface.

E. C. Poultney (*Ry. Mech. Engr.*, Sept. and Oct., 1921) gives tables of dimensions and proportions of British locomotives, using the above factors. A summary of these factors for locomotives built between 1910 and 1920 is given in Table 16.

LOCOMOTIVE BOILERS.—The weight and dimensions of locomotive boilers are in nearly all cases determined by the limits of weight and space to which they are necessarily confined. In general, within these limits a locomotive boiler cannot be made too large. The Am. Ry. Master Mechanics Assoc. Committee of 1902 advised the ratios of heating to grate surface given in Table 17. These figures should be modified by the formulas on locomotive proportions adopted by the same body in 1916. See p. 14–36.

LOCOMOTIVE PROPORTIONS (Committee of Am. Ry. Master Mechanics Assoc., 1916).—Obtain tractive force from weight limitations on drivers, service, type, etc. See p. 14–05.

Let A = area of cylinder, sq. in.; A_g = area of grate-surface, sq. ft.; D = diam. of drivers, in.; d = diam. of cylinders, in.; F = tractive force, lb.; H_f = heating surface of firebox, sq. ft.; P = boiler pressure, lb. per sq. in.; s = stroke, in.; W_c = weight of coal, lb. per hr.; W_s = total weight of steam required, lb. per hr.; W_f, W_t = respectively, evaporation by firebox (including combustion chamber and arch tubes), and by tubes and flues, lb. per hr. Then $d = \sqrt{FD/0.85\,Ps}$; Hp. $= 0.212\,PA$ for saturated steam; $= 0.0229\,PA$ for superheated steam. Maximum Hp. is assumed at piston speeds of 700 ft. per min. with saturated steam, and 1000 ft. per min. with superheated steam. $W_s = 27.0 \times$ Hp. for saturated steam; $= 20.8 \times$ Hp. for superheated steam. $W_c = 4 \times$ Hp. for saturated steam; $= 3.25 \times$ Hp. for superheated steam. $A_g = W_c/120 =$ Hp./30 for saturated steam; $=$ Hp./36.9 for superheated steam. $W_f = H_f \times 55$; $W_t = W_c - W_f$.

0–6–0	Superheated	4.6	1103	70.5	9.0	6.1	1160	80.0
"	Saturated	4.7	980	64.8	8.9	5.9	1020	76.2

* $F.B.S.$ = firebox surface; S_t = total heating surface, including superheater when used.

Table 17.—Recommended Ratios of Heating-surface to Grate-surface

Fuel	Passenger		Freight	
	Simple	Compound	Simple	Compound
Free-burning bituminous	65 to 90	75 to 95	70 to 85	65 to 85
Average bituminous	50 to 65	60 to 75	45 to 70	50 to 65
Slow-burning bituminous	40 to 50	35 to 60	35 to 45	45 to 50
Bituminous slack and free-burning anthracite	35 to 40	30 to 35	30 to 35	40 to 45
Low grade bituminous, lignite and slow-burning anthracite	28 to 35	24 to 30	25 to 30	30 to 40

Basis of evaporation is 10 lb. of water per hr. per sq. ft. of heating surface. Ratio of cu. ft. of firebox volume to sq. ft. of grate surface should range from 5.5 to 6 for bituminous coal, and from 4.5 to 4.85 for anthracite. Ratio of tube length to tube diameter should be about 100. Ratio of superheating to total saturated steam heating-surface should be about 0.22 without combustion chamber, and 0.29 with combustion chamber.

CYLINDER SIZES usually are such that the engine just will overcome the adhesion of the wheels to the rails under favorable conditions. Let W = weight on drivers, lb.; P = tractive force, lb., $= 0.25\,W$ for passenger engines, $= 0.24\,W$ for freight, $= 0.22\,W$ for switching; p, p_b = respectively, mean effective and boiler pressure, lb. per sq. in.; D, d, = respectively, diam. of drivers and cylinder, in.; s = length of stroke, in.; $p = 0.85\,p_b$. Then $W = 4\,P = 4\,d^2\,ps/D = 4\,d^2 \times 0.85\,p_b\,s/D$.

$$d =$$

Von Borrie gives for the diameter d_1 of the low-pressure cylinder, $d_1^2 = 2\,ZD/ps$, where Z = tractive force required, usually 0.14 to 0.16 × adhesion. Internal machine friction is deducted in ascertaining p, whose value depends on the cylinder volume ratio. Indicator experiments give the following values:

	Cylinder Volume Ratio	p/p_b	p when $p_b = 176$
Large-tender engines................	1 : 2 or 1 : 2.05	42	74
Tank engines......................	1 : 2 or 1 : 2.2	40	71

PRESSURES AND STRESSES IN LOCOMOTIVE PARTS (Brian Reed, *Engr.*, June 17, 1932).—An analysis of a large number of locomotives built since 1919, the majority between 1926–32, was made to determine stresses in the various parts. The locomotives represent British and American practice and also locomotives used in Europe and in other countries. The original article contains many tables of dimensions, stresses, calculations, etc., which are summarized below.

Main and Side Rods.—Most of the main and side rods were of high tensile strength Ni-Cr steel. The vertical and inertia forces were calculated on the assumption that the steam pressure in the cylinder equaled 0.33 normal working pressure, and speed in m.p.h. was equal to the driver diameter in inches. Twenty connecting-rods of material of a yield point of 40 tons (2240 lb.) per sq. in. or over gave the following average stresses per sq. in. Tensile at small end, 10,790 lb.; vertical, 11,350 lb.; horizontal, 12,950 lb. Values of (length/radius of gyration) ranged from 40 to 80 vertically and 120 to 205 horizontally. Inertia stresses are reduced by the lighter sections permissible with alloy steel. Average inertia stress in the alloy steel side rods of locomotives on seven different railroads was 8500 lb. per sq. in., while the average inertia stress in twelve rods of class C carbon steel was 14,100 lb. per sq. in., with a lowest value of 9,600 lb.

Straight Driving Axles and Crank-pins.—Stresses are due to the resultant of spring load and piston thrust, combined with the twisting moment to obtain the equivalent bending moment. An analysis of the stresses in a 4–6–0 locomotive of the Southern Ry. (British) showed a combined bending stress on the axle of 203,840 lb. per sq. in., a bearing pressure due to spring load of 159 lb. per sq. in., and a bearing pressure due to piston load of 1030 lb. per sq. in. The combined bending moment on the crank-pin was 7,765,760 in.-lb., and the equivalent bending moment of the force necessary to turn one wheel was 14,564,480 in.-lb. The stress in the crank-pin was 13,960 lb. per sq. in. and the bearing pressure 2000 lb. per sq. in. The average bearing pressure on the main axle of 30 locomotives built between 1922 and 1932 was 1730 lb. per sq. in., with upper and lower limits of 2120 and 1415 lb.; bending stress averaged 16,650 lb. per sq. in., with upper and lower limits of 22,100 and 7850 lb. per sq. in.

Single Throw Crank-axles for 3-Cylinder Engines.—The stress on the crank-pin is much lower than in a 2-cylinder engine. The pin diameter is much the same, but the piston thrust is usually much greater in a 2-cylinder engine. An analysis of stresses and bearing pressures on the inside crank-pins and journals of 3-cylinder engines on six railroads gave the following values, lb. per sq. in.: Bearing pressure on outside pin, maximum, 1820; minimum, 1495; average, 1667; bending stress on outside pin, maximum, 19,667; minimum, 7840; average, 15,870; bearing pressure on inside pin, maximum, 1140; minimum, 757; average, 999; bending stress on inside pin, maximum, 10,640; minimum, 6832; average, 8769; spring load bearing pressure on journal, maximum, 175; minimum, 150; average, 166; piston thrust load on journal maximum, 1100; minimum, 915; average, 970. Average crank-pin bearing pressure of 20 2-cylinder engines was 1320 lb. per sq. in.

Coupled Axle Boxes.—Bearing pressures per sq. in. of projected area are higher than for main driving axles on the same engine. A study of axle boxes on over 50 engines, covering all classes of service, gave average bearing pressures, lb. per sq. in., of: Fast passenger engines, 177; mixed traffic engines, 195; freight and switching engines, 208.

Truck, Trailer and Tender Axle Boxes.—An analysis of 30 truck axle boxes in fast passenger and mixed traffic showed an average bearing pressure of 150 lb. per sq. in. of projected area, and in freight service of 155 lb. Fifteen trailer axle boxes showed an average bearing pressure of 194 lb. per sq. in., and 15 tender axle boxes showed 230 lb. These correspond closely to the values recommended by the Am. Ry. Assoc. See p. 14-26.

Crosshead Guides.—Stiffness, rather than bending stress, is the criterion of good design. Table 18 shows the proportions, stresses and deflections of the guides in a variety of engines. Deflection has been calculated at point of maximum connecting-rod thrust, and in no case does maximum thrust coincide with mid-point of crosshead travel. The best position for the outer support is near mid-stroke.

Crossheads and Crosshead-pins.—Triple guides have been adopted in a number of locomotives to reduce slipper pressure. In a decapod on the Penna. R. R., triple bearing faces, one above the other, are necessary to take the thrust in the forward direction of 9.85 tons, resulting from a piston load of 81.5 tons. Four-bar arrangements are subject to high stresses and pressures, but the variation between top and bottom limits is not as wide as with 1- and 2-bar designs. Average values of slipper pressure, lb. per sq. in., are:

	One Bar	Two Bars	Three Bars, Forward	Three Bars, Backward	Four Bars
Average.......	69	66	62	101	85
Upper.........	89	85	78	128	93
Lower.........	58	40	55	68	79

Crosshead-pin bearing pressures per sq. in. of projected area may be taken as 5000 lb. In 25 designs the highest value, lb. per sq. in., was 6400; lowest 4050; average, 4800. In these same pins, bending stress, lb. per sq. in., was: highest, 10,600; lowest, 5250; average, 6620. The pin was considered as a beam supported at the ends and uniformly loaded, bending moment being taken as $WL/8$.

Piston-rods.—An examination of 20 class D carbon steel rods showed an average tensile stress at the center of 5800 lb. per sq. in., with 9200 lb. at the smallest cross section. Twelve alloy steel rods showed an average stress of 7325 lb. per sq. in. at the center, and 9850 lb. per sq. in. at the smallest cross section.

6. LOCOMOTIVE DETAILS

The following locomotive details are condensed from the standards and recommended practice adopted by the American Railway Association in the year following each title.

AXLES (1927).—Locomotive Driving Axles. Dimensions are shown in Fig. 9 and Table 19. Axles 9 1/2 in. diam. or over may be hollow or solid, flush with hubs or project 1/8 in. beyond hub faces, in which case increase dimension H by 1/4 in. Dimensions B, D and F apply to main axle; on other axles, length of wheel fits and journals depend on dimensions of main axle. Diameter of axles between journals may equal diameter of journal less limit of wear. Length of journals = length of bearing + 1 in. Engine frames should be so spaced that central plane of journal coincides with central plane of frame. Allowable bearing pressure, lb. per sq. in., are: passenger engines, 175; freight and switch engines, 200.

Formula for Calculating Stress in Main Axle.—Let A = crank radius, in.; B = 1/2 difference in distance between cylinder center lines and frame center lines, in.; $C = \sqrt{A^2 + B^2}$; P = piston thrust, lb.; S = fiber stress, lb. per sq. in.; Z = section

Table 18.—Stresses in Crosshead Guides

* Applies to non-booster axles only, rough turned between wheel fits.

Trailer Truck Axles.—Dimensions are given in Fig. 10 and Table 21. Outlines in dotted lines are optional. The enlarged middle section is standard for engines with booster. Allowable bearing pressures, lb. per sq. in., are: passenger engines, 200; freight engines, 210.

AXLE AND CRANK-PIN MOUNTING PRESSURES (1931) recommended for mounting driving and trailing axles and crank-pins are: Cast-iron wheel centers, 10 tons per inch of axle or pin diameter; cast-steel wheel centers, 15 tons per inch of diameter; allowable variation 10% in both cases.

CENTERS AND KEYS.—Dimensions for centers and keys for all axles are given in Fig. 11.

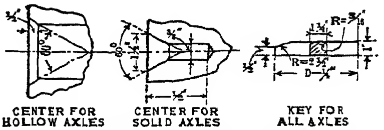

Fig. 11. Axle Center and Key Dimensions

CONNECTING- AND SIDE-RODS (1923).—**Main rods**, Fig. 12, should have tapered fluted section, flanges as narrow as consistent with good design, a setting-up wedge in front of crank-pin, with single-nutted bolts, riveted over, one grease cup, composition bronze bearings at each end, and an approved adjusting feature at front end. Rods, straps and details should be of good material and as light as possible.

Side-rods, Fig. 13, in general, should be of the same construction; the main parallel connection may have a floating bushing. Ample side clearance at knuckle pins, solid oil cups, and single or castle nut for knuckle pins, with cotter or lock nut are essential. Tapped plugs, top and bottom, prevent bushings turning. Knuckle pins should be hollow. Offsets or special shapes are undesirable, except to avoid interference. Collars on inside of bushings are desirable. No welding of any kind may be used to fasten keys, wedges, etc.

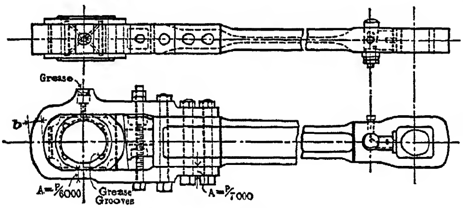

Fig. 12. Main Rod

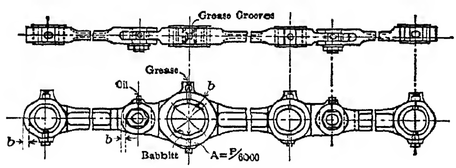

Fig. 13. Side Rods

The following notes on stresses on rods are from *Proc.* Am. Ry. M. M. Assoc., 1911. Stresses in main rods are tension and compression, due to piston pressure and inertia of reciprocating weights, and bending due to centrifugal force acting vertically. Stresses in compression are always greater than in tension, and those due to cylinder pressure are greater than those due to reciprocating weights. Stresses in side-rods are tension and compression, due to part of the piston pressure transferred through the main crank-pin, and to the rod sliding one or more drivers of unequal diameter, or when passing curves. Bending stresses also exist, due to centrifugal force acting vertically. The limit of the force to slide drivers is the coefficient of friction between wheel and rail, which may be taken as 0.3. Each rod is assumed to be able, when starting, to slide the *pairs* of drivers it rotates; at running speed it need slide drivers on one side only. Calculations of rods may be based on 375 r.p.m. for fast freight and passenger engines, and 420 r.p.m. for fast passenger engines. For Mallets a special figure should be used.

Table 22.—Standard Axles for Locomotive Tenders

(American Railroad Association)

Letter	Capacity, lb.	Journal Diameter and Length, in.	Diameter, in.		Length	
			At Wheel Seat	At Center	Center to Center of Journals	Overall
A	15,000	3 3/4 × 7	5 1/8	4 1/4	6′ 3″	6′ 11 1/4″
B	22,000	4 1/4 × 8	5 3/4	4 3/4	6′ 3″	7′ 0 1/4″
C	31,000	5 × 9	6 1/2	5 3/8	6′ 4″	7′ 2 1/2″
D	38,000	5 1/2 × 10	7	5 7/8	6′ 5″	7′ 4 1/2″
E	50,000	6 × 11	7 5/8	6 7/16	6′ 6″	7′ 6 3/4″

Let A, a, = respectively, area, sq. in., and depth, in., of section; b = width of section, in.; B = unit load, lb.; C = maximum unit compressive stress, lb.; C_1, C_2 = respectively, maximum unit compressive stress for transverse and vertical bending; c, c_1, c_2 = coefficients (see Table 23); D = diam. of drivers, in.; d = cylinder diam., in.; E = modulus of elasticity; F = centrifugal force, lb.; G = weight of rod, lb.; l = length of rod, in.; M = bending moment, in.-lb.; m = section modulus = m_h, m_v, axis horizontal and vertical respectively; n = constant = 1 for both ends round; = $^1/_4$ for both ends fixed; p_b = maximum boiler pressure, lb. per sq. in.; p = maximum piston pressure, lb. per sq. in.; P = maximum compressive stress at end of rod, lb. per sq. in.; P_m = maximum end load, lb.; R = length of crank, in.; r = radius of gyration, in., = r_v, r_h for axis vertical and horizontal, respectively; s = offset of rod, in.; S = stress, lb. per sq. in.; T = ultimate tensile strength of steel; W = weight of reciprocating parts.

For fast freight and passenger engines, if $p < 4\,WR$, $4\,WR$ should be substituted for p. The rod body should be considered as a strut with load p or $4\,WR$, and as a beam subject to bending due to whip at high speeds. Main rods usually are tapered, and often fluted. Calculation should be based on the value of A at the center, and $A >$ $(P_m/10{,}000)$. Stresses are computed by the column formula $C = B/\{1-(nB/\pi^2E)(l/r)^2\}$. With C = 10,000, $(l/r) \gtreqless 80$ when neutral axis is vertical, and $(l/r) \gtreqless 160$, with neutral axis horizontal. With neutral axis vertical, $r = b\sqrt{12}$; horizontal, $r = a\sqrt{12}$. Substituting these values in $(l/r) \gtreqless 80$ and $(l/r) \gtreqless 160$, respectively, then l = 23, b = 46 a, whence if l, center to center of pins, < 23, $(l/r) < 80$, and if $l < 46\,a$, $(l/r) < 160$.

In Offset Rods, where the vertical center lines of the bearings are not in the same plane or in the plane of the center of the body, a bending stress is created equal to $P_m\,s/m_v$, which increases stress in the main body.

Knuckle Joints, on rods of 3-coupled and 4-coupled engines, are flexible both horizontally and vertically. If drivers on one side are not in perfect alignment, slight bending stresses occur, in addition to the compression stresses. When knuckle joints are flexible both horizontally and vertically, $l/r \gtreqless 110$ instead of 160.

Bending Stress Due to Whip at High Speed is at a maximum at 0.6 l from crosshead end in main rods, and at the center in side rods. The section at these points, therefore, is the governing section.

Simplified Formulas may be used for checking or for approximate results, within a small percentage of those found by the accurate formulas. These are based on centrifugal force F and on bending moment M. For side rods $M = 0.125\,Fl$, and for main rods $M = 0.064\,Fl$. $G = 0.2833\,Al$, and $GR = 0.2833\,AlR$, where 0.2833 = weight of 1 cu. in. of steel. The following relations hold:

	265	325	375	420
	$2GR$	$3GR$	$4GR$	$5GR$
M (side rods) = ...	$0.071\,Al^2R$	$0.106\,Al^2R$	$0.142\,Al^2R$	$0.177\,Al^2R$
M (main rods) = ...	$0.036\,Al^2R$	$0.055\,Al^2R$	$0.073\,Al^2R$	$0.091\,Al^2R$

The stress due to whip, $S_w = M/m$, should be added to the maximum stress due to end load; the sum should not exceed $^1/_6$ ultimate tensile strength of the steel.

Checking Formulas. For main rods, $A \geqq P/10{,}000 = 0.7854\,d^2pb$; for side rods, $A = 0.15\,WD/R$. For rods with knuckle pins, flexible transversely,

$$C_1 = (P/A)/\{1 - (Pl^2/675{,}000{,}000\,A)\}.$$

For all other rods, $C_1 = (P/A)/\{1 - (Pl^2/1{,}200{,}000{,}000\,Ar_v^2)\}$.

For vertical bending, all rods, $C_2 = (P/A)/\{1 - (Pl^2/300{,}000{,}000\,Ar_h^2)\}$.

For rods without offset, use the value of C_1 or C_2 that is larger as the value of the stress S, lb. per sq. in., in the rod. $S = c_2(l^2r/b) + c_1(P/A)$. $S < {}^1/_6\,T$ if $l < 46\,a$ or $23\,b$, and if $A > P/(^1/_8\,T)$. For offset rods, use the value of C_2, or of $C_1 + (Ps/m_v)$ that is larger, for the value of S. $S = c\,(Al^2r/m_h) + c_1\,P(1/A) + (s/m_h)$.

Allowable stresses on various sections of rod ends are shown in Figs. 12 and 13, except at points marked b. If minimum areas of the two members differ, take A as double the area of the smaller. Minimum areas at points b are: For main rods, $A = PX/30{,}000\,b$; for side rods, $A = PX/60{,}000\,b$, where X = average diam. of eye or spread of jaws.

Table 23.—Values of c, c_1 and c_2

Revolutions per Minute =		265	325	375	420
Main rod	c	0.036	0.055	0.073	0.091
	c_1	.500	.500	.400	.300
	c_2	.22	.33	.44	.55
Side-rod	c	0.071	0.106	0.142	0.177
	c_1	.500	.500	.500	.500
	c_2	.43	.64	.85	1.06

Knuckle Joints for Side-rods (Fig. 14).—Material: For knuckle-pins and rods, medium-grade forged steel A.R.A. specifications; for optional taper key, tire steel; for rod bushing, hard bronze or case-hardened steel. Bronze bushings may float in the rod. Hollow boring of knuckle joint pin is optional.

Bearing Pressures, lb. per sq. in., on knuckle joint pin are: $T/DL \leqq 4000$; $T = 0.3\,WR/r$, where T = thrust, lb.; W = weight on pair of drivers, lb.; R, r = respectively, radius of driving wheel and crank, in.; D and L are pin dimensions. See Fig. 14. Diameter of the threaded part of the pin is:

When D =	T =
3 in.	2 1/2 in.
4 in.	3 in.
5 in.	3 in.
6 in.	3 1/2 in.
7 in.	3 1/2 in.

See also Checking Formulas for Main and Side Rods, p. 14–28.

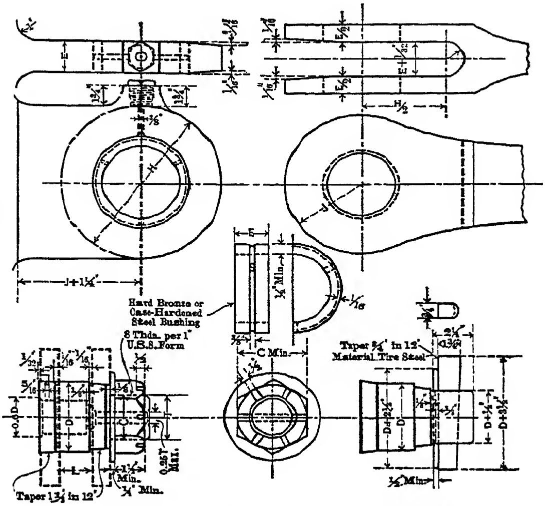

FIG. 14. Knuckle Joints and Knuckle Pins

CRANK-PINS (1928).—The designs of main crank-pins, Fig. 15, and other crank-pins, Fig. 16, are for steel, ultimate tensile strength, 80–85,000 lb. per sq. in. (A.R.A. material specifications for axles, shafts, and forgings). Determining factors of main pin design, depending on size of engine and power required, are piston thrust and location of center line of cylinders in relation to hub face of wheel, *i.e.*, dimensions L, Fig. 15. Following are formulas for fiber stress, bearing pressures, thrust, etc.:

Main Crank-pins.—$f = TL/S < 16{,}000$ lb.; $P = T/(A \times B)$; $p = t/(C \times D)$; where f = fiber stress, lb. per sq. in.; T = piston thrust, lb.; t = side rod thrust, lb.; P = bearing pressure, main rod bearing; p = bearing pressure, side-rod bearing, lb. per sq. in.; S = section modulus = $0.098\,C^3$ for solid pins; = $0.098\,(C^4 - E^4)/C$ for hollow pins; for other symbols see Fig. 15. P and p should not exceed 1600 lb. per sq. in., and $A \leqq B$. Thrust on side-rod bearing equals combined thrust on all coupled crank-pins except main pin. Hollow pins are optional, and of the following dimensions:

C, in.	6–6 1/4		9–9 3/4	10–10 1/2	10
$E_{max.}$,	2	2 1/2	3 1/2	4	4 1/2
F, in.	1	1	2		2

Other Crank-pins.—$f = t \times 0.5\,B/S < 10{,}000$ lb.; $t = 0.3\,WR/r$; $p = t/(A \times B) < 1600$ lb.; $S = 0.098\,A^3$; where W = weight on pair of drivers, lb.; R = radius of driving wheel, in.; r = radius of crank, in.; other notation as for main pins or as in Fig. 16.

Either double or castle nuts may be used on the male threaded end with collar; double nuts are preferred. For front driving wheels or where space is limited, the designs Fig. 16*b* or *c* may be used; the latter is stronger, but the former is more generally used.

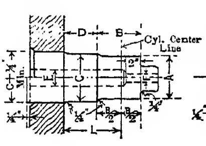

FIG. 15. Main Crank-pin

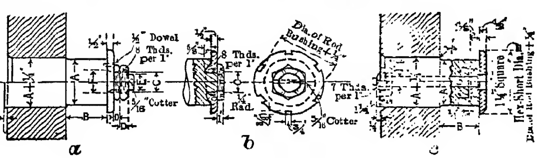

FIG. 16. Coupled Wheel Crank-pins

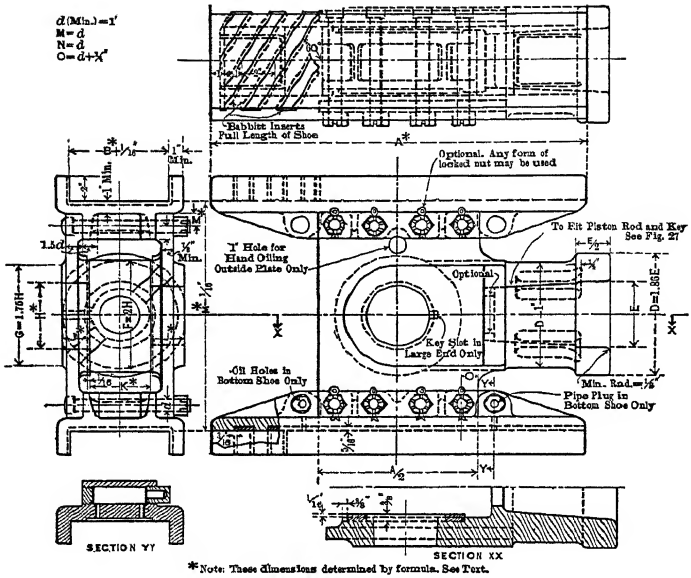

FIG. 17. Alligator-type Crosshead

CROSSHEADS AND GUIDES (1929).—Alligator-type crossheads (Fig. 17) are recommended. Dimensions of crosshead depend mainly on dimensions of the crosshead-pin (see below) and of the guides. Both are determined by allowable bearing pressures; guide dimensions also depend on other dimensions of the engine. Width of guide, B, depends on center line distance between engine cylinders and clearance between crosshead and front crank-pin (minimum clearance = 1 in.). Length of crosshead, A, is such as to make bearing pressure on guide < 100 lb. per sq. in. Let Z = bearing pressure,

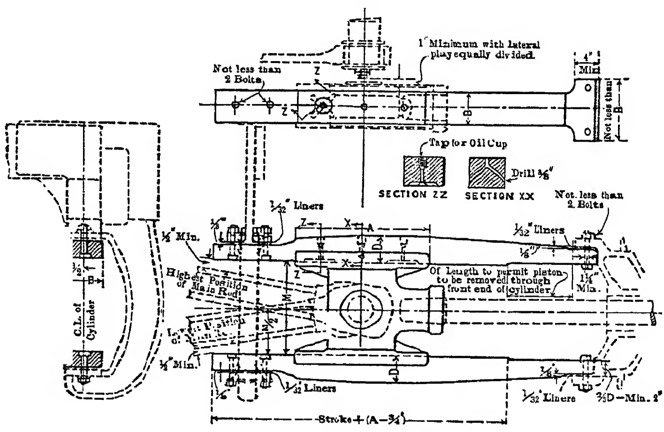

FIG. 18. Crosshead Guides

lb. per sq. in.; P = piston thrust, lb.; T = upward thrust of crosshead, lb.; R = length of main rod, in.; S = stroke, in.; C = vertical distance from plane of driving axle to center line of cylinders, in. Then $Z = T/(A \times B) < 100$; $T = P(^1/_2 S + C)/R$, whence dimension A can be found. Spread of guides, M, depends on clearance between main rod and the end of the guides, at the highest and lowest positions of the rod (see Fig. 18); $^1/_2$ in. is minimum clearance. Dimensions H, J and K (Fig. 17) depend on the dimensions of the crosshead-pin.

Dimension E governs dimensions of piston-rod boss, and depends on design of the rod. See Piston-heads and Rods, p. 14–34. Taper bolts of minimum diameter d = 1 in., taper $^1/_{16}$ in. in 12 in., driven into reamed holes and secured with castle nuts and split cotters, fasten shoes to crosshead. Crossheads are cast steel (A.R.A. specification, grade B), and shoes are cast-iron (A.R.A. specification for cylinders); for heavy fast passenger engines they may be medium bronze without babbitt inserts (A.R.A. specifications for bronze bearings). Bolts are mild steel.

Maximum depth of guide bar, D, $= \sqrt{6\ TI/4\ fB}$, where I = overall length of guide, in.; B = width of guide, in.; f = fiber stress, lb. per sq. in. = 8000 max. Lubrication is through three oil holes in top guide, one at crosshead mid-travel, one 6 in. back of forward edge of crosshead in extreme rear position, and one 6 in. ahead of rear edge of crosshead in extreme forward position; the lower guide is lubricated by oil holes in the lower shoe. Upper and lower shoes are fitted with babbitt inserts, 1 in. wide, dovetailed into the shoe, and set at an angle of 60 deg. to the line of travel of the crosshead. Wear is taken up by shims between guides and supporting lugs on cylinder heads and guide yokes.

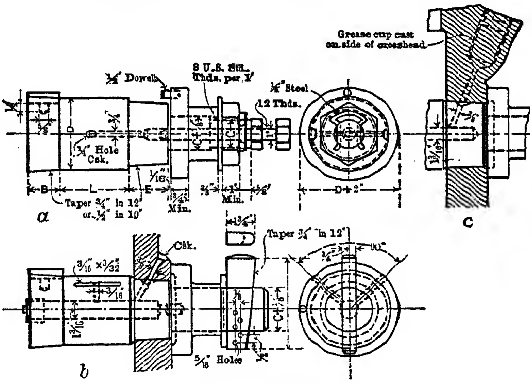

FIG. 19. Crosshead-pins

Crosshead-pins (1929).—Dimensions of pins, Fig. 19, are determined by piston thrust. Let P = piston thrust, lb.; D and L = diameter and length, in., respectively, of crosshead-pin in main rod; S = crosshead-pin bearing pressure, lb. per sq. in. Then $(T/DL) = S < 4800$, D or L being assumed. Dimension C depends on D as follows:

D, in. =	3	5	6
C, in. =	$2\,^1/_2$	3	$3\,^1/_2$

Dimensions B and E are found by formula $T/\{D \times (B + E)\} = S < 5000$; S = crosshead-pin bearing pressure on side plates, lb. per sq. in.; $B = E$, or B (min.) $= E - ^1/_4$ in. Crosshead-pins are forged steel, A.R.A. specification. Pins are held in position by a nut with cotter pin; a taper key, as shown, is an alternative method. Grease lubrication of pins is recommended, but is difficult with a keyed fastening. Fig. 19*b* is a recommended method for oil and Fig. 19*c* a method of grease lubrication for keyed fastenings.

DRIVING AND ENGINE TRUCK BOXES (1928).—Material is cast steel (A.R.A. specification for carbon steel castings, 1923). For driving boxes, dimensions are given in Fig. 20 and Table 24; engine truck boxes in Fig. 21 and Table 25. Details of cellar design and fitting and grooving of brasses have not been standardized (1934). Fig. 21 shows construction for 2-wheel engine trucks using semi-elliptical plate springs. Modified as in Fig. 22 it may be used on 4-wheel front trucks of passenger engines.

DRIVING AND TRAILING WHEELS FOR LOCOMOTIVES (1907. Revised 1928). —**Driving Wheels.**—Cast-steel driving-wheel centers should be uncut and shrinkage slots omitted. If total weight of locomotive permits, rims should be cast solid without cores, and have full bearing on tires; sectional area should be approximately 45% that of the tire when new. Hubs and solid rim sections, Fig. 23*b* and *c*, are recommended for all designs where weight and counterbalance limits permit. Cored rim, Fig. 23*f*, *g*, *h*, and elliptical spoke section, Fig. 23*j*, *k*, are alternatives. Fig. 23*j*, *k*, is an optional arrangement of reinforcing webs between spokes. Solid counterweights are recommended, cast integral with driving wheel center wherever the desired counterbalance can be so obtained. Small lead pockets, Fig. 23*f*, permit closer adjustment than solid counterweights. Solid cast counterweights usually are satisfactory on all except main driving wheels. They sometimes can be used on main wheels of relatively large diameter.

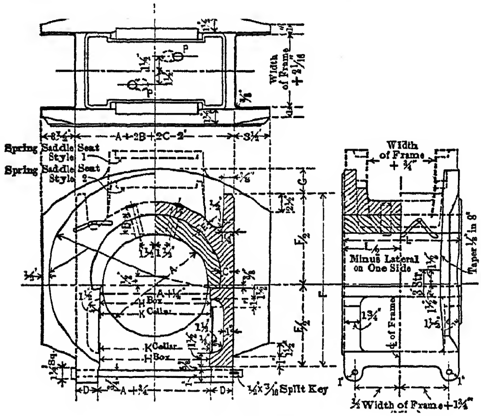

Fig. 20. Driving Box

Trailer Wheel.—Material recommended is cast steel (A.R.A. specification, 1918, for carbon steel castings); hubs, rims and spokes are similar in design to those of driving wheels. The relation of hub bore and journal dimensions, and of whee diameter and number of spokes is as follows (see Fig. 24). Shrinkage tires should be used in all cases.

ECCENTRIC CRANKS

CRANK ARMS (1931).—Designs in Fig. 25 are for forged medium steel (A.R.A. Standard specification for axles, shafts, and other forgings), but are suitable for electric cast steel. Forged eccentric cranks should be machined all over. Bolts are drive fits in straight reamed holes. Channel milling is optional in forged steel cranks. Dimension *D* is made to suit crank-pin. The bronze ring is made to suit main rod, and may be omitted if not required by main rod design. The eccentric

pin is made to suit eccentric rod bearing, and may be forged solid with the crank arm, or made separately, pressed in, and riveted over.

FRONT AND BACK CYLINDER HEADS (1929).—Front and back heads for cylinders up to 32 in. diam., and for boiler pressures up to 300 lb. per sq. in. are shown in Fig. 26. Material is grade B cast steel, A.R.A. specification. Number of studs, $N = A/a$; $A = {}^1/_4\pi D^2Pc/T$; where A = total cross-sectional area at root of thread, of all studs, sq. in.; a = cross-sectional area of one stud; P = boiler pressure, lb. per sq. in.; D = mean diam. of cylinder head joint, in.; c = factor of safety = 8; T = ultimate tensile strength of stud material, lb. per sq. in. Pitch of studs $\leqq 3\,{}^1/_2 \times$ diam. of stud.

PISTON-HEADS AND RODS (1928).—Piston-heads may be either wrought or cast steel (minimum tensile strength, 60,000 lb. per sq. in.). Fig. 27 and Table 26 are designs of piston-head, a solid one-piece head and a two-piece head with the bull ring bolted or riveted to it. Arrangement and style of packing and bull rings, and methods of facing their peripheries with anti-friction metal are optional. Bearing pressures should not exceed 5 lb. per sq. in. for passenger engines, or 6 lb. per sq. in. for freight engines. Bearing pressure = W/V, where W = (weight of piston-head exclusive of packing rings + weight of piston-rod nut + ${}^1/_2$ weight of rod, lb.); V = projected area of head, sq. in., exclusive of packing rings, bearing on bottom of cylinder.

Piston-rods may be of annealed carbon steel, 80,000 lb. per sq. in. minimum tensile strength (A.R.A. specifications, revised 1926), for medium carbon steel forgings. Heat-

treated steel (A.R.A. specifications for forgings of either quenched and tempered carbon, or quenched and tempered alloy steel) is preferable.

Diameter of rod, of threaded end, dimensions of slot and distance from slot to end of rod are functions of the piston thrust. They are determined by the formulas, $A = \sqrt{P/5183}$; $B = 0.163 + \sqrt{P/7068}$; $C = P/(10{,}000 \times \text{mean diam.})$; $D \times E = P/20{,}000$; Area $MM = P/9500$; where P = piston thrust, lb. The other symbols are given in Fig. 27.

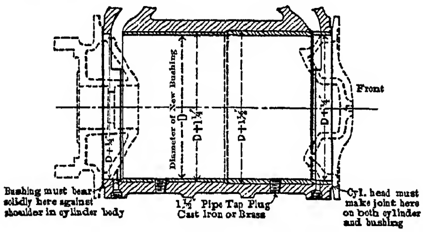

Fig. 28. Cylinder Bushings

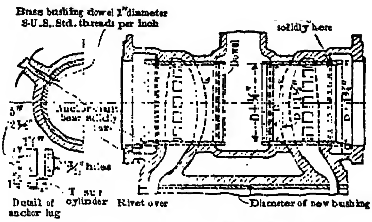

Fig. 29. Steam Chest Bushing

Dimensions of the nuts depend on the value of B as above determined, and are as follows:

B, in. =	2	2 1/4	2 1/2	2 3/4	3	3 1/4	3 1/2	3 3/4	4	4 1/4	4 1/2	4 3/4	5
G, in. =	2	2 1/4	2 1/4	2 1/2	2 1/2	2 3/4	2 3/4	3	3	3 1/4	3 1/2	3 3/4	4
F, in. =	3 1/8	3 1/2	3 7/8	4 1/4	4 5/8	5	5 3/8	5 3/4	6 1/8	6 1/2	6 7/8	7 1/4	7 5/8

Piston-rod and Crosshead Key Tapers, Fig. 27, are respectively: Rod (on diameter), 3/4 in. in 12 in.; key, 1/2 in. in 12 in.; or rod, 1/4 in. in 5 in.; key, 3/8 in. in 12 in.

STEAM CHEST AND CYLINDER BUSHINGS (1930).—New cylinders are fitted with bushings of close-grained gray iron (A.R.A. standard material specification for locomotive cylinders). See Figs. 28–30. If d = diam. of cylinder or steam chest bore, in., and D = outside diam. of bushing, in.,

$$D = d + 0.00025\,d \text{ for cylinders,}$$

$$\text{and } D = d + 0.000375\,d \text{ for steam chests.}$$

Bushings are cold pressed into cylinders and steam chests, and bored in line with each other after insertion. Steam edges of ports in steam chest bushings are machined. Steam ports in cylinder bushings are formed by drilling a series of holes and chipping out bridges between, after bushing is in place, edges being filed smooth. Figs. 29 and 30 show two methods of anchoring bushings in steam chests. Fig. 30 provides for long valve travel with minimum length of steam chest.

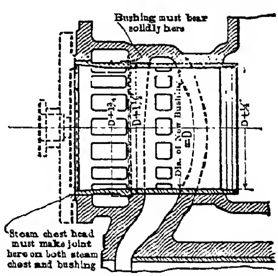

Fig. 30. Steam Chest Bushing

STRESSES IN LOCOMOTIVE BOILERS (1915) APPLYING TO NEW CONSTRUCTION ONLY.—**Longitudinal Barrel Seams and Patches.**—*a.* In figuring net section of plate, use diameter of rivet hole. *b.* In figuring rivet shear, use actual diameter of driven rivet. *c.* In figuring stress in plate and shear in rivet if junction of firebox wrapper sheet and barrel is not cylindrical, use maximum diameter. Surfaces subject to bending under pressure must be adequately braced. *d.* When boiler shells are cut for steam domes or manholes, strength of metal in flange and liner shall equal that of metal removed. If separate flange is used at base of dome, its entire net area is to be assumed as reinforcement. If dome sheet is welded vertically and flanged direct to boiler shell, a vertical distance 2 in. from base of flange is assumed as reinforcement, using net area less rivet holes and 28,500 lb. per sq. in. as ultimate tensile strength.

Longitudinal Gusset Braces and Flat Surfaces.—*a.* In diagonal braces, allow for the angularity of the brace. *b.* Use either sectional area of the brace or strength of attachment of brace to shell, whichever is lowest. *c.* In determining strength of gusset braces for supporting back head and tube sheets, select minimum of: 100% of rivet-bearing area; 80% of rivet shear area; 90% of gusset plate area, measured at right angles to longest edge of gusset sheet. *d.* Calculation of stress in gusset braces covers both the section of the plate and strength of fasteners; use lowest net strength. *e.* Flat stayed surfaces are figured with the boundary of unsupported flat surface located at a distance equal to outside radius of flange measured from inside of shell. *f.* No supporting value shall be assigned to the stiffness of flat plates on flat surfaces. *g.* Allow no staying or supporting value for reinforcing plates, as back head liners, but consider them only as mechanical reinforcements. *h.* 2 in. beyond the outer row of flues on tube sheets is assumed to be self-supporting. *i.* Deduct area of dry pipe hole in calculating area to be stayed on front tube sheet. *k.* T-irons or members subject to bending, are calculated without addition for strength of plate; stress in such beam and abutments not to exceed 12,500 lb. per sq. in. Spacing of rivets over supported surface shall conform to specification for stay bolts. No allowance for value of such beams is made in calculating total areas of longitudinal braces attached thereto. *l.* When a number of diagonal stays support a flat surface, the proportion of area allotted to each brace shall be: (entire net area to be stayed) ÷ (entire net area of braces). If any individual brace appears to receive more than its fair proportion of load, it shall be investigated separately as to the area supported by it. *m.* Patches on barrel of a boiler to be designed with longitudinal and circumferential seams at least equal in strength to main longitudinal and circumferential barrel seams. Patches may be applied to flat stayed surfaces with properly designed single-riveted seams without impairing the strength of the sheet.

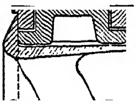

FIG. 31. Piston-valve Ring

Stay Bolts. Radial Stays and Crown Bar Bolts.—*a.* In figuring net area of stay bolts to obtain the stress, area of tell-tale hole shall be deducted. *b.* Area at root of thread must depend on type of thread used. *c.* In determining area for figuring stress on stay bolts, the area of one stay bolt shall be deducted from the rectangle included between any four stay bolts. *d.* In boilers with crown bars supported on firebox side sheets and sling stays, the sling stays are considered as carrying the entire load.

Dry Pipes (1922).—Recommended practice for dry pipes is as follows:

Nominal Size, in.	5	6	7	8	9
Inside Diam., in.	5.047	6.065	7.023	8.071	8.941
Outside Diam., in.	5.563	6.625	7.625	8.625	9.625
Thickness, in.	0.258	0.280	0.301	0.277	0.342

PISTON-VALVE RING shown in Fig. 31, and known as the "L" ring, was recommended by a committee of the Am. Ry. Master Mechanics Assoc. (1916). The spacing, or bull, ring shown with it was also recommended.

EXHAUST NOZZLES usually are circular with a single opening, but for anthracite burning locomotives the double nozzle is favored. For saturated steam the diameter of the single nozzle is about 0.25 × cylinder diameter D. For superheated steam the diameter is about 0.225 D. The combined area of the two openings of double nozzles is made equal to that of the corresponding single nozzle. The net area of opening, with a bridge, is made as large as before the bridge was applied. A nozzle with four projections extending a short distance across the circular opening of the usual type, known as the Goodfellow type, was developed by the Penna. R. R. system at its locomotive testing plant. The projections are of triangular section with the edges turned downward. A considerable increase in locomotive capacity has been effected by means of this nozzle. See *Ry. Age-Gazette*, Apr. 9, 1915.

Multiple-opening exhaust nozzles of enlarged area have had extended application, and provide an effective means of filling a large-diameter stack, thereby reducing the velocity of the gases and the work lost on their discharge to atmosphere. Fig. 32 shows a 6-opening nozzle on the Timken roller-bearing locomotive. The nozzle usually has six thin triangular openings, extending to the center. Width across the top of the nozzle may be as much as 16 in. In this type of nozzle the area of opening may be 40% greater than that of the usual circular nozzle, with no decrease in draft but with considerably lower back-pressure. The decrease in back-pressure gives a greater drawbar pull, but shows no gain in engine efficiency in ordinary service. Two forms of nozzle are used. One has openings extending to the center, the other has a solid center to which a circular plate is bolted. By varying the diameter of this plate the area of the nozzle opening can be adjusted.

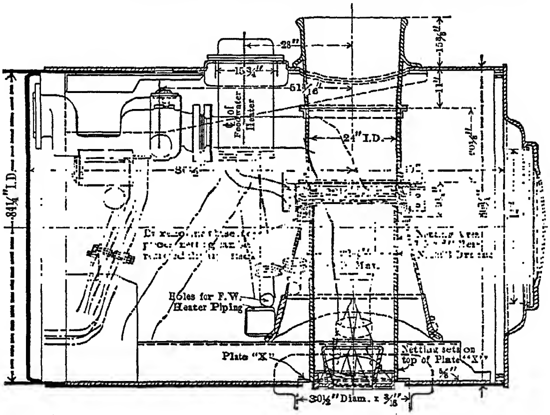

FIG. 32. Front-end Arrangement of Timken Locomotive

LOCOMOTIVE FRAMES (Committee of Am. Ry. Master Mechanics Assoc., 1911). —An approximate formula for the sections of bar frames in either wrought-iron or cast steel is $S = T/C$, where S = sectional area of frame, sq. in.; T = piston thrust = (area of piston $\times$ boiler pressure); C = a constant; see Table 27.

This formula gives sectional areas back of main pedestal, approximately 15% less than similar areas at or ahead of main pedestal. Depth of top rail, ahead of front pedestals, must not be less than that of top rail over front pedestals. The width of frame is made proportional to the weight and power of the locomotive. Very heavy frames, over 5 in. wide, are difficult to make satisfactorily in hammered iron; cast steel seems to be the only suitable material. For locomotives with trailing trucks, a slab spliced to the main frame behind the rear drivers generally is used.

In cross bracing it is recommended that the ties be fastened for the full length of the pedestal jaw, vertically, on the rear pedestal of each driving wheel, or as close an equivalent to this as conditions will permit. The thickness of the bosses on cast-steel cross-tie braces should be not less than $1^1/_2$, preferably 2, times the diameter of the bolt used in fastening.

All bolt heads, where possible, should be next to the castings to insure a full bearing on the bolt. Diameter of frame bolts at thread should be the nearest $^1/_8$ in. to $w/4$, where w = width of frame; the body of the bolt should be made $^1/_{16}$ in. larger. For fastening pedestal jaws together at the bottom, the clip binder or pedestal cap is used more than any other method.

Table 27.—Value of Constant C.

Section at	Sections from Cylinders to Main Pedestals (Including Top Rail Over Main Pedestal)	Back of Main Pedestal
Top of pedestals	2500–2700	2900–3200
Top rail between pedestals	3000–3200	3500–3800
Lower rail between pedestals	4300–4500	5100–5300
Integral single rail at back of cylinder keying lug	1600–1800	....

A cast-steel frame for a 2-10-0 type locomotive built in 1918 for the Penna. Railroad System, has top rail $9\,{}^1/_2$ in. wide and $7\,{}^1/_2$ in. deep between pedestal jaws. Between pedestals the top rail is 7 in. wide, 8 in. deep. The bottom rail is 7 in. wide, 6 in. deep. This frame is 44 ft. 9 in. long; each side weighs 21,225 lb.

VALVE-GEARS.—The Stephenson gear, Fig. 33, is a combination of two eccentrics with a link connecting the extremities of the eccentric rods. By adjusting the position of the link, the valve rod may be put in direct connection with either eccentric or may take intermediate positions between them. The lead decreases as the cut-off is advanced. While it is possible to use the Stephenson as an outside gear, it is not well adapted to such a position, and is generally known as an inside gear.

The Walschaerts gear, Fig. 34, invented by Egide Walschaerts in 1844, allows strengthening the locomotive frame by cross-bracing and is easily accessible from outside the locomotive. It has constant lead and takes its motion from both the crosshead and crank-pin.

The Baker gear, Fig. 35, has a constant lead and variable preadmission.

The Southern gear, Fig. 36, is a modification of the Hackworth type of radial gear. The movement of the valve is obtained from a return crank on the main crank-pin. The eccentric rod is driven from this return crank, and is suspended, near its forward end, from a block which slides in a curved link. The direction of running and point of cut-off are determined by the position of the block in the link.

Types of Valve Gears Used on American Railroads

POPPET OR LIFTING VALVES for steam admission and exhaust are used extensively on locomotives in Europe. The Lentz and Caprotti are used. A Giesl-Gieslingen (*Ry. Mech. Engr.*, May, 1930) states that the Austrian Railways have over 400 locomotives with poppet valves, and have definitely abandoned the piston valve.

The Lentz valves, Fig. 37, are driven by a light form of Walschaerts valve gear which moves a swinging cam shaft to operate the valves. When the engine is drifting the poppet valves automatically are lifted from their seats and open a connection between the back and front of the piston.

The Caprotti valve, Fig. 38, consists of poppet-type double-seated balanced valves operated by revolving cams driven from one of the driving axles by bevel gears and a central drive shaft. The cams are carried in oil-tight boxes, mounted one above each cylinder. The boxes support the cam mechanism and enclose the oil bath in which cams and rollers operate. The valves are light drop forgings of Cr-Ni steel.

STOKERS (From Committee Report of Am. Ry. Assoc.).—Stokers seldom are used on locomotives of tractive force less than 55,000 lb. Consensus of opinion is that stoker-fired locomotives burn more coal than hand-fired, the percentages of difference ranging from 10 to 40 in favor of hand firing. In these percentages, no account is taken of the advantages resulting from uniform steam pressures and better performance over the division.

In the Street stoker, coal is delivered to the base of a chain-conveyor, which elevates it to a point from which it falls by gravity to distributing nozzles in the back head of the boiler. The Duplex stoker carries the coal up by two screws, on either side of the fire-door. The Hanna stoker elevates the coal by one screw to a point above the fire-door. The Standard stoker feeds coal by a vertical screw through the grate at the rear end of the firebox. These stokers use steam jets to scatter or distribute the coal over the grate. The distributing tubes are fixed in the Street, Duplex, and Standard and movable in the Hanna.

In the Elvin stoker, the coal is distributed by two mechanically-operated shovels or swinging arms operating through the fire-door opening. The Crawford is an underfeed stoker. The coal is fed by pushers operating in two retorts extending the whole length of the firebox at grate level. Coal is pushed forward and over the edges of the troughs onto the grate. A scraper conveyor in the tender delivers the coal in front of the first pusher in each retort.

EXHAUST STEAM INJECTOR (Clarence Roberts, *Ry. Mech. Engr.*, May, 1921). —The exhaust steam injector is used for boiler feeding on about 4000 locomotives in England and the British Colonies and to some extent in France. It is claimed, in England, that the device effects an average saving in fuel of 10%. It has a steam inlet nozzle of much larger cross-sectional area than that of a live steam injector of similar capacity, to provide for the larger volume of exhaust steam.

In a later form (see *Engg.*, Jan. 20, 1922), with 1 lb. of exhaust steam pressure, feedwater can be delivered against a boiler pressure of 150 lb. For boiler pressures above 150 lb., supplementary live steam must be used. With 5-lb. exhaust pressure it can deliver against a boiler pressure of 180 lb. The supplementary live steam amounts to less than 2 1/2% of the evaporation of the boiler. The feedwater is delivered at from 200° to 220° F.

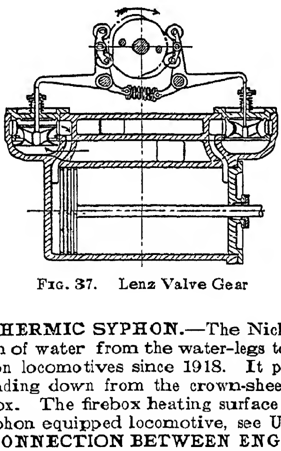

Fig. 37. Lenz Valve Gear

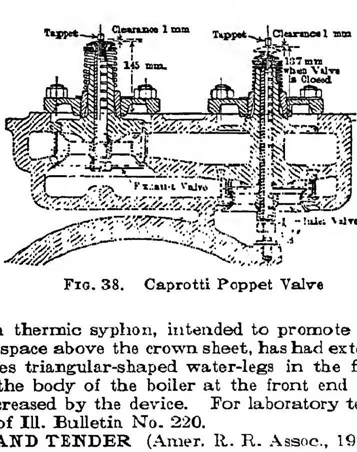

Fig. 38. Caprotti Poppet Valve

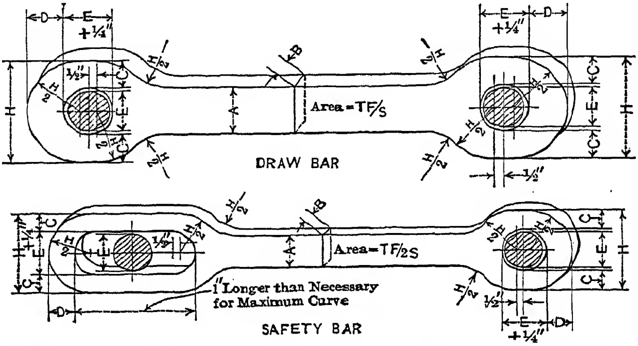
THERMIC SYPHON.—The Nicholson thermic syphon, intended to promote circulation of water from the water-legs to the space above the crown sheet, has had extensive use on locomotives since 1918. It provides triangular-shaped water-legs in the firebox extending down from the crown-sheet to the body of the boiler at the front end of the firebox. The firebox heating surface is increased by the device. For laboratory tests of a syphon equipped locomotive, see Univ. of Ill. Bulletin No. 220.

CONNECTION BETWEEN ENGINE AND TENDER (Amer. R. R. Assoc., 1920).—Drawbars between engine and tender should be straight throughout their full length. Working stress, based on the normal tractive effort of the locomotive, should not exceed 4500 lb. per sq. in.; factor of safety should be not less than 10. If a central safety bar is used, the same limit of stress and safety factor as in the drawbar should be required. A simple formula for designing drawbars and pins is $A = TF/S$, where A = area through body of bar, sq. in.; T = tractive force, lb.; F = factor of safety $\geqq 10$; $S = 45{,}000$ = tensile strength of wrought iron, lb. per sq. in.

Area of each drawbar pin or safety-bar pin = 75% of area through body of bar. The area of the pin is based on the cross-section of a straight bar without bends or offsets and with a depth of pocket not more than 1 in. greater than the thickness of the bar. An offset or bent bar must be of greater cross-section than a straight bar, but it is not necessary to increase the size of pin accordingly. Fig. 39 is a diagram of a satisfactory general form of drawbar. Table 28 gives dimensions of drawbars for various tractive forces. Material in drawbars, safety bars, safety chains and their pins should be refined

wrought iron of ultimate tensile strength not less than 45,000 lb. per sq. in. The use of steel in any of these parts is not recommended.

Safety bars are considered more satisfactory than safety chains for locomotives of 45,000 lb. tractive force, or over. A central safety bar, located immediately beneath the drawbar, is recommended for new locomotives. When a safety bar (at side of drawbar) must be used, Fig. 39 and Table 29 may be used in determining the principal dimensions.



A = Width of Body of Bar
B = Depth of Body of Bar

F = Factor of Safety
H = E + 1/2 + 2C
T = Tractive Force
S = Fiber Stress

FIG. 39. Safety and Draw Bars

A drawbar or safety-bar pin should be considered as a beam fixed at both ends, with a load equal to the rated tractive force of the locomotive. For the condition of bending, $M = WL/8$, and $Z = 0.98\,d^3$. $S = M/Z = (WL/8)/0.98\,d^3 = WL/0.82\,d^3$ or $d = \sqrt[3]{WL/0.82\,S}$, where S = tensile stress, lb. per sq. in.; M = bending moment; W = trac-

tive force, lb.; L = depth of pocket, in.; Z = moment of resistance; d = diameter of pin, in. Assuming a working stress of 4500 lb. per sq. in., and allowing $^1/_8$ in. on the diameter of the pin for wear, $d = \sqrt[3]{WL/3600} + {}^1/_8$ in. (formula for bending). For the condition of shear, $F = W \times (L - H)/L$, and $S_1 = 0.7854\, d^2$, where S_1 = shearing stress, lb. per sq. in.; F = maximum shearing load, lb. per sq. in.; H = $^1/_2$ depth of bar eye, in. A shearing stress usually is taken as (0.8 × tensile stress) when considering wrought-iron or steel. Then

$$\sqrt{\frac{W \times (L - H)/L}{0.8 \times 0.8 \times 4500}} + {}^1/_8 \text{ in.} \quad \text{(Formula for shear)}$$

Calculations should be made both for shear and bending and the maximum figure taken as the diameter of the pin.

ROLLER BEARINGS FOR LOCOMOTIVES.—The first application of roller bearings on the driving axles of a large locomotive, and their performance in service are described by T. V. Buckwalter. See *Trans.* A.S.M.E., RR-56-1, 1934. The 4–8–4 locomotive, Timken No. 1111, was built in 1930. Roller bearings were used on all axles and also on the crank-shaft and idler gear of the booster. It was built as large and powerful as the clearance limits of the principal U S. railroads would allow. Rated tractive force at starting is 63,700 lb.; boiler pressure, 250 lb.; cylinder diam. and stroke, 27 × 30 in.; driving wheel diam., 73 in.; weight on each driving axle, 66,000 lb. The roller bearings on the driving axles have no adjustable mechanism. Forces due to piston thrust are transmitted and absorbed in a complete train of moving parts of hardened steel, comprising pedestal liner, trunnion guide, hardened wear plates on bearing housing, inner and outer races of the bearing together with the rolls. Completely housing the driving axles and the use of bearings to restrain the axle on a complete circle, eliminates pounding while under steam and while coasting. In 1932, after two years in freight and passenger service on a number of railroads throughout the U. S., 120,000 miles were completed without developing roller bearing troubles of any kind. A study of the bearings then indicated that wheel bearings, excepting driver cones, should have a life expectation of 1,000,000 miles and the driver cones 500,000 miles. Driving and truck axles are lubricated by immersing the bearings in an oil bath, whose level is approximately $^1/_2$ in. below the enclosure level. The lubricant was changed but three times in the two years of operation and little lubrication was added between changes. Thrust reactions due to curvature of track or flange thrusts are taken on the roller bearing surfaces of the tapered bearings. No provision, such as hub liners, for side thrust need be made.

The normal temperature rise of the bearings varied from 15° F. on the engine truck to 40° to 50° on the tender. On the driver bearings it is 15 to 20° above atmosphere. In zero weather service, frost normally adhered to bearing housings and ends of axles. The approximate cost of roller bearing equipment, including bearings and housings and application parts for the 4–8–4 locomotive, not including tender, was $8,000.

LOCOMOTIVE TENDERS.—(Paul T. Warner, *Baldwin Locomotives*, Oct., 1932). Up to 1924, tender frame and tank were made separate, the frame acting as a carriage. With high-capacity tenders, the frame is a substantial steel casting united to the tank to prevent weaving and buckling. Tender frames now are constructed of the water bottom type in a single steel casting to which the tank is riveted or welded. Some tenders are welded throughout. The water capacity of tenders ranges from 18,000 to 25,000 gal., with corresponding fuel capacities ranging from 25 to 30 tons of coal or up to 6,000 gal. of oil. The high-capacity tender usually is carried on two 6-wheeled equalized pedestal trucks. The truck frame is a one-piece steel casting carrying a bolster suspended on swing links. Clasp brakes with shoes on front and back of each wheel are used. Tenders with water capacities from 15,000 to 25,000 gal., when loaded, have weights as follows, in percentage of total locomotive weight: Fast passenger locomotive (4–6–4), 80%; fast freight and passenger (4–8–2, 2–8–4, and 4–8–4), 78%; freight (2–10–2 and 2–10–4), 76%; freight, articulated types, 55%.

COUNTERBALANCING OF LOCOMOTIVES (Recommended Practice Am. Ry. Assoc., 1931).—The following diagrams and formulas illustrate the method recommended for calculating the weight and position of counterbalance to fully balance the out-of-plane action of the revolving weights. Cross balancing of coupled drivers is not considered.

Considering the main driver only, two counterweights are required to completely balance forces set up by revolving overhanging weights, one in the same wheel as the crank-pin, and one in the opposite wheel. Consider the moments produced by the various weights acting at their respective distances from a reference plane through the counterbalance center of the opposite wheel, as shown in Fig. 40. The counterweight required

in the adjacent wheel directly opposite the crank-pin hub and acting at crank-pin radius is

$$W_c = \{(W_1 A + W_2 B + W_3 C + W_4 D)/2B\} + W_t/2$$

where A, B, C, D, E, all in inches, are as in Fig. 40. W_1 = weight of crank-pin hub; W_2 = weight of part of side rod; W_3 = weight of back end of main rod; W_4 = weight of eccentric crank; W_t = total revolving weights = $W_1 + W_2 + W_3 + W_4$. All weights are in pounds and include the included part of the crank-pin.

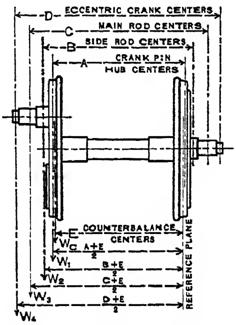

Fig. 40. Counterbalancing

The resulting cross-force F, Fig. 41a, acting in the plane of the counterbalance of the opposite wheel, is balanced in the opposite wheel by a counterweight $(W_c - W_t)$ at crank-pin radius. As the cranks in the wheels are set 90° apart, to combine the counterweight necessary to balance this cross-force with the counterweight opposite the crank-pin, it is necessary to set the final counterweight at an angle θ to the line through the crank and axle centers.

$\theta = \tan^{-1}(W_c - W_t)/W_c$, and the amount of counterweight at angle θ is $\sqrt{W_c^2 + (W_c - W_t)^2}$. If the right crank leads the left, the counterbalance in the right wheel must be advanced through angle θ and set back the same amount in the left wheel. If the left crank leads the right, the reverse is true.

Amount of final counterbalance $= r\sqrt{W_c^2 + (W_c - W_t)^2}/R$, where R = distance from center of gravity of final counterbalance to axle center, in.; r = crank radius, in.

The balancing of 50% of the reciprocating weights is recommended. If W_x = total reciprocating weight, the percentage of reciprocating weight actually balanced is $100\{(W_x/2) - (W_c - W_t)\}/W_x$. The value $(W_c - W_t)$ is the deficiency in revolving balance which must be deducted from reciprocating balance, as the revolving weights first must be satisfied.

Example.—Two-cylinder locomotive, 2–8–2 type; cylinder, 28 in. diam., 30 in. stroke; driver diam., 69 in.; weight on drivers, 257,000 lb.; weight of locomotive, less tender, 376,000 lb. Weights of parts, lb., including included part of crank-pins and bushings: W_3, back end of main rod, 964; W_4, eccentric crank, 153; W_2, side rod at main wheel, 718; W_1, crank-pin hub, 395; side rod, crank-pin and hub on intermediate driver, 730; side-rod, crank-pin and hub, 1st and 4th drivers, 400; W_x, reciprocating parts, including piston, cross-head, wrist-pin, union link and front end of main rod, 1888; W_t, total revolving weight, 2230. Dimensions, in.; C, cylinder centers, 92; B, side-rod centers, 76 3/4; D, eccentric crank centers, 104 3/4; A, crank-pin hub centers, 63 1/2; B, counterbalance centers, 63; R, radius of center of gravity of counterbalance, 15 1/2; r, radius of crank-pin, 15. Right crank leading, 90°.

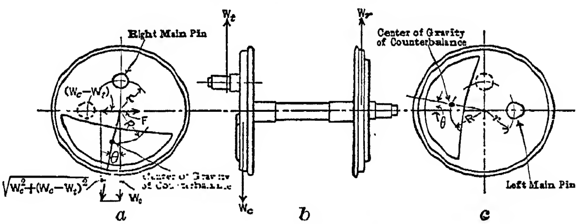

Fig. 41. Counterbalancing

$$W_c = \{(W_1A + W_2B + W_3C + W_4D)/2E\} + W_t/2$$
$$= [\{(395 \times 63\ 1/2) + (718 \times 76\ 3/4) + (964 \times 92) + (153 \times 104\ 3/4)\}/(2 \times 63)] + (2230/2)$$
$$= 2582 \text{ lb.}$$

$$\theta = \tan^{-1}(W_c - W_t)/W_c = (2582 - 2230)/2582 = 0.13632 = 7°46'.$$

Counterweight crank-pin radius $= \sqrt{W_c^2 + (W_c - W_t)^2} = \sqrt{2582^2 + 352^2} = 2606$ lb. Final counterbalance required to balance revolving parts

$$= r\sqrt{W_c^2 - (W_c - W_t)^2}/R = (15 \times 2606)/15\ 1/2 = 2522 \text{ lb.}$$

Percentage of reciprocating balance

$$= 100\{(W_x/2) - (W_c - W_t)\}/W_x = 100\{(1888/2) - 352\}/1888 = 31.4\%,$$

which should be equally distributed among the drivers.

Rules for counterbalancing, adopted by different locomotive builders, are quoted in a paper by Prof. Lanza (*Trans.*, A.S.M.E., x, 302). See also *Trans.*, A.S.M.E., vol. xvi, 305; and *Trans.* Am. Ry. Master Mechanics Assoc., 1897. W. E. Dalby's book Balancing of Engines (Longmans, Green & Co., 1902) contains a very full discussion of this subject. See also Henderson's Locomotive

Operation (*The Ry. Age*, 1904), and Balancing of Locomotives, S. H. Jenkinson, *New Zealand Jour. of Science and Technology*, Jan., 1919. The Balancing and Dynamic Rail Pressure of Locomotives, R. Eksergian, *Trans.* A.S.M.E., RR-51–5, May-Aug., 1929. Lawford H. Fry (Locomotive Counterbalancing, *Trans.* A.S.M.E., RR-56-2, June, 1934) describes a detailed method of cross-balancing, modifying and extending the Am. Ry. Assoc. method given above. See also The Balancing of Three-cylinder Locomotives, F. L. Baxter, *The Engr.*, July 26, 1935.

LOCOMOTIVE WHEEL BALANCING MACHINE.—The Great Western Ry. (England) driving wheel balancing machine comprises a pair of bearings, each supported on four springs, so arranged that the bearing floats with the axle if the wheels are out of balance when spun. A 35-Hp. motor drives the wheels through an extensible shaft with a Hooke joint at each end. A tachometer indicates the speed in m.p.h. For each type of wheel, the calculated revolving and reciprocating masses to be balanced are represented by weights attached to the crank-pins. For inside-cylinder engines, the weights are split and strapped to the crank-pin. To obtain correct results, the weights representing that portion of the reciprocating masses to be balanced should revolve in the plane in which these masses reciprocate. For coupled wheels, the weights representing reciprocating masses are brought into the plane of the connecting-rod, piston, crosshead, etc., by temporary extensions on the crank-pins.

7. POWER BRAKES

The following notes are abstracted from a paper by L. K. Sillcox (*Trans.* A.S.M.E., 1928).

THE AIR BRAKE consists of: Air pump or compressor and main reservoir on the locomotive; engineman's brake valve for controlling brake operations; brake pipe or continuous pipe running throughout the train, connected between cars by flexible hose, for air supply and brake control; triple valve located on each car to charge, apply and release the brakes automatically in response to changes in brake-pipe pressure; auxiliary reservoir on each car; brake cylinder on each car, whose piston is connected, through suitable levers, to the brake shoes.

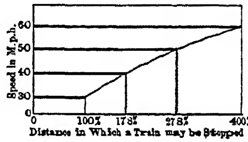

FIG. 42. Comparative Stopping Distances of Train from Various Speeds

Passenger-car brake refinements are: A supplementary reservoir under each car to give high brake-cylinder pressure in emergency application; graduated release, allowing brake-cylinder pressure to be exhausted in steps; quick recharge of auxiliary reservoirs; modifications in valve structure to increase certainty of quick emergency action when desired without possibility of undesired quick action; quick action emergency if brake-pipe pressure falls below a predetermined point; increased certainty and flexibility of brake application and release in service operation.

Freight-car brake refinements for long trains are: Quick-service feature, to make brakes in ordinary service braking much more prompt and positive in application; uniform or restricted recharge feature, to enable auxiliary reservoirs on head and rear ends of long trains to recharge in nearly the same time; uniform or retarded release feature to more uniformly exhaust brake-cylinder pressure on head and rear ends of long trains.

LAWS GOVERNING RETARDATION.—Let A, a, = acceleration, mi. per hr., and ft. per sec., respectively; e = overall efficiency of foundation brake rigging; F, F_1 = retarding or accelerating force, lb. per ton; f = average coefficient of brake shoe friction; g = acceleration due to gravity = 32.2; m = mass = w/g; P = braking effort, lb.; R_c = curve resistance, lb.; R_g = grade resistance, lb.; R_t = train resistance on level tangent, lb.; S = total distance covered, ft.; S_1 = distance, ft., to reduce speed from V_2 to V_1; S_2 = distance traversed, ft., before braking force is effective; t = time, sec.; w = weight, lb.

The fundamental formula is force $= ma = aw/g = 2000\,a/g$ per ton weight;

$a = A \times (5280/3600) = 1.467\,A = (V_2 - V_1)/t.$

$S = \{(V_1 + V_2)/2\}1.467\,t,$ and $t = S/\{(V_1 + V_2)/2\}1.467.$

$A = \{(V_2 - V_1)(V_1 + V_2)/2\,S\} \times 1.467^2 = 1.467^2\,(V_2^2 - V_1^2)/2\,S.$

$F = (2000/32.2)\{(V_2^2 - V_1^2)/2\,S\} \times 1.467 = 67\,(V_2^2 - V_1^2)/S = Pef + R_t + R_c + R_g.$

In train operation F may be increased 5% to provide force for rotational acceleration, whence $F_1 = 70\,(V_2^2 - V_1^2)/S.$

$$S_2 = 1.467\,V_2 t, \text{ and } S_1 + S_2 = 70\{(V_2^2 - V_1^2)/F\} + 1.467\,V_2 t.$$

In stopping a train, V_2 = speed at which brake is applied, and $V_1 = 0$. Then $S = S_1 + S_2 = (70\,V_2^2/F) + 1.467\,V_2\,t.$

Assuming that braking effort is instantaneously effective, $t = 0$ in the above equation,

and $S = 70\,V_2^2/F$. The distance in which a train may be stopped with a constant retarding force F, thus varies with the square of the initial speed. See Fig. 42.

The distance S may be decreased by increasing the retarding force F, or decreasing the time t in which braking effort becomes effective. The actual braking force F obtainable at the wheel rim is reduced by low efficiency of foundation rigging, e, and the uncertain and varying coefficient of friction, f, between shoe and wheel. See Table 30 for values of factor ef. The maximum value obtainable of $F = Pef$ is 180% × 0.141; the minimum value is 125% × 0.70 = 0.0875. To prevent wheel sliding, maximum braking coefficient must not exceed adhesion between wheel and rail. Fig. 43 shows stopping distances with 100% retardation. Distances in practice are about 4 times those shown in Fig. 43, allowing an adhesion factor of 25%.

FIG. 43. Stopping Distances with 100% Retardation

TYPES OF FOUNDATION BRAKE RIGGING are shown in Fig. 44. Let F = force of brake cylinder-pressure × piston area; B = brake shoe pressure per pair of shoes; N = number of pairs of brake shoes per car, whence NB = total brake shoe pressure; R = total lever ratio = NB/F; W = weight of car empty; P = braking ratio = NB/W; a, b, c, etc. = length of lever arms as shown in Fig. 44. Then for the various arrangements of rigging, the following relations hold:

Arrangement A:

$B = F\{a(c + d)/(bd)\}$

$N = 4$

$R = 4\{a(c + d)/bd\}$

$P = (4F/W)\{a(c + b)/bd\}$

Arrangement B:

$B = Fa/b$

$N = 6$

$R = 6\,a/b$

$P = (6\,F/$

Arrangement C:

$\{$

$N = 6$

$R = 6\,ac(e + f)/bf(c + d)$

$P = (6\,F/W)\{ac(e + f)/bf(c + d)\}$

Arrangement D:

$\{$

$= 4$, or 6

$+ f)/bdf\}$.

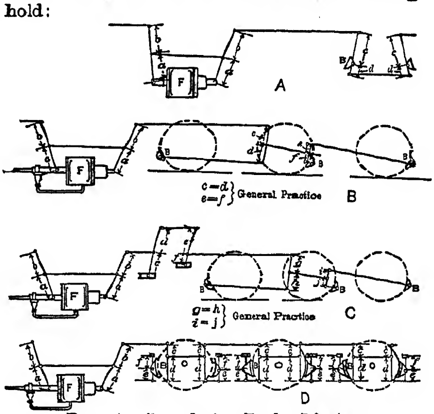

FIG. 44. Foundation Brake Riggings

BRAKING RATIOS, the total brake shoe pressure against the wheels of a locomotive or car divided by the weight, are given by S. G. Downs (*Ry. Mech. Engr.*, May, 1930). Steam railway passenger-train cars for service operation are braked at a ratio of 90% of the light weight; for emergency operation, 150%. The standard freight car for service operation is braked at 60% of its light weight; for emergency operation, 65%. Electrically-propelled cars in rapid transit service normally are braked at 100% of the light weight; for emergency, 140%. Single-unit street cars are braked at ratios of 100 to 120%.

Table 30.—Efficiency Factors (Values of *ef*)

Speed, m.p.h.	Braking force, percent	Clasp brake		Single shoe	
		Plain	Flanged	Plain	Flanged
30	125	0.141	0.169	0.108	0.112
	150	.129	.154	.099	.103
	180	.118	.141	.090	.094
60	125	.103	.122	.074	.090
	150	.094	.112	.068	.082
	180	.086	.102	.062	.075
80	125	.092	.109	.070	.074
	150	.084	.100	.064	.068
	180	.077	.092	.059	.062

An extreme variation in gross to tare ratio on freight cars is found on the coal cars of the Virginian R. R., weighing 75,000 lb. with a capacity of 120 tons. They are equipped with a special form of empty-and-load brake which involves the use of three brake cylinders. The braking ratio is 40%, empty and loaded.

The clasp form of brake is most desirable for heavy cars, as it permits the heavy brake work to be distributed over two shoes per wheel, thereby keeping shoe temperature low with resultant higher coefficient of friction. It also eliminates longitudinal thrust on the journal bearings and the tendency to force the journal brass out of its normal position.

LOCOMOTIVE STANDARDS AND RECOMMENDED PRACTICE.—A manual issued by the Am. Ry. Assoc., 1922, gives specifications for materials for locomotives. Standards and recommended practice for parts, as wheels, tires, axles, etc., rules for inspection and testing of locomotive boilers and rules for fuel economy on locomotives are given. See also specifications of Am. Soc. Test. Matl.

8. LOCOMOTIVE PERFORMANCE

LOCOMOTIVE TESTS OF THE PENNA. R. R.—Eight locomotives were tested in the dynamometer testing plant built by the P. R. R. Co. at the St. Louis Exposition in 1903. The principal results obtained are shown in Table 31.

The conclusions derived are: The coal used in these tests was a semi-bituminous, containing 16.25% volatile combustible, 7.00% ash and 0.90% moisture. The maximum boiler capacity ranged from 8 1/2 to more than 16 lb. of water evaporated per hour per sq. ft. of heating surface. Little or no advantage was found in the use of Serve or ribbed tubes. The boiler efficiency decreases as the rate of power developed increases. Furnace losses due to excess air are no greater with large grates properly fired than with smaller ones. The boilers with small grates were inferior in capacity to those with large grates. No special advantage is derived from large firebox heating-surface. The tube heating-surface is effective in absorbing heat not taken up by the firebox. The steam consumption of simple locomotives operating at speeds and cut-offs commonly used ranges from 23.4 and 28.3 lb. per I.Hp.-hour; of compound locomotives, between 18.6 and 27 lb.; with superheating the minimum steam consumption was reduced to 16.6 lb. of superheated steam. The simple engine used 40% more steam than the compound at 40 r.p.m., 27% more at 80 r.p.m. and only 7% more at 160 r.p.m.

The lowest figures for dry coal consumed per dynamometer Hp. were approximately:

		40	80	160	240
Revs. per min		40	80	160	240
Compound freight engine	lb. (		2.25	3.25	....
	dyn		800	800	....
Compound passenger engine	lb. coal		2.8	2.3	3.0
	dynamometer Hp.		600	900	1000

The frictional resistance of the engines showed an extreme variation ranging from 6 to

Table 31.—Locomotive Tests at St. Louis Exposition

Engine Performance

		1.8	6.2–7.7		

38% of the indicated horsepower. Frictional losses increased rapidly at speeds in excess of 160 r.p.m. It appears that machine friction is closely related to lubrication. With oil lubrication a stress at the drawbar of approximately 500 lb. is required to overcome the friction of each coupled axle, while with grease the required force is from 800 to 1100 lb.

The Penna. R. R. later removed the testing plant to Altoona and continued to operate it. Some test results with freight and passenger locomotives are given in Table 32.

ECONOMY OF HIGH PRESSURES (*Bull.* No. 26, Univ. of Ill. Expt. Station).—Tests of a locomotive with cylinders 16 × 24 in. at the Purdue University locomotive testing plant gave results as follows:

Boiler pressure, lb. per sq. in.......	120	140	160	180	200	220	240
Steam per I.Hp.-hour, lb..........	29.1	27.7	26.6	26	25.5	25.1	24.7
Coal per I.Hp.-hour, lb...........	4	3.77	3.59	3.50	3.43	3.37	3.31

In the same tests boiler economy at different rates of driving and different pressures was determined, the results leading to the formula $E = 11.305 - 0.221\ H$; E = lb. of water evaporated from and at 212° F. per lb. of Youghiogheny coal; H = equivalent evaporation per sq. ft. of heating surface per hour, with an average error not exceeding 2.1% for any pressure.

LOCOMOTIVE SUPERHEATER TESTS ON PENNA. R.R. LOCOMOTIVE (C. D. Young, *Proc.* Franklin Inst., 1914).—A Schmidt fire tube superheater, or an altered form of it, was used in all the tests. The normal superheater consisted of tubes arranged in 32 groups in large flues in the boiler. (See Fig. 45.) Each superheater element comprised four seamless steel tubes, outside diam. 1 7/16 in., 0.148 in. thick. To obtain a range of superheat, superheaters of 1/4-, 1/2-, 3/4- and full-length, and short returns at the header were used. The shortened superheaters were not expected to develop an arrangement suitable or desirable for use in regular service; their purpose was to obtain wide variations in superheat.

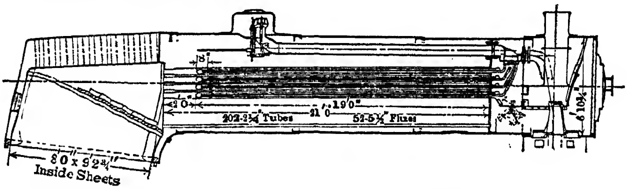

Fig. 45. Locomotive Boiler Arrangement for Superheater Test

Considering only the economy in steam consumption resulting from superheat, Figs. 46 and 47 give authentic data on economy due to superheat, unobscured by other variables.

Fig. 46 indicates that for every increase in superheat at every cut-off there is a saving in steam. At 15% cut-off, at the speed of these tests (240 r.p.m.), for every 20° rise in superheat the water is reduced 1 lb. At 50% cut-off this increases to a requirement of about 40° rise for the same reduction in water rate. With a cut-off of 15% and a superheat of about 70° a water rate of 19 lb. per I.Hp.-hr. can be obtained, while if the cut-off is extended to 50% at the same speed, the superheat must be increased to 300° if the water rate is to remain 19 lb. The importance of the length of cut-off is apparent.

Table 32.—Penna. R. R. Locomotive Tests

Engine Performance

Maximum I.Hp.: 2–10–2 freight locomotive, 3486; 4–6–2– passenger locomotive, 3184

Using Superheated Steam	Freight, Limited Cut-off		Passenger

Coal used—Penna. bituminous: Volatile matter, 34.9%; ash, 7.7%; moisture, 1.2%; calorific value, 14,467 B.t.u. per lb. Coal was hand-fired.

EVAPORATION IN LOCOMOTIVE BOILERS.—Table 33 from Merriman's Civil Engineer's Handbook, gives the average evaporation in locomotive boilers per pound of coal from feedwater at 60° F. into steam at 200 lb. per sq. in. In bad-water districts, 10% should be deducted from the figures in the table for each $^1/_{16}$ in. of accumulated scale, and 1% for each grain per gallon of foaming salts. Heating-surface used in computing Table 33 includes only water-evaporating surface, and does not include superheater surface.

DISTRIBUTION OF HEAT OF COMBUSTION IN LOCOMOTIVE BOILERS.—J. T. Anthony (*Jour.* A.S.M.E., Sept., 1917) states that the firebox furnishes only 5 to 10% of the total heating-surface, but is responsible for 25 to 50% of the total evaporation, due to the fact that its heating-surfaces are ideally disposed for the absorption of radiant heat. It is common practice to design locomotives to deliver their rated tractive effort when burning 120 lb. of coal per sq. ft. of grate per hour. Of the heat contained in the coal, 53% is absorbed by the boiler and 47% lost. Of the heat lost, 27% is chargeable to the furnace,   , to the heating-surfaces, and 14% is unavoidably lost in the front end gases.

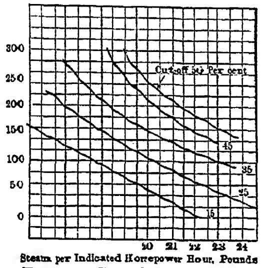

FIG. 46. Superheat and Steam Consumption, Simple Locomotive

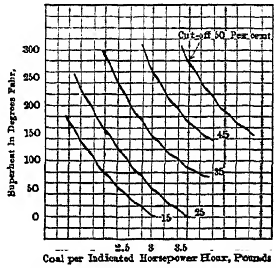

FIG. 47. Superheat and Coal Consumption, Simple Locomotive

BRICK ARCH TESTS.—Tests of a Mikado type locomotive made by the Penna. R. R. locomotive testing plant at Altoona in 1916, shows the value of the brick arch in the firebox. The arch equipment was of the Security sectional type, supported on water tubes, Fig. 48. A high-volatile bituminous coal, sized by being passed over a screen, and hand-fired, was used. The advantages which could be ascribed to the arch were: Maximum evaporation when using high-volatile coal was increased 15.5%; a lower smoke density was observed; increased evaporation per pound of coal, which for ordinary rates of working represents an economy in coal of from 6 to 8%; higher boiler efficiency at all rates of evaporation was obtained.

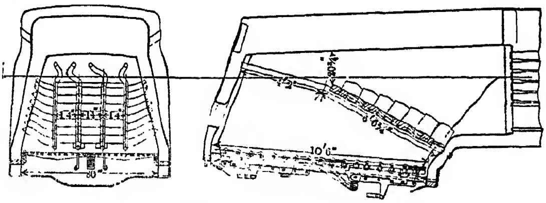

FIG. 48. Firebrick Arch Locomotive Furnace

LOCOMOTIVE BOOSTER TESTS (*Ry. Age*, Sept. 16, 1922).—Tests of a booster on a stationary testing plant, with steam slightly superheated, show that with 200 lb. steam pressure, a maximum drawbar pull of about 11,000 lb. can be obtained with trailing wheels 45 in. diameter. This pull decreases to about 10,500 lb. at 5 m.p.h. and to about 9300 lb. at 10 m.p.h. The mechanical efficiency was between 90 and 95%. The maximum B.Hp. of the booster engine was 316 at 17.8 m.p.h., and the steam consumption ranged between 6000 lb. at 5 m.p.h. and 15,000 lb. at 20 m.p.h., or between 40.8 lb. and 43.4 lb. per B.Hp.-hr. The booster had a 2-cylinder double-acting engine, with cylinders 10 × 12 in. and cranks set at 90°. The gear ratio between engine shaft and trailer axle was 14 to 36.

LOCOMOTIVE FEEDWATER HEATING (Thomas C. McBride, *Trans.* A.S.M.E., xlii, p. 307, 1920).—Waste heat to heat the feedwater may be obtained from the waste gases in the smokebox or stack and the exhaust steam. Waste gas heaters cannot be used with cold water, as accumulations of condensation and soot affects their efficiency. The exhaust-steam heater may be either: 1. Open or injection; the exhaust steam comes in direct contact with the cold feedwater, and water condensed from the exhaust steam is mixed with the feedwater; 2 Closed or surface; heat from the exhaust steam passes to the feedwater through thin sheets of metal, generally thin brass tubes. Tables 34 to 36 give data regarding the performance of locomotive feedwater heaters.

A report of a committee of the Am. R. R. Assoc. (1920) on feedwater heaters for locomotives, states that a test of a Worthington open-type heater on a 2–8–2 locomotive on the Penna. Railroad showed that feedwater entering the heater at temperatures between 39° and 41° F. is heated to between 178° and 211° F.

Table 37 shows the weight and heat of the steam used by the engines and boiler feed pump, and the heat recovered by the heater. The exhaust steam drawn from the exhaust passages and condensed in the heater, weighed from 1735 to 7722 lb. per hr., or from 12 to 15% of the feedwater used by the boiler. The heater locomotive was operated at rates of boiler feeding of from 14,480 to 52,475 lb. per hr., the latter rate being close to the possible maximum with this locomotive. A closed-type heater tested on the same 2–8–2 locomotive gave typical test results as shown in Table 38. The heater contained 192 brass tubes, 5/8 in. outside diam., 46 in. long. Total heating-surface was 121 sq. ft.

In tests with the closed heaters the condensed exhaust steam was not recovered. Later designs return this condensation to the tender tank.

WEIGHT OF EXHAUST STEAM CONDENSED.—With the open-type feedwater heater, the exhaust steam used to heat the water is condensed and becomes a part of the boiler feedwater supply. While it would be possible to weigh this condensation by

drawing off the water from the heater and then returning it, this method would be impracticable, as heat would be lost and the regular action of the heater interfered with. Instead of weighing this condensation, its weight is calculated from the observed temperature of the steam and water by the formula $S = \{W(h_1 - h_0)\} \div (H - h_1)$, where S = exhaust steam condensed and added to feedwater, lb. per hr.; W = weight of feedwater from tank, lb. per hr. (deducting losses); h_0 = heat in feedwater from tank, B.t.u. per lb. (cold water); h_1 = heat in feedwater from heater, B.t.u. per lb. (hot water); H = heat in exhaust steam, B.t.u. per lb. (at heater). Weight of steam condensed as found by this formula, is added to weight of feedwater from tank; total is water fed to boiler.

PISTON VALVE LEAKAGE. (*Engg.* July 4, 1919).—In an investigation by the Penna. R. R. of the leakage of locomotive piston valves, a full size valve was operated under 200 lb. per sq. in. pressure with saturated and superheated steam. Results were as follows: A 12-in. diam. valve with two $1/2 \times 5/8$-in. rings at each end, operated in a plain bushing with saturated steam, leaked from 171 to 183 lb. per hr. at each end. With steam superheated 100° F., the leakage ranged from 194 to 210 lb.; at 200° F. superheat, from 181 to 197 lb.; at 300° F. superheat, from 122 to 132 lb. Length of valve travel (2 to 6 in.) and speed (strokes per min.) had little effect upon leakage. No difference in leakage was found between the step and diagonal form of ring joint. Rings with $1/16$ in. side clearance showed somewhat less leakage than the same rings closely fitted in the grooves. The steam pressure in the ring grooves back of the rings was found to be the same as the steam chest pressure when the valve was at rest. Pressure did not fall under the first or steam side ring, when in motion, but under the second or exhaust side ring, the pressure ranged from 50% to 80% of steam chest pressure.

CONTROL LOCOMOTIVES FOR ROAD TESTS (R. P. Wagner, *Trans.* A.S.M.E. RR–51–4, 1929).—Instead of a train, a specially arranged locomotive under steam is coupled to the rear end of the dynamometer car. The valve gear is placed in full reverse; the exhaust nozzle is shut off to prevent drawing in gases from the front end. A port in the exhaust pipe admits air from outside, which is compressed in the cylinders and blown off at variable pressure through a hand-controlled valve. To protect the cylinders from heating beyond 850°, hot water is admitted into the exhaust (or in this case, inlet) pipe. This water, which is ready for evaporation, rapidly absorbs the heat developed during the compressing process and prevents the temperature rising.

The engineer of the brake locomotive adjusts his engine to maintain the speed under all circumstances. The locomotive under test maintains an even drawbar pull. The weight of the imaginary train thus is adjusted in accordance with the varying grades. If the dynamometer car permits indicating, in addition to reading, of drawbar pull, speed, work performed, all temperatures by automatic resistance thermometers, together with a continuous analysis of combustion gases, this method probably is as efficient as that of a stationary testing plant.

POWDERED FUEL FOR LOCOMOTIVES.—Attempts to fire locomotives with powdered fuel have met with difficulties which have prevented its extensive use, but a successful application in Germany is described by R. Roosen (*Trans.* A.S.M.E. RR–52–8, 1930). The burner consisted of a hollow truncated cone, Fig. 49, whose large end was closed by a spray plate perforated with about 1900 nozzle-shaped holes. At the smaller end is a device to mix the coal dust and air. Two of these burners were placed below the firebox back-head on a 3-cylinder 2–8–2 German State Railways locomotive (Fig. 50) with 2100 sq. ft. heating-surface, and 42 sq. ft. grate area. Each spray plate injects about 3300 lb. of fuel per hour. An intensity of combustion of 316,000 B.t.u. per hour per cu. ft. of furnace volume was attained. The steam generated was 20.5 lb. per hour per sq. ft. of heating surface.

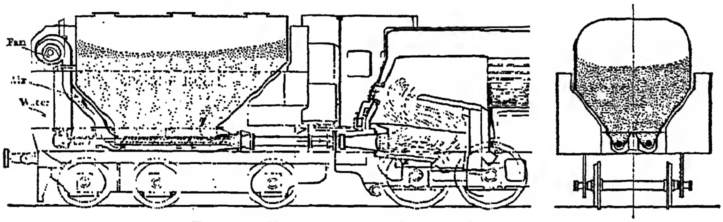

Fig. 50. Layout of Stugg Locomotive

9. TRACKS, GRADES AND CURVES

RAILS USED ON STEAM RAILROADS (C. W. Gennet, Jr., *Ry. Age*, Mar. 15, 1921).—Table 39 and Fig. 51 show the dimensions of the rails used by the principal railroads in the United States in 1921. The abbreviations are: R.E. = Am. Ry. Engg. Assoc.; A.R.A. = Am. Ry. Assoc.; A.S.C.E. = Am. Soc. of Civil Engrs.; P.S. = Pennsylvania System; L.V. = Lehigh Valley; D.L. & W. = Delaware, Lackawanna and Western; C. of N. J. = Central Railroad of New Jersey; C. & N.W. = Chicago & Northwestern; G.N. = Great Northern; A.T. & S.F. = Atchison, Topeka & Santa Fe; C.P.R. = Canadian Pacific Railway; C.N.R. = Canadian National Railway.

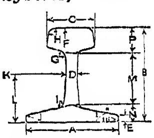

Fig. 51. Rail Sections (See Table 39)

The Penna. R. R. 152-lb. rail described by T. J. Skillman (*Ry. Age*, Aug. 8, 1931) is shown in Fig. 52. It is the heaviest and stiffest rail used on any railway, and was designed to safely sustain an axle load of 100,000 lb. at 100 m.p.h. It is 8 in. high, 6 $^3/_4$ in. base and weighs 152 lb. per yd. The 130-lb. rail, standard since 1916, was designed for axle loads of 80,000 lb. at 80 m.p.h. The 152-lb. rail is 75% stiffer than the 130-lb. rail. Chemical composition is: C, 0.70–0.85; Mn, 0.70–1.00; P, 0.04 max.; Si, 0.15–0.30.

VELOCITY GRADES (Amer. Ry. Master Mech. Assoc. *Proc.*, 1914).—If a ruling grade can be approached at a speed of from 25 to 45 m.p.h., it will be possible to haul heavier trains over the grade than those calculated for a constant speed or dead pull. The formula to be used is $G_m = 3.5 \times (V_1^2 - V_2^2)/L$, where G_m = percent of grade to be deducted from actual grade; V_1 = initial speed, m.p.h.; V_2 = speed at top of grade; L = length of grade, ft. The equivalent grade is found by deducting G_m from the actual grade, and the tonnage rating is calculated for the equivalent grade.

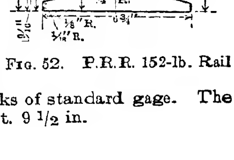

Fig. 52. P.R.R. 152-lb. Rail

GAGE OF TRACK ON CURVES (Am. Ry. Eng. Assoc. Manual, 1915).—Curves of 8° or under should be standard gage. The gage should be widened $^1/_8$ in. for each 2° or fraction thereof over 8°, to a maximum of 4 ft. 9 $^1/_4$ in. for tracks of standard gage. The gage, including widening due to wear, should never exceed 4 ft. 9 $^1/_2$ in.

ELEVATION OF CURVES (Am. Ry. Eng. Assoc. Manual, 1915).—The approximate formula $E = 0.00066\,DS^2$ will give essential theoretically correct elevation for ordinary practice, where E = elevation, in., of the outer rail at gage line; D = degree of curve; S = speed, m.p.h. Ordinarily an elevation of 8 in. should not be exceeded.

CURVES IN RELATION TO WHEEL BASE (*Locomotive Data*, Baldwin Locomotive Works, 1920).—The sharpest curve to which two pairs of flanged wheels will adjust themselves depends upon their distance apart, the diameter of the wheels and the size and shape of the flanges. Assuming the M.C.B. standard for flanges and rails, and that the gage is not widened on the curve, a sufficiently accurate formula for all practical purposes is: $R = (W/2)\sin\alpha$, where R = radius of sharpest curve that can be passed; W = wheel base; α = angle the flanged wheels make with the rails. The value of $\sin\alpha$ for various diameters of wheels is:

Diam. of wheels, in.	20 to 24	25 to 30	31 to 40	41 to 50	51 to 60
$\sin\alpha$	0.117	0.107	0.09	0.08	0.075

When a truck is used, the swing must be sufficient to allow the locomotive to pass the curve. An approximate formula then is $R = WT/2S$, where W = distance from center pin of truck to rear of rigid wheel base; T = distance from center pin of truck to front of rigid wheel base; S = one-half of the total swing of the truck; R = radius of the sharpest curve which can be passed. All dimensions must be in the same unit. Figs. 53 and 54

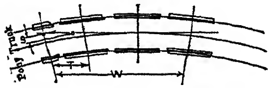

FIG. 53. Two-wheel Truck

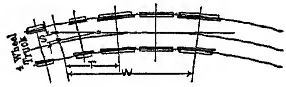

FIG. 54. Four-wheel Truck

show how these dimensions are taken for 2-wheel and 4-wheel trucks. For an extended discussion of this subject, see *Trans.* A.S.M.E., xlii, 1920. Also *Ry. Mech. Engr.*, April and May, 1931.

10. MISCELLANEOUS DATA

According to a publication of the Committee on Public Relations of the Eastern Railroads there were in 1931 on the Class I railroads of the U. S., 55,400 locomotives, 2,200,000 freight cars and 51,750 passenger-cars, operating over 430,000 miles of tracks. Since 1911 the average tractive force of steam locomotives has been increased 62%, to 45,800 lb. The capacity of freight cars has been increased 27%, to 47 tons, in the same period. The average 1931 freight train carried 733 tons of freight in a train of 48 cars, at an average speed of 14.8 m.p.h. In 1920 the fuel required in freight service per 1000 gross ton-miles was 197 lb.; in 1931 it was 137 lb., a decrease of 30%. In the same period the fuel per passenger train-mile has been reduced from 18.8 lb. to 14.5 lb., or 23%.

AIR CONDITIONING.—Air conditioning applied to railway passenger cars means so controlling temperature and moisture of the air that atmospheric conditions in the car are those most suitable for the comfort of passengers. In general practice, temperature only is directly controlled, but there is an incidental precipitation of moisture on the cooling coils of the apparatus, which carries away odors and dust from the air. Provision sometimes is made for adding moisture to the air as needed. Air conditioning requires that the car windows be kept closed. As outside air that is introduced passes through filters, the air in the car is cleaner than when conditioning is not used.

Three general methods of obtaining the necessary refrigeration for air cooling are used:

1. Ice Water Circulating System.—Water is sprayed over ice in a bunker beneath the car floor, or sometimes in the vestibule. The cooled water then is circulated through pipe coils in the upper deck of the car. Air from the car, together with some outside air, is driven by a fan through the cooling coils and discharged into the body of the car.

2. The Mechanical Compressor System uses a closed refrigeration cycle for cooling, as in the ice system. The handling of the air and the cooling coils are the same.

3. The Steam-jet or Water-vapor System.—Refrigeration is produced by spraying water into a partially evacuated, heavily insulated chamber. The sprayed water evaporates and lowers the temperature of the remaining water, which then is circulated in the air-cooling units. Cooling coils and air circulation are the same as in the other systems.

Refrigerants.—The refrigerants used are water vapor in the steam-jet system, and Freon in the compressor systems. A temperature of 50° F. is obtained with water vapor

at a vacuum of 29.637 in. of mercury. Freon (F 12) is an inert gas with a boiling point of −22° F. at atmospheric pressure.

The Main Units of the air conditioning apparatus usually are located beneath the car floor; the air-cooling coils are placed at the top of the car, either at the ends or at the center.

Power for compressor, pumps, air-circulating fans and control, is obtained either directly from the car axle or from an axle-mounted generator and storage battery unit.

The air conditioning apparatus has the following approximate ratings. Water pump motors, 1/4 to 3/4 Hp.; fan motors for air circulation, 1/2 to 1 Hp., depending on whether bulkhead or duct air distribution is used; compressor motors, 5 to 11 1/2 Hp.; axle generators, 7 1/2 to 15 kw.; Storage battery, 400 to 1000 amp.-hr.

Distribution of Air.—Two general systems for distributing the cooled air are in use: 1. The bulkhead system; air is discharged into the car through grilles located near the ceiling, either at one or both ends of the car, or in some installations, at the center. 2. The duct system; air is carried in ducts which have openings designed to distribute the air uniformly throughout the interior of the car.

It is usual to install a steam radiator coil in front of the cooling coil, so that the system can be used as an aid to heating in cold weather and the advantages of filtered, circulated air obtained at all times.

The air handled per car ranges from 1200 to 2400 cu. ft. per min., and the fresh air continuously added from outside may be up to 50% of the air circulated through the car.

WEIGHING PLANTS FOR LOCOMOTIVES (C. C. Bailey, *Ry. Age*, Sept. 3, 1921). —A large scale for weighing locomotives at the Eddystone plant of the Baldwin Locomotive Works has a capacity of 450 tons. The main scale platform is in six sections, each designed to carry a concentrated load of 150,000 lb.; 24 individual wheel scales are mounted on this platform scale, each of 50,000 lb. capacity. The weigh beam of the platform scale is graduated to 895,000 lb. by increments of 5000 lb., with an auxiliary beam of 5000 lb. capacity by increments of 50 lb., giving a total of 900,000 lb. The scale is mounted on a concrete foundation 110 ft. long, 11 ft. wide and 3 ft. deep. Tests of the scale show that the sum of the wheel loads obtained by means of the individual scales varies 0.5% from the total weight recorded by the platform scales.

MILL-TYPE CARS.—A special gondola car is used by several railroads to transport long structural steel shapes. One of these on the Penna. R. R. is 70 ft. 3 in. long over couplings, 65 ft. 6 in. long inside and 7 ft. 7 1/2 in. wide. The sides are 3 ft. 6 in. high. The car weighs 62,000 lb.; normal capacity is 140,000 lb., and load limit 148,000 lb. The cubic capacity is 1738 cu. ft. It is carried on two 4-wheel trucks, each with a wheel base of 5 ft. 8 in.

AUTOMOTIVE VEHICLES

By Ralph A. Richardson

1. GENERAL INFORMATION

Most passenger automobiles, trucks and buses have 4-cycle engines. Some trucks and buses use high-speed oil or Diesel engines. Cylinders vary from 4 to 16 per engine; some buses use two 6- or 8-cylinder engines. Passenger cars in the low price field have 6 or 8 cylinders; the upper price classes have from 8 to 16. A majority of trucks and buses use 6 cylinders. The brake-horsepower (B.Hp.) output ranges from 40 to 200, the engines peaking at 3000 to 4000 r.p.m. Over a period of years the tendency has been to increase power output and engine speed.

PERFORMANCE FACTORS.—Several useful performance factors may be derived if an automobile engine is assumed to be a gas pump, that at a given time has approximately the same output per cubic inch of displacement and the same specific fuel consumption as all other engines. Then from known specifications, factors representing car performance, economy and wear may be determined, by which to compare one car with another.

Engine r.p.m. per Car-mile per Hour (m.p.h.) is useful for comparing the ratio between engine speed and vehicle speed. It is also useful in deriving the other performance factors. The equation is: Engine r.p.m. per m.p.h. $= E_r = (5280 \times R)/(C \times 60)$, where $R =$ rear axle gear ratio; $C =$ rear wheel rolling circumference, ft., $= \pi \times$ tire diam. (approx.). E_r varies between 48 and 58, averaging 53. A high value usually indicates a high-speed engine.

Cubic Feet per Car-mile (Q_c) is an economy factor showing how much mixture the engine pumps per car mile traveled. It assumes all engines to have the same carburetion, breathing capacity and distribution charactertistics, a safe assumption when comparing most automobile engines over a period of a few years. This factor represents gasoline used per mile of car travel. The equation is: $Q_c = (5280\,R/C) \times (D/2)$. $D =$ engine displacement, cu. ft.; R and C are as before. In present (1935) passenger cars, Q_c depends on the size of engine, and varies as follows in the several price fields: Low from 135 to 220; lower medium, from 190 to 250; upper medium, from 230 to 350; high, from 270 to 380. A low value indicates probable low fuel consumption, in miles per gallon. As a rule, small European cars are designed for high economy, and Q_c may be as low as 63. This value was obtained on a Morris Minor Coach of 51.7 cu. in. displacement.

Cubic Feet per Ton-mile, (Q_t) is a performance factor showing the amount of mixture pumped per ton of vehicle moved per mile, and represents the power-weight ratio. It assumed that all engines develop the same brake M.E.P. at the same road speeds. This is sufficiently accurate for purposes of comparison. The equation is

$$Q_t = (5280\,RD/2C) \times (2000/W),$$

where $W =$ car weight, lb., loaded with passengers, gas, oil, water and equipment; R, D and C are as before. In American passenger cars, Q_t ranges from 100 to 135; average, 112. A high value indicates high performance as to acceleration high gear, hill climb and maximum speed. In European small cars, Q_t may be as low as 63, the value for the Morris Minor.

Feet of Piston Travel per Car-mile, T_p, is a factor giving wear in the engine. The equation is $T_p = (5280\,R/C) \times 2\,S$, where $S =$ stroke, ft.; R and C are as before. T_p ranges from 1750 to 2725 for American cars. European cars have values of about the same range.

COEFFICIENT OF FRICTION BETWEEN TIRES AND ROAD SURFACE is the force required to cause tires to slide, divided by normal pressure between tires and road. It has two values: F, when sliding is impending; f, when sliding is under way. See Table 1. If $P_s =$ force required to start sliding, $P_u =$ force required for uniform sliding, $w =$ normal pressure between tire and road, then $F = P_s/w$ and $f = P_u/w$. With hard-packed snow on pavement, F may be from 0.17 to 0.20; f from 0.12 to 0.15. Ice and sleet on pavement reduce F to as low as 0.08, and f to 0.07.

THE RESISTANCE OF MOTOR VEHICLES on level road is made up of rolling resistance and air resistance. Grade resistance is an additional factor on hills. Knowing

total resistance, the horsepower required to propel the vehicle at any speed may be calculated.

Rolling Resistance depends on road surface characteristics, type and condition of tires and friction of wheel bearings. It ranges from 12 to 30 lb. per 1000 lb. of vehicle on smooth roads. An average value for smooth concrete is from 17 to 20 lb. On rough roads, gravel, or dirt, it may be 100 lb. or more. It is fairly constant throughout the speed range.

Air Resistance depends on the aerodynamic characteristics of the body. It varies as (speed)^2, and is, therefore, of great importance at high speed; at speeds above 50 m.p.h., air resistance is the major part of total resistance. Air resistance is directly proportional to the projected frontal area, the shape of the body and (wind velocity)^2. Let R_a = air resistance, lb., K = coefficient of resistance, A = projected frontal area, sq. ft., V = air velocity past body, m.p.h. Then $R_a = KAV^2$. K varies with the shape of the body, being greatest for shapes with sharp corners and large flat areas normal to the wind, and least for streamline shapes. Lay gives the value of K as 0.00155 for a 1930 sedan as found from model tests. A good average for sedans as found by tests on full size bodies is 0.0019 to 0.0020. Material reductions are possible by using large radii for all corners.

Frontal areas range from 26 sq. ft. for small cars to 33 sq. ft. for the largest. This factor is determined largely by the passenger seating capacity and can be changed but little.

If R_t = total resistance, lb., W = total weight of car and passengers, lb., r = rolling resistance, lb. per 100 lb. of car, K, A, V as before, then $R_t = (Wr/1000) + KAV^2$.

Power Required to Drive the Car at any speed is Hp. $= R_t(V/375)$.

2. ENGINE DETAILS

THE COOLING SYSTEM dissipates waste heat. Several types are possible. Water-cooling, with either thermosyphon or pump circulation has been most used. Direct air cooling has been successful. An evaporative cooling system, in which the water surrounding cylinders is always at boiling temperature also is possible. In this system the radiator is a condenser for the steam.

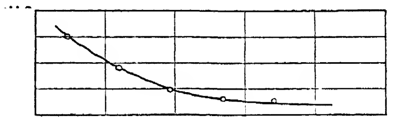

Fig. 1. Heat Dissipation from Typical Passenger Car Radiator Section

In design of the water-cooled system the most severe load is used, *viz.*, that imposed by air temperature of 110° F., and car speed of 15 to 25 m.p.h. (1000 engine r.p.m.) with wide-open throttle. The quantity of heat to be dissipated varies with engine design, being greatest for L-head, and least for valve-in-head engines. Specific heat of cooling water varies between 45 and 75 B.t.u. per B.Hp. per min. at 1000 r.p.m. Design of the system depends on variables associated with the fan, water pump and radiator section. Fig. 1 shows heat dissipation from a typical passenger car radiator section. A temperature rise of 80° F. is the maximum possible with existing sections, and is the difference between air and upper radiator tank water temperatures. For best operation, upper tank temperatures should be approximately 165° F., although under most severe load 210° F. may be tolerated.

A propeller fan delivers the proper amount of air through the radiator. Fan horse-

power varies as (speed)^3, while delivery, cu. ft. per min., varies directly with speed. Fig. 2 shows test results of three typical fans mounted behind a radiator section.

Thermostats to obtain quick warming of cylinder walls, especially in winter, prevent crankcase dilution. They begin to open at 135° F. and are fully open at 140° F. Radiator shutters, thermostatically operated, also are used to obtain rapid warming.

ANTI-FREEZE.—Denatured alcohol solutions, to which there are two principal objections, are most generally used. The solution evaporates, especially on heavy runs; unless it is tested periodically and sufficient replacement alcohol added, both motor and radiator are apt to be damaged by freezing. Alcohol solution or vapor will damage car finish. The strength of solution necessary to protect against freezing depends on the temperature. The following are the proportions of 90% (180° proof) denatured alcohol and water required at various temperatures.

Freezing Point......	+10° F.	0° F.	−10° F.	−20° F.	−30° F.
Parts of Alcohol....	2 1/2	3			
Parts of Water.....	5 1/2	5	4 1/2	4	3

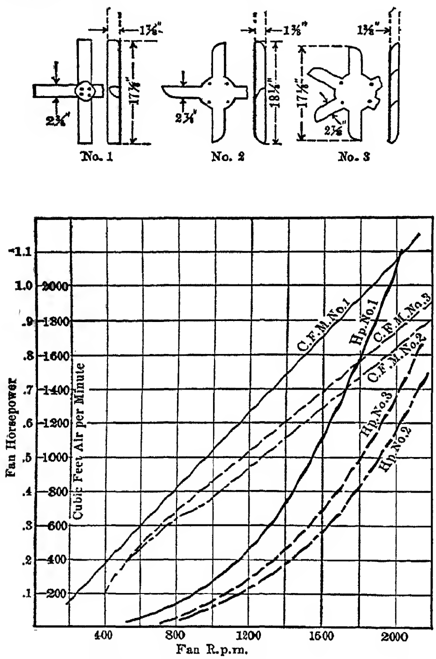

FIG. 2. Fan Tests. Horsepower and Air Delivery

Distilled glycerine and ethylene glycol solutions cost more than alcohol, but do not evaporate; only water need be added to replace evaporation. Solution lost mechanically, by leakage, foaming, etc., must be replaced by fresh solution. These solutions, under ordinary conditions, do not injure car finish. The principal objection to glycerine and ethylene glycol solutions is their tendency to loosen iron rust and scale in the water passages of the engine, thus making difficult the maintenance of leakproof connections. The entire cooling system must be cleaned and flushed before glycerine or ethylene glycol is used, and cylinder head gaskets and pump packing must be tightened or replaced. Cylinder head gaskets must be tight to prevent solution leaking into the crankcase, where it may gum and cause sticking of moving parts. Pump packing must be tight to prevent air being drawn into the cooling system, otherwise, foaming and other difficulties may result.

Salt solutions, as calcium or magnesium chloride, sodium silicate, etc., honey, glucose and sugar solutions and oils are unsatisfactory for automobile radiators.

CYLINDER ARRANGEMENT AND NUMBER are usually determined by the economics of manufacture, and by vibration characteristics. Fig. 3 compares the forces in engines of most of the usual cylinder combinations. The analysis was made on engines of the same displacement and the forces are plotted to scale.

Cylinders of passenger cars usually are cast iron, cast en block. In truck and bus engines, steel cylinder liners often are used. The minimum thickness of section recommended for cast iron is $^3/_{16}$ in., but up to $^1/_4$ in. may be used for large-bore cylinders for passenger cars and trucks. Average thickness for passenger cars is $^7/_{32}$ in. Minimum thickness of steel sleeves with radial stiffening ribs is $^1/_8$ in.; inserted steel sleeves usually are $^3/_{16}$ in. thick. Cylinder blocks should have a Brinell hardness of 187 to 202 in the cylinder bore and at the valve seats. If these parts are so located in the casting as to cool slowly, they will be hard at the edges, corners and thin sections, and of hard machinability if made of unalloyed iron giving above hardness values. Additions of Ni and Cr

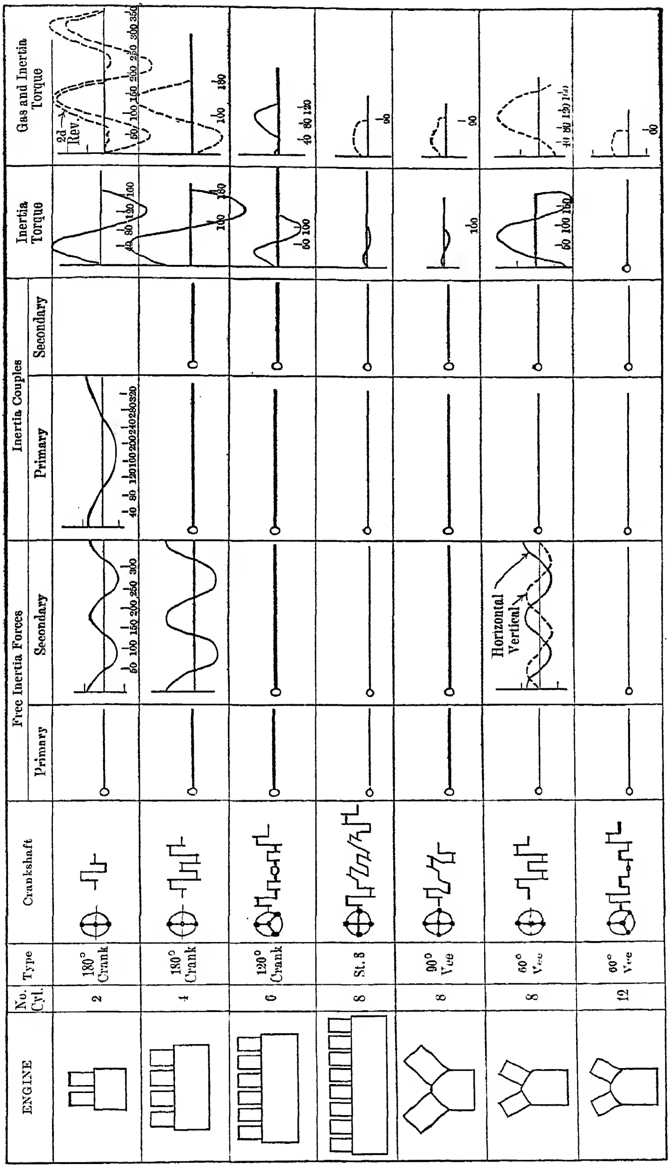

Fig. 3. Forces Acting in the Engine

Table 2.—Compositions of Cast Irons for Automotive Engine Cylinders

(A. L. Boegehold, Regional Meeting, A.S.T.M., Detroit, March, 1930)

Cylinder Iron No.	C, total	Mn	P, max.	S, max.	Si	Cr	Ni
1	3.15–3.30	0.55–0.75	0.20	0.12	2.00–2.40	0.06–0.16	0.03–0.08
2	3.15–3.30	0.55–0.75	0.20	0.12	2.00–2.40	0.05–0.07	0.25–0.35
3	3.15–3.50	0.50–0.80	0.20	0.12	1.75–2.25	....	1.00–1.50

counteract this tendency. An addition of 1 1/2 % Ni also lowers the coefficient of expansion. Tensile strength should be 35,000 lb. per sq. in. when cast in a 1/2-in. section. Table 2 gives composition of cast irons much used for cylinders.

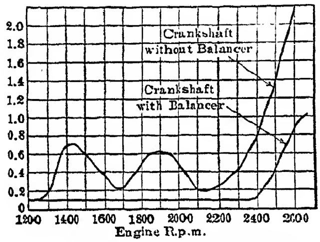

Fig. 4. Torsional Vibration of Crankshaft

CRANK-SHAFTS for automobile engines are forgings of plain carbon steel (S.A.E 1045). Alloy steels usually are unnecessary, since bearing sizes limit the diameter to a value where plain carbon steel is strong enough. A main bearing between each crank throw, between each 2 throws or each 4 throws all are in successful use. Limiting the number of bearings reduces center distances between cylinders and makes possible a shorter engine.

Crank-shaft Vibration.—Crank-shafts are counterweighted to reduce centrifugal forces and bearing loads. In practice, 50% of the centrifugal forces should be balanced by the counterweights to obtain satisfactory smoothness. Static and dynamic balance is required. The limits vary from 1/4 to 1 oz.-in. In long crank-shafts (6 or more cylinders), torsional vibration at resonant speeds produces vibration which must be eliminated. 4-cylinder or V-8 engines usually have a short stiff crank-shaft with a natural frequency above normal driving speeds. Torsional vibration in an automobile engine crank-shaft is produced by a resonance of the torque impulses of the engine with the natural frequency of torsional vibration of the crank-shaft; they are excited by the gas pressure on the piston and by inertia forces of reciprocating parts. Gas pressures recur every two engine revolutions and inertia forces every revolution. The forces are periodic and may be repre-

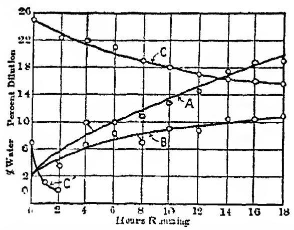

Fig. 5. Dilution of Oil vs. Hours of Running. *A*. Fresh oil, standard operation. *B*. Fresh oil, 1/3 of carburetor air drawn through crank-case. *C*. Polluted oil, 1/3 of carburetor air drawn through crank-case. *C'*. Water in oil, 1/3 of carburetor air drawn through crank-case. Fuel used 70% gasoline, 30% kerosene.

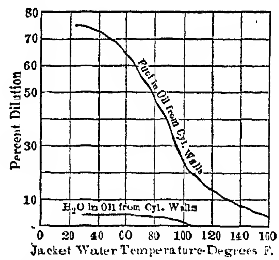

Fig. 6. Effect of Jacket Water Temperature on Dilution of Oil from Cylinder Walls

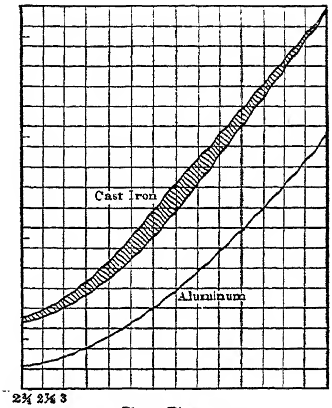
sented by harmonic sine functions, $f \times$ r.p.m., where f = frequency = 1/2, 1, 1 1/2, 2, 2 1/2, 3, 3 1/2, 4, 4 1/2, 5, 5 1/2, 6, etc. The crank-shaft responds to excitation by the gas or inertia forces with a vibration whose frequency equals that of the exciting forces. The natural frequency of torsional vibration of a crank-shaft is determined by the shaft stiffness and inertia of the shaft, connecting-rods and pistons. It is proportional to (stiffness ÷ inertia). Since long crank-shafts cannot be built stiff enough to make the natural frequency of torsional vibration occur above normal driving range, a balancer is necessary. A torsion balancer or Lanchester damper are two types generally used. Fig. 4 shows the amplitude of vibration of a crank-shaft with and without a torsion balancer.

CRANK-CASE AND CRANK-CASE VENTILATION.—The upper half of the crank-case may be either cast iron or aluminum alloy, cast with the cylinders or separately. It must

be sufficiently rigid to prevent deflection, due to engine operation, misaligned crank-shaft bearings, camshaft bearings and camshaft drive mechanism. The lower half of the crank-case is an oil reservoir, holding 5 to 10 qt., depending on size of engine. American practice provides ventilation through the crank-case to remove water and light ends of the fuel which blow past the pistons. This water is washed from the walls by the oil and deposited in the crank-case. During choking, especially in cold weather, large quantities of fuel also may be blown past the pistons into the oil. Water in the crank-case tends to corrode bearing surfaces of the crank-shaft, piston-pins, cylinder walls and valve gear. Corrosion is most severe with gasolines high in sulphur. A blast of air through the crank-case holds oil dilution and water content to a minimum. See Fig. 5.

Fig. 6 shows tests of fuel dilution and water dilution on cylinder walls of an automobile engine which had stood out all night before the test. Initial jacket water temperature was 5° F.



G. 7. Relative Weight of Cast-iron and Aluminum Pistons

PISTONS.—The most common piston material is cast iron or aluminum alloy; magnesium also has been used. Cast iron gives long life with little wear; it can be fitted to closer limits and distorts less than aluminum. Aluminum has the advantage of light weight and higher heat conductivity. Fig. 7 compares the weights of typical cast-iron and aluminum pistons. The weight of the piston assembly is held within limits of $^1/_{16}$ to $^3/_{16}$ oz. to insure good engine balance. Clearance for cast-iron pistons may be taken as from 0.00075 to 0.001 in. per inch of cylinder bore, and approximately double this for aluminum. No exact rule is possible, as clearance depends on piston design and the duty to which it is subject. Some manufacturers plate cast-iron pistons with tin to prevent scoring and seizing. The piston then may be fitted as closely as 0.0005 to 0.001 in. or have a light drag fit in the bore.

The piston is fitted with three or four piston rings. The upper rings are plain; the lower one or two are oil control rings. The plain rings are from $^3/_{32}$ to $^5/_{32}$ in. wide; the oil rings from $^1/_8$ to $^3/_{16}$ in.

VALVES AND VALVE MECHANISM.—Fig. 8 shows the most common arrangement of valves. The I-head, commonly known as valve-in-head or overhead valve, gives a

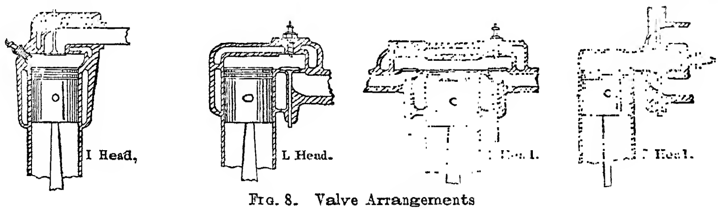


Fig. 8. Valve Arrangements

simple combustion chamber with a minimum heat loss to cooling water due to the small water jacketing. The L-head gives simplified valve action. The T-head requires two camshafts, but permits large valves and low lifts. It requires the greatest amount of water jacketing. The F-head has the intake valve over the exhaust valve, and is a combination of overhead and L-valves.

Valve Material must withstand high temperature without corrosion. For intake valves, which operate cooler than exhaust valves, S.A.E. 3140 or chrome-nickel steel is used. Exhaust valves are made of Silchrome-, chrome-nickel- or tungsten-steel.

Valve Mechanism Design depends on many variables. The valve timing selected can give power either at high or at low engine speeds. To obtain best performance at high speed entails a sacrifice at low speed and *vice versa*. A compromise must be made to obtain the results desired. Fig. 9 shows the effect of varying intake timing on a single-cylinder

test engine, 3 1/8 in. bore, 4 1/2 in. stroke, with overhead valves. Fig. 10 is a timing diagram for a typical passenger car engine.

Cam shape has much to do with the operation of the valves. Moving parts should be of light weight to reduce inertia forces. Good valve follow should be sought. This requires: 1. A maximum of acceleration in as short a time as rigidity of the system will permit; 2. A minimum of deceleration continued over as long a time as is consistent with (1); 3. A minimum of reversals of forces in the acceleration curve. A cam contour so designed should give maximum volumetric efficiency and optimum valve follow. See Fig. 69.

G. 9. Intake Timing and Engine Performance

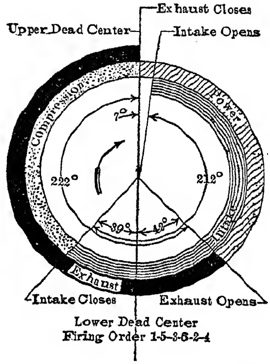

FIG. 10. Typical Valve Timing Diagram

Valve Springs.—Valves are closed by helical coiled springs. One of the greatest difficulties with such a spring is its tendency to vibrate or "surge" at definite speeds, depending on the natural vibration frequency of the spring. This frequency can be calculated by Ricardo's formula for helical springs, $n = 531\sqrt{R/W}$, where n = frequency, vibrations per min., R = scale of the spring = load, lb., necessary to deflect it 1 in., W = weight of active part, lb. If (cam r.p.m. × an integer) = n, a resonant vibration results. At low speeds, the amplitude is small but at some operating speeds it becomes large enough to cause the coils to close and the springs will produce a sound.

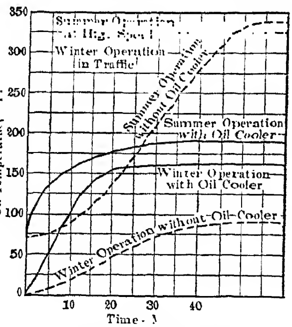

FIG. 11. Effect of Water-cooled Oil-cooler on Oil Temperature

Formulas used to calculate round wire springs are:

$$P = \pi S d^3/8d = fGd^4/8\,D^3N; \quad R = GD^4/8\,D^3N;$$

$$S = fGd/\pi D^2N; \quad f = \pi D^2NS/Gd, \quad n = S/4.78f,$$

where P = pressure of spring, lb.; R = scale of spring (see above); S = stress, lb. per sq. in.; G = modulus of elasticity in torsion; f = deflection of spring, in., under load P; d = diameter of wire, in.; D = pitch diameter of coil, in.; N = number of active turns of spring; n = frequency, cycles per min.

High-carbon steel, low in manganese, or chrome-vanadium spring steels are used.

AIR FLOW THROUGH VALVES.—Valve port size, timing and lift must be proportioned correctly to obtain high volumetric efficiency. Valve lift usually is about 1/4 port diameter; in slow speed engines a material gain in air flow can be obtained by lifts of 1/3 port diameter. The air flow through a valve port with 30° seats is greater than through one with 45° seats. Gas velocity through the port is given by the approximate formula, $V = D^2sN/8qdh$, where D = cylinder diam., in.; V = gas velocity, ft. per sec.; s = piston stroke, in.; d = port diam. in.; h = mean valve lift (in. from valve lift diagram); q = period of opening, degree of crankshaft rotation. This formula assumes the valve to be open for the duration shown on the diagram, and the valve

annulus to be a cylindrical surface. If the valve is tapered a correction factor should be applied as follows:

For 30° seats, $A_1 = A_2\{0.866 + (0.375)(h/d)\}$

for 45° seats, $A_1 = A_2\{0.707 + (0.353)(h/d)\}$

$V_2 =$ [illegible]

where V_2 = velocity corrected for seat angle; V_1 = velocity, assuming a flat seat; A_1 = area of conical annulus, sq. in.; A_2 = area of cylindrical annulus, sq. in.

ENGINE LUBRICATION must prevent metal-to-metal contact and remove excess heat from the bearings. Oil is fed to bearing surfaces by force or splash. Dippers on the connecting-rods pick up the oil from troughs kept full by a circulating pump, and splash it to the bearings. When pressure is used, a gear pump forces oil through holes in the crank-shaft to the main and connecting-rod bearings. The connecting-rod may be drilled to allow oil to flow to the piston-pin. A pressure of 30 to 40 lb. per sq. in. at 30 m.p.h. car speed is usual.

Oil Coolers may be used to control oil temperature. In summer, they keep the temperature low and in winter they provide a quick oil warm-up and a higher stabilized temperature. Fig. 11 shows the effect on summer and winter oil temperatures of a water-cooled type oil cooler.

Oils for Lubricating automobile engines are classified by S.A.E. standards of viscosity. S.A.E. 30 is used for normal driving conditions, S.A.E. 20 and 10 for winter temperatures, and S.A.E. 40 to 60 for high-speed driving in warm weather. 10-W and 20-W are special oils for sub-zero winter driving. Viscosity is the most important property of oil from the automobile standpoint. It affects starting friction, oil circulation, oil consumption, oil pumping, smoking in exhaust, fouling of spark plugs, carbon formation in the engine, oil pressure, crank-case dilution and noise. Volatility also is important at high speeds. Fig. 12 shows the effect of high speed on oil consumption of two oils of different volatility.

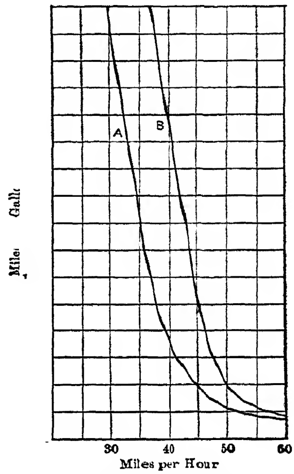

Fig. 12. Effect of Car Speed on Oil Consumption

3. ENGINE DESIGN

KINEMATICS OF THE ENGINE (Air Service Information Circular, No. 421, H. Caminez and C. W. Isler.).—To determine the principal forces acting in the engine, the motion of the pistons and the connecting-rods relative to the crank-shaft is found; the angular velocity is taken as constant because of the large inertia of the flywheel and uniformity of torque in multi-cylinder engines. In Fig. 13*a*, which is a diagram of the usual arrangement of pistons, connecting-rod, and crank-shaft, let L = connecting-rod length, center to center in., $= BD$; R = crank radius, in. $= OD$; θ = crank angle from top center position, deg.; ϕ = angle of connecting-rod with center line of cylinder, deg.; s = piston travel, in. $= AB$.

Piston- and Connecting-rod Position for various crank angles can be found by a diagram drawn to scale or by mathematical analysis. With the arrangement of Fig. 13*a*,

$$s = (R - R\cos\theta) + (L - L\cos\phi) \quad [1]$$

and $\phi = \sin^{-1}(R/L)\sin\theta. \quad [2]$

Combining [1] and [2], piston travel =

$$s = R\left[1 - \cos\theta + (L/R) - \sqrt{(L/R)^2 - \sin^2\theta}\right] \quad [3]$$

and percent of piston travel

$$= {}^1/_2\left[1 - \cos\theta + (L/R) - \text{[illegible]}^2 - \sin^2\theta\right] \quad [4]$$

Equation [4] has been solved at every 10° of crank angle for the usual ratios of found in automobile engines. See Table 3.

Velocity.—Let v_c = crank-pin velocity, ft. per sec.; v_p = piston velocity, ft. per sec.; N = r.p.m.; R = crank radius, in.; $(d\theta/dt)$ = angular velocity of connecting-rod; f_v = crank angle factor for piston velocity. Then, referring to Fig. 13*b*, and considering linear velocity of the crank-pin as

$$v_c = R(d\theta/dt) = (2\pi N/60) \times (R/12), \qquad [5]$$

$$\frac{d\theta}{dt} = \frac{R}{L}\,\frac{\cos\theta}{\cos\phi}\,\frac{d\theta}{dt} = \frac{\cos\theta}{\ } = v_- =$$

$$= v_c f_v; \qquad [7]$$

$$f_v = \sin\theta + \cos\theta\tan\phi = \sin\theta\,[1 + \{\cos\theta/\sqrt{(L/R)^2 - \sin^2\theta}\}] \qquad [8]$$

The crank angle factor for piston velocity, f_v, may be found graphically. In Fig. 13*a* it is OH/OD. Table 4 gives values of f_v for ratios of L/R generally used in automobile engines. Since ϕ, the connecting-rod angle, is small, the resulting error from substitution of $\sin\phi$ for $\tan\phi$ in [7] and [8] will be small. Making this substitution the approximate equations are:

$$v_p = v_c\{\sin\theta + {}^1/_2\,(R/L)\sin 2\theta\}; \qquad [9]$$

$$f_v = \sin\theta + {}^1/_2\,(R/L)\sin 2\theta. \qquad [10]$$

Acceleration.—The exact expression for piston acceleration for the arrangement in Fig. 13*a* is complex and not commonly used. The approximate equation in general use is

$$a = (v_c^2/R)\{\cos\theta + (R/L)\cos 2\theta\} = (v_c^2/R) \times f_a, \qquad [11]$$

where a = linear acceleration of piston; f_a = crank angle factor for piston acceleration.

$$f_a = \cos\theta + (R/L)(\cos^2\theta/\cos^3\theta) - \sin\theta\tan\phi \quad \text{(Exact)} \qquad [12]$$

$$f_a = \cos\theta + (R/L)\cos 2\theta \quad \text{(Approx.)} \qquad [13]$$

Table 5 gives values of f_a for ratios of L/R generally used in automobile engines. Table 6 is a comparison of exact and approximate values.

INERTIA AND CENTRIFUGAL FORCES are caused by the motion of the pistons and connecting-rods. In a fixed-cylinder engine, piston motion is linear; the resulting forces are purely inertia forces. The motion of the connecting-rods is more complex. For an exact solution of the forces produced by the rod, it is necessary to consider the components of its motion. The motion of the rod may be analyzed as a translation of its center of gravity, with the linear velocity and acceleration of the piston combined with an angular velocity and acceleration about the piston-pin. This motion of the rod sets up in each of its elements three separate forces: *a*, an inertia force due to linear acceleration in the direction of the cylinder axis; *b*, a centrifugal force due to angular velocity about the piston-pin; *c*, an inertia force due to angular acceleration about the piston-pin. These forces are very closely approximated by assuming the mass of the connecting-rod to be divided between the piston-pin and the crank-pin in inverse

proportion to the distance of the respective pins from center of gravity of the rod. The crank-pin portion produces a centrifugal force, the piston-pin portion produces an inertia force. To obtain the weight at either end, support the rod on knife edges directly over the center line of the bearings, the axis of the rod being horizontal. The knife edge under the end to be weighed rests on scales. Results can be verified by comparing the sum of the weights of the two ends with the total weight of the rod. The centrifugal force acting at the crank-pin in the direction of the crank-throw is

$$F_c = 0.0000284 W_c RN^2, \qquad [14]$$

where F_c = centrifugal force, lb.; W_c = weight of lower end of connecting-rod, lb.; R = crank radius, in.; N = r.p.m. The inertia force acting in the direction of the cylinder is

$$F_i = -0.0000284 W_i RN^2 f_a \qquad [15]$$

where F_i = inertia force, lb.; W_i = reciprocating weight = weight of piston assembled plus upper end of connecting-rod, lb.; f_a = crank angle factor for piston acceleration.

Resultant Forces on Piston.—The gas pressure acting on the piston is obtained at various crank angles from the indicator diagram. Fig. 14 is a typical indicator card for an automobile engine. Two values of indicated mean effective pressure are given. If an experimental indicator card is not available, a theoretical card can be calculated. The total gas force is this pressure multiplied by piston area. Equation [15] determines the inertia force at various crank angles. Then if F_a = resultant force along cylinder axis, F_g = force on piston due to gas pressure, F_i = inertia force,

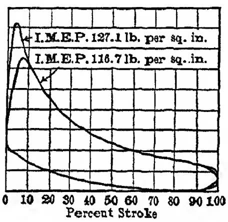

FIG. 14. Typical Indicator Card

$$F_a = F_g + F_i \qquad [16]$$

Piston Side Thrust due to the force acting along the cylinder axis is

$$F_s = F_a \times \tan\phi, \qquad [17]$$

where F_s = piston side thrust, lb.; F_a = resultant force along cylinder axis, lb.; ϕ = connecting-rod angle, deg. For the arrangement of Fig. 13*a*, F_s may be expressed in terms of crank angle θ by

$$F_s = F_a \{\sin\theta / \sqrt{(L/R)^2 - \sin^2\theta}\}. \qquad [18]$$

Piston side thrust is found throughout a complete cycle and is plotted *vs.* crank angle and *vs.* piston travel. The area of the latter curve is proportional to the piston friction loss if the coefficient of friction remains constant. From the average height of this curve, the average side thrust during the power stroke and during the complete cycle is determined.

Piston side pressure, lb. per sq. in., equals (total piston side thrust) ÷ (projected bearing area). Since the piston diameter usually is relieved above the lower piston ring, only that portion below the lower ring is considered in determining effective bearing area.

Torque.—The torque due to forces acting in the cylinder at any instant during the cycle is

$$T = F_a \times R \times f_v, \qquad [19]$$

where T = torque, lb.-ft.; F_a = resultant force along cylinder axis, lb.; R = crank radius, ft.; f_v = crank angle factor for piston velocity. The resultant torque in a multi-cylinder engine is the algebraic sum of the instantaneous torques of the individual cylinders. To find this resultant, the angular relation of the cycles in the various cylinders must be considered. This analysis gives the indicated torque, as frictional forces are not considered.

The mean torque can be obtained from a curve of torque *vs.* crank angle by using a planimeter. The ratio of the maximum to the mean torque of the engine is determined and used in later calculations.

Resultant Force on Crank-pin is found by combining graphically the resultant force along the connecting-rod axis with the centrifugal force due to the weight of the lower end of the connecting rod. Use equation [14]. Let F_d = resultant force along the connecting-rod axis; F_a = resultant force along cylinder axis; ϕ = connecting-rod angle. Then

$$F_d = F_a / \cos\phi. \qquad [20]$$

In equation [20] a plus (+) force denotes a force producing compression in the rod, a negative (−) force one producing tension. With the arrangement shown of Fig. 13*a*, F_d can be expressed in terms of the crank angle θ by

$$\overline{n^2\,\theta}. \qquad [21]$$

Fig. 13*b* shows a graphic determination of the resultant force on the crank-pin. F_c is laid off to scale along the center line of the crank-throw. F_d represents a positive force acting along the connecting-rod and is drawn parallel to it. The resultant force, F_r, represents, to scale, the magnitude of the force acting on the crank-pin at the angle shown. The direction of F_r with respect to engine axis, crank-throw and connecting-rod is given by angles α, β and γ respectively. F_r is obtained at various crank angles throughout the cycle, and plotted on a polar diagram with respect to the engine axis and crank throw, to determine maximum and mean forces. These forces give connecting-rod bearing loads.

Resultant Force on Crank-shaft Bearings.—The load distribution on the crank-shaft bearings depends on the rigidity of the crank-shaft and the crank-case, the alignment of the bearings, and the clearances between the journal and the bearings. These factors cannot be predetermined, and an exact analysis of the load distribution between the various crank-shaft bearings is not possible where more than two main bearings are used.

An empirical method for computing the forces acting on the main bearings of a crank-shaft where there is a main bearing at each side of the crank-pin is as follows: The forces acting on the crank-shaft bearings are obtained by assuming the force at the crank-pin, together with the centrifugal force resulting from the weight of the crank-pin and crank-cheeks, to be equally divided between the two crank-shaft bearings at each side of the crank-pin. End bearings are loaded on only one side, by half of the force of the crank-pin combined with half the centrifugal force due to the crank-pin and crank-cheeks of the crank-throw. The same loading is applied on both sides of the center and the intermediate bearings.

If more than one crank-pin bearing or crank-throw is located between each pair of main crank-shaft bearings, the load distribution on the main bearings is found by treating each section of the crank-shaft between two main bearings as a uniform beam rigidly supported at the center line of the main bearing bolts. The reactions on the main bearings A and B due to a force F_r on a crank-pin located between them is

$$R_a = F_r\{b^2(3a + b)/(a + b)^3\}, \qquad [22]$$

$$R_b = F_r\{a^2(a + 3b)/(a + b)^3\}, \qquad [23]$$

where R_a and R_b = bearing reactions at bearings A and B, respectively; F_r = resultant force on crank-pin; a and b = distance between center line of crank-pin and center line of main bearings, respectively. The resultant force on a crank-shaft bearing is the vector sum of the reactions due to the crank-pin loads. In determining the resultant force, consideration must be given to the direction relative to the engine axis of each separate reaction. Both the relative positions of the crank-pins and their cyclic relation also must be considered.

BEARING ANALYSIS.—Maximum and mean bearing pressures are determined by dividing the maximum and mean resultant forces acting on the bearing by the projected area of the bearing. In determining projected bearing area, only the straight portion of the bearing length is considered as effective. The resultant pressures are expressed in pounds per square inch.

The rubbing factor PV on the bearing, lb. per sq. in. $\times$ ft. per sec., is the product of the rubbing velocity of the journal and the mean bearing pressure. The rubbing velocity in ft. per sec. is

$$V_r = \pi(D/12) \times (\text{r.p.m.}/60), \quad [24]$$

where V_r = rubbing velocity of bearing, ft. per sec.; D = bearing diameter, in. Table 7 gives bearing data for two typical automobile engines.

CONNECTING-ROD STRESS ANALYSIS.—Stress, S_c, in connecting-rod shank, due to direct compression, is calculated by Rankine's formula,

$$S_c = (F_r/A) + m\,(L^2/I_x)\,F_r, \quad [25]$$

or

$$= (F_r/A) + m\,(L_1^2/4I_y)\,F_r, \quad [26]$$

where F_r = resultant force along connecting-rod axis; A = area of shank cross section, sq. in.; I_x and I_y = moment of inertia of area about x–x and y–y axes, respectively (see Fig. 15); L = length of connecting-rod, in.; L_1 = length of shaft as in Fig. 15, in.; m = constant for steel column = 0.000526. For equal compressive strength of the shank cross-section in both planes, $I_y = (L_1/L)^2 \times (I_x/4)$.

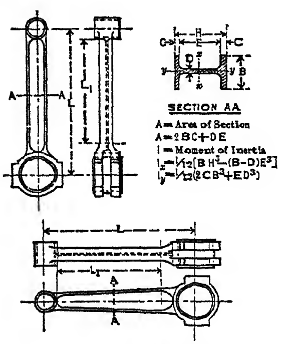

Fig. 15. Connecting Rod

Considering the rod as a uniform section extending from piston-pin center to crank-pin center, the *whipping force* that results from transverse acceleration of the rod, is approximately

$$F_w = (wAL/2g) \times (\pi N/30)^2 \times (R \sin\theta/12)$$
$$= 0.00000402ALN^2R \sin\theta, \quad [27]$$

where F_w = whipping force, lb.; A = area of shank cross-section, sq. in.; L = length of connecting-rod, center to center, in.; N = r.p.m., R = crank radius, in.; θ = crank angle, deg.; w = weight of material, lb. per cu. in. = 0.283; g = acceleration due to gravity = 32.2.

F_w is considered as a distributed load varying uniformly from zero at the piston-pin to a maximum at the crank-pin end of the rod. Such a loading is assumed to produce a reaction of 1/3 total load at the piston-pin and 2/3 total load at the crank-pin. The reactions are small and are neglected in determining bearing loads. The bending moment produced by F_w in a section of the connecting-rod shaft at distance x from the piston pin is

$$M_w = (F_w x/3)\{1 - (x^2/L^2)\}. \quad [28]$$

Maximum bending moment, M'_w, occurs at the section where $x = 0.577L_1$ and is $M'_w = 0.1283\,LF_w$. The stress set up in the shank cross-section due to the whipping section is $S_b = M_w/Z$, where S_b = fiber stress due to whip, lb. per sq. in., Z = section modulus of shank area about axis parallel to piston-pin.

PISTON-PINS are made of a carburizing steel, usually from bar stock; seamless steel tubing sometimes is used. S.A.E. steels, 1015, 1020, 2520 and 6115 are used. The case depth of carburization is 0.030 in. to 0.045 in. Pins are ground and lapped to a fine satin finish. Hardness is about Rockwell C–60.

Oil is supplied to the pin either by splash from the connecting-rod bearings or by pressure through gun drilling in the connecting rod. Clearance in the bearing surface is a light push fit. That in the locking part of the pin is at least 100-lb. forced fit. Pins usually are locked either in the piston or in the upper end of the connecting-rod; sometimes the pin floats both in piston and rod. Bearing pressures due to explosion pressure vary between 2000 and 3500 lb. per sq. in. of projected area. Bearing pressure = F/DB lb. per sq. in., where F = force on piston, lb., D = outer diameter of the pin, in., B = length of bearing in connecting-rod, in.

To determine stresses, consider the pin as a beam supported at the center of the piston-pin bosses, and loaded uniformly at the connecting-rod upper bearing. The resulting maximum stresses are:

$$S_t = (32/\pi)D/(D^4 - d^4) \times F\,(2L - B)/8, \quad [29]$$

$$S_s = F/2A = F/\{\pi/2)(D^2 - d^2)\}, \quad [30]$$

where S_t = tensile stress, lb. per sq. in.; S_s = shearing stress, lb. per sq. in.; d = inner diameter of the pin, in; L = distance between centers of piston bosses, in.; other notation as above.

4. AUTOMOBILE FUELS AND COMBUSTION

HEAT CONTENT.—Gasoline, either cracked or straight run, is the ideal fuel for automobile engines. Its heat content is high. See Table 8. Columns 4 and 5 show the total, gross or high heating value, *i.e.*, B.t.u. liberated by a unit amount of gasoline burned with oxygen in a constant volume enclosure, the products of combustion CO_2, SO_2 and H_2O being cooled to the initial temperature and H_2O condensed to a liquid. Columns 6 and 7 show the net or low heating value, *i.e.*, B.t.u. liberated at constant pressure. This value is the most significant in calculating engine efficiencies, as, in most practical applications, combustion occurs at constant pressure and the H_2O formed is not condensed. The average specific gravity at 60° F. of commercial gasoline is 0.74.

VAPOR LOCK.—The 10% point of the A.S.T.M. distillation curve indicates the approximate temperature of the gasoline at which vapor lock troubles in the fuel line may occur. Summer gasolines range from 125° to 150° F. and winter gasolines from 105° to 140° F. A more accurate indication of the tendency to vapor lock is the Reid vapor pressure.

Table 9 gives measured temperatures in the liquid gasoline flowing through the fuel system in a typical automobile.

STARTING CHARACTERISTICS.—For easy starting, especially in cold weather, volatility is the most important fuel property. In winter, all of the gasoline will not evaporate in the manifold; an excess must be supplied to enable the portion which does evaporate to form an explosive mixture. The excess is supplied by the choke, which changes the mixture ratio from the normal of about 13 : 1 to as low as 0.3 : 1. Fig. 16 shows the air-fuel ratios required to produce an explosive mixture. The 10% points also are shown on the curve.

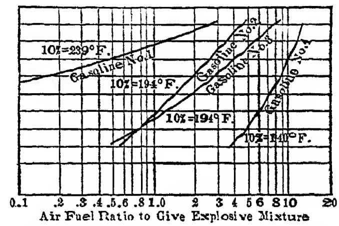

FIG. 16. Variation, with Temperature, of Air-fuel Ratios for Explosive Mixtures

Bouncing Pin Indicator (Fig. 18) indicates the intensity of knock. It comprises a steel rod which rests on a diaphragm exposed to pressures in the combustion chamber. Knock causes the pin to bounce up, closing the contact points. These points, and either a gas-evolution burette or a knockmeter, are connected in series in an electric circuit. The burette. Fig. 19, is filled with 10% H_2SO_4 solution, and the gas generated by electrolysis of this solution is measured. The knockmeter is a device to integrate current, resulting from knock, flowing in the bouncing pin circuit.

Reference Fuels and Octane Number Scale.—The common reference scale, expressed in terms of octane number, has been adopted by both

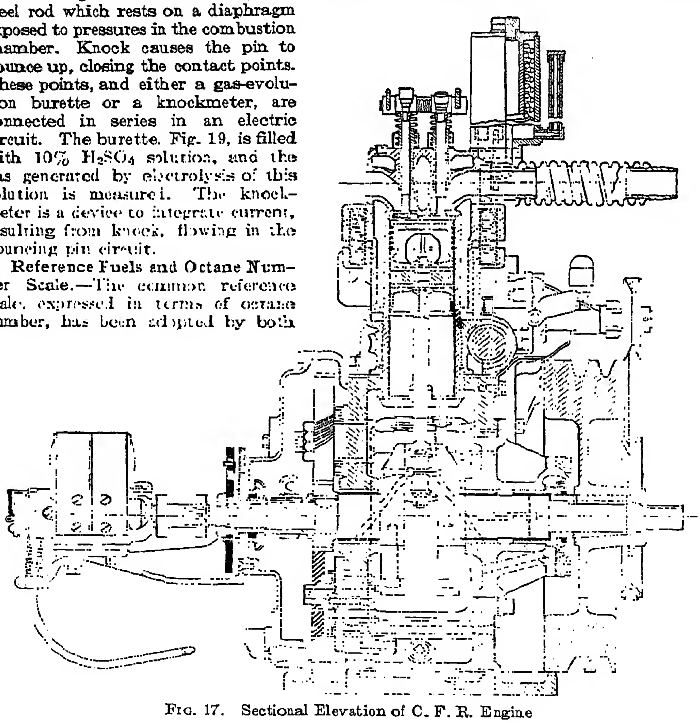

FIG. 17. Sectional Elevation of C. F. R. Engine

the oil and automobile industries. Two pure hydrocarbons, both readily available and with a constant antiknock value, are the basis of the octane number scale. One, normal heptane, has very low antiknock value. Its source is the sap of the Jeffrey pine, grown on the Pacific coast. The second, iso-octane (2,2,4-trimethyl pentane) of high antiknock quality, is made synthetically from tertiary butyl-alcohol.

The octane number of any gasoline is the percentage by volume of octane in the octane-heptane mixture that just matches the gasoline in antiknock quality, as determined in the C.F.R. engine by the standard procedure. Thus, if a gasoline is matched by a mixture of 60 parts octane and 40 parts heptane, its octane number is 60. The octane number of gasolines ranges from 40 to 87. Premium fuels are 78; average grade, from 60 to 70; fighting grade aviation gasoline, 87.

The test data, Fig. 20, show the increase in power, brake M.E.P., octane number requirements, and the decrease in specific fuel consumption (lb. per B.Hp. per hr.) when compression ratio is increased. These curves indicate trends only and show performance in a test engine.

5. FUEL SYSTEM

CARBURETORS.—Carburetors act as metering devices and should: *a.* Properly proportion the air-fuel ratio at different loads; *b.* Correct for temperature changes; *c.* Provide suitable accelerating mixtures; *d.* Have low air resistance, to maintain high volumetric efficiency. Commercial carburetors embodying these principles may be classified according to metering principle as plain tube and air valve. The former uses a Venturi tube to obtain a nearly constant mixture ratio throughout the major portion of its range. The latter uses the depression of an air valve for the same purpose. Other devices to obtain the desired characteristics over the entire speed and load ranges are: Metering pins, idle jets, compensating jets, double Venturis, pressure bleeds, and numerous others. Many of these are common to both plain tube and air valve carburetors.

MIXTURE RATIOS at full throttle should be approximately 13 : 1 (lb. of air per lb. of fuel), and about 15 : 1 at part-throttle level-road operation to give greater economy. For all other loads, the ratio should be between these two. Part-throttle economizers and full-throttle enriching devices are added to carburetors to obtain this double range feature. For accelerating, a rich mixture is necessary and is provided by pressure on the float chamber or a fuel pump. For starting, especially in cold climates in winter, the carburetor must supply a very rich mixture. Only about 6% of the fuel can be evaporated to form a combustible mixture at 0° F. A choke to provide mixture ratios of 0.3 : 1 to 0.8 : 1 at 0° F. is necessary for starting at low cranking speeds.

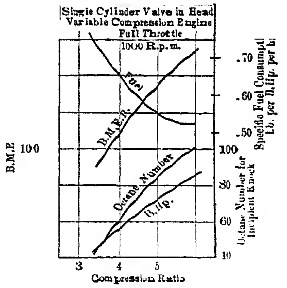

FIG. 20. Power, Fuel Consumption and Octane Number Requirements at Various Compression Ratios

MANIFOLDING.—An ideal manifold should supply an equal charge of identical fuel-air ratio established by the carburetor to all cylinders at all speeds, loads and rates of acceleration. It is desirable that the manifold have equal demand intervals on a branch, established either in the firing order or in the manifold design.

Distribution of mixture to the cylinders is complicated by less than half the liquid being vaporized by the carburetor. To obtain better vaporization heat is supplied in the manifold. Heat reduces volumetric efficiency and should be used as little as possible. Hot spots surrounding the throttle are effective, especially at part-throttle. To vaporize liquid in suspension at full throttle, it must strike a hot spot at 90° to the path of travel.

Liquid distribution concerns not only the manifold but also the carburetor, intake ports and valves. Turbulent or spiraling air flow tends to upset liquid distribution.

Violent spiraling tends, by centrifugal force, to throw all liquid drops to the walls of the manifolds. If spiraling is mild, distribution may be bettered by air straighteners. Manifolds of simple design are, in general, the best. In multi-cylinder engines, especially above 6 cylinders, multiple carburetors are necessary. Pronounced bumps or cavities at the tee, against which the mixture impinges, tend to increase turbulence and are undesirable. A straight section of at least (2 × manifold diam.) between elbow and siamese port is desirable to permit the mixture to resume normal flow.

FUEL FEED.—A constant supply of gasoline must flow to the carburetor from the tank during operation of the engine. Fig. 21 shows a typical positive engine-driven pump used for this purpose. Diaphragm *a* draws fuel from the tank and feeds it to the carburetor under pressure of the spring *c*. Diaphragm *a* is pulled down positively by lever *f* to draw fuel, but link *e* allows it to remain down if the carburetor float-valve is closed.

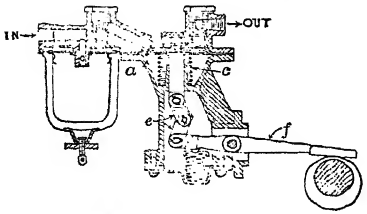

Fig. 21. Fuel Pump

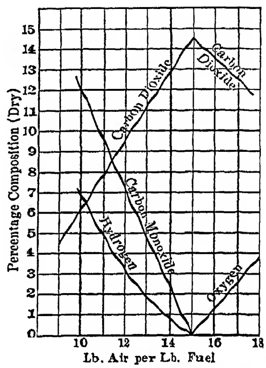

Fig. 22. Relation of Exhaust Gas Composition and Mixture Ratio

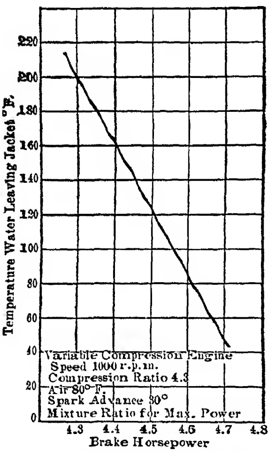

Fig. 23. Relation of Power and Jacket Water Temperature

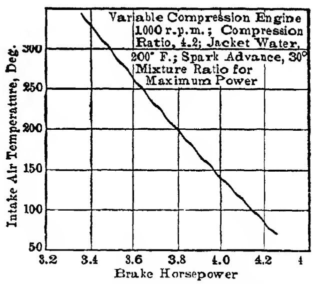

Fig. 24. Relation of Power and Carburetor Air Temperature

EXHAUST GAS COMPOSITION.—Fig. 22 shows the approximate relationship between exhaust gas composition and mixture ratio in the engine. This curve may be used to determine the mixture ratio of an entire engine or a single cylinder by measuring the CO content of the gases. Distribution in a multi-cylinder engine can be studied by making an analysis of the gases from each cylinder.

EFFECT OF ENGINE VARIABLES ON POWER OUTPUT.—Figs. 23–26 respectively show the effect of jacket water temperature, carburetor air temperature, spark advance and mixture ratio on power output of a single-cylinder variable-compression test engine. Fig. 20 shows the effect of changes in compression ratio, brake M.E.P., fuel consumption and octane number requirements for the fuel under stated conditions. Increase in compression ratio, jacket water temperature, carburetor air temperature

and spark advance increases the tendency of the engine to knock. Carburetor mixture ratio also affects this tendency, which decreases with a mixture leaner or richer than about 13 : 1, which ratio varies with different fuels. Low jacket water temperature has greater effect than low intake air temperature in reducing knock.

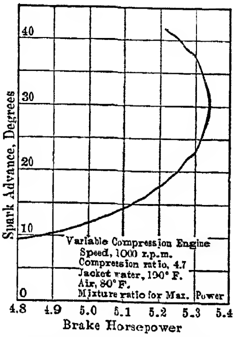

FIG. 25. Relation of Power and Spark Advance

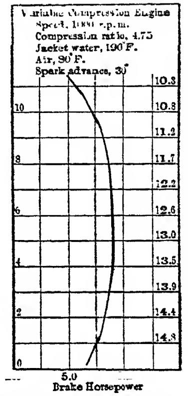

FIG. 26. Relation of Power and Mixture Ratio

The curves show relative effect of the variables and cannot be applied directly to all engines. They are useful in showing trends. In Fig. 24, the loss of power is directly due to the loss in volumetric efficiency with increased air temperature. Fig. 25 shows the characteristic of an optimum spark advance for given engine speed, compression ratio, mixture ratio and temperature conditions. Fig. 26 shows the characteristic of an optimum carburetor setting for specific engine conditions for maximum power.

6. ELECTRICAL SYSTEM

Electrical systems in American passenger cars operate at 6 volts; in European cars at 12 volts. The electrical circuit diagram, Fig. 27 is typical of 1935 practice on a medium-price 6-cylinder engine. The ignition coil converts the low voltage from the storage battery to a high voltage which will jump the spark plug gap. Fig. 28 shows the effect

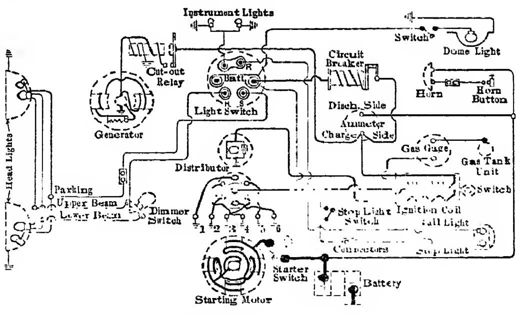

FIG. 27. Electrical Circuit Diagram

of a primary voltage on secondary voltage in a typical 6-volt coil. The spark plug gap should be from 0.015 to 0.018 in. for high-compression engines and from 0.018 to 0.022 in. for low-compression engines.

In a 6-volt generator, the field generally is shunt wound with 3d brush regulation of current. A cut-out, mounted in the generator allows current to flow to the battery when the generator speed has reached a point where generator voltage is greater than battery voltage. Fig. 29 shows current-speed characteristics for a typical shunt-wound generator with 3d brush regulation.

Engagement of the starter pinion with the fly-wheel gear is made by a manual shift lever. Two other systems are used, a semi-automatic and an automatic engaging mechanism. The motor is series-wound to give *high starting torque*. The starter will crank a warm engine at about 165 r.p.m. and a cold engine (0° F.) at about 35 r.p.m.

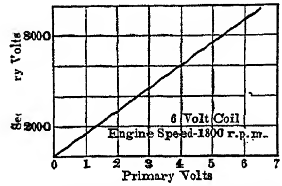

FIG. 28. Effect of Primary Voltage on Secondary Voltage

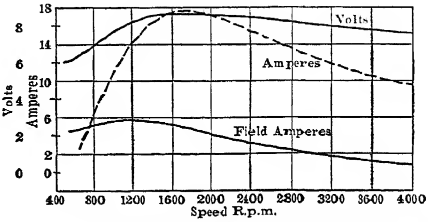

FIG. 29. Third Brush Generator Charging a Half-charged 13-plate Battery

7. CHASSIS

FRAMES AND SPRINGS.—The body, fenders, radiator, engine, transmission and wheels are attached to the motor vehicle frame. Strength and rigidity are the chief requirements of the frame. Usually, the two side members are channel section, with tubular or channel cross members riveted to them. To obtain greater torsional rigidity, X cross members sometimes are used. Fig. 30 shows a so-called double drop frame which uses X cross bracing. The dimensions of frame section range as follows: Depth, 5 to 9 in.; width, 1 $^3/_4$ to 3 in.; thick- to $^3/_{16}$ in. The smaller values refer to light cars and the larger to the heaviest.

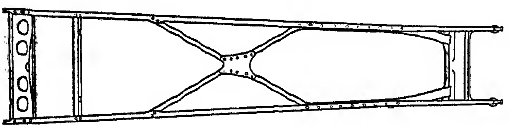

FIG. 30. Double Drop Frame with X Cross Bracing

Methods of Drive.—The three main methods of drive are: Hotchkiss (Fig. 31), torque tube (Fig. 32), and independent spring suspension (Fig. 33). In the Hotchkiss, driving and braking torque is taken through the front and rear springs. In the torque tube, the drive is taken through a hollow tube enclosing the propeller shaft and firmly connected at either end to the rear axle and transmission. In independent rear spring suspension, the rear axle housing is mounted on the frame. Universal joints, between the wheels and drive gears, are necessary to allow for the motion between the frame and wheels. The vertical motion of each rear wheel is therefore independent of the other. Front wheels may be similarly mounted so their motion is independent.

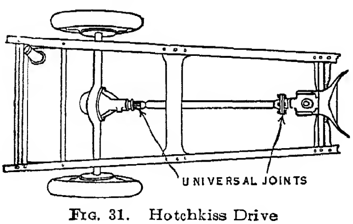

FIG. 31. Hotchkiss Drive

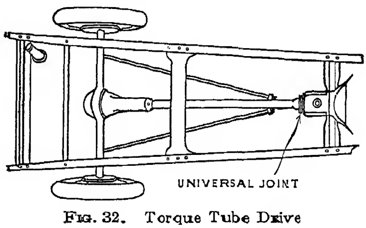

FIG. 32. Torque Tube Drive

Deflection of Semi-elliptic Springs may be found from the beam formula $D = WL^3/48EI$, where D = deflection, in.; W = weight, lb.; L = length, in.; E = modulus of elasticity; I = moment of inertia. The initial deflection so found determines the period of vibration. An approximate formula for the period of semi-elliptic springs is $V = \sqrt{35{,}300/D}$, where D = initial deflection, in.; V = period, vibrations per min. For rear springs, $V < 90$ gives good riding characteristics. In semi-elliptic front springs V should be more than double the rear to prevent resonance between the front and rear springs causing a pitching motion. In individual front wheel suspension, the front and rear springs can be about the same, which eliminates pitching. To control the springs, shock absorbers are used, some of which may be adjusted or are self-adjusting for different types of roads.

Factors other than springs contributing to good riding quality are: 1. Low unsprung weight; 2. Low center of gravity; 3. Long wheel-base; 4. Soft springs; 5. Good shock absorption; 6. Rebound control; 7. Large section tire; 8. Proper weight distribution; 9. Adjustable seats; 10. Proper seat cushions and springs.

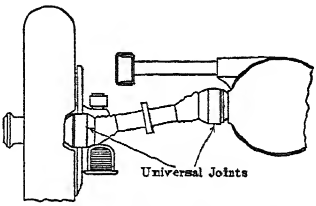

FIG. 33. Independent Rear Spring Suspension Drive

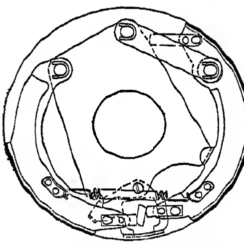
BRAKES must be able to stop the car quickly from any speed at which it may be driven, with good control and without undue change in the rate of deceleration. They must be able to withstand continuous operation to keep the speed low on long grades and to hold a parked car stationary. Legal requirements call for two brakes, a hand-lever-



G. 34. Two-shoe Brake

FIG. 35. Three-shoe Brake

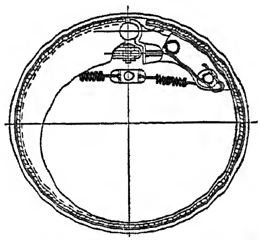


FIG. 36. Internal Band Brake

operated parking and emergency brake, and a foot-pedal service brake. Brakes on all four wheels always are used. As a rule, automobile brakes are (1935) of the internal type. Details of design vary greatly. Fig. 34 shows a two-shoe, and Fig. 35 a three-shoe type. Fig. 36 is an internal band type. Fig. 37 is an internal hydraulic brake.

The brakes must dissipate the kinetic energy of the moving car by converting the energy into heat, which must be radiated by the drum surface. The energy at maximum speed ranges from 600,000 ft.-lb. in a small car to 2,000,000 ft.-lb. in a large one. A stop from maximum speed generates from 0.70 to 0.90 B.t.u. per sec. per sq. in. of drum surface. Fig. 38 shows the stopping distances from various speeds at various rates of deceleration. Fig. 39 shows desirable limits of pedal pressure and deceleration. Requirements for a good brake are: 1. Minimum variation under conditions of operation; 2. Low pedal pressure; 3. Pedal pressure proportional to retardation; 4. Smooth and quiet action; 5. Permanent equalization; 6. Long life and infrequent adjustment; 7. Accessibility and simplicity of adjustment.

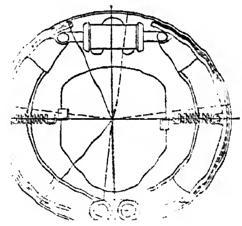

FIG. 37. Internal Hydraulic Brake

Brake Linings have much to do with meeting the above requirements. Three general types are used: Woven asbestos, impregnated with oxidizing oils; folded and rubberized asbestos cloth; molded homogenous mixture of asbestos fiber with other materials to

act as a binder and govern the coefficient of friction. The characteristics of these types are: *Woven Linings.* Wear well; easy to install; coefficient of friction gradually increases as lining wears. *Folded Linings.* Generally increase and decrease in friction value as wear progresses through the layers of cloth and compound. *Molded Linings* (flexible) usually have a higher friction coefficient than hard, dry linings and vary more with temperature changes. Hard, dry linings use a phenolic or bakelite type of binder instead of volatile oils, rubber or gums; wearing characteristics are excellent. Fig. 40 shows variation in coefficient of friction with speed, load and temperature of several lining materials.

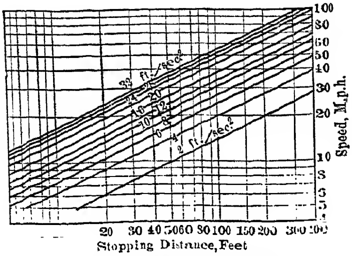

Fig. 38. Stopping Distances at Various Deceleration Rates

Drum material and design materially affect brake operation. With severe service, scoring is a problem. Cast iron, or steel with a centrifugally-cast inner layer of cast iron, is much used to resist scoring. Deep drawing steel (S.A.E. 1010 or 1025) also is used.

The division of applied effort between the front and the rear wheels depends on wheelbase, height of center of gravity, distribution of car weight on front and rear wheels and coefficient of friction between tires and road. The weight transfer, due to deceleration, also should be considered for which Fig. 41 may be used.

Example.—Assume static weight distribution to be: Front wheels, 40%; rear wheels, 60%; r = (height of center of gravity) ÷ wheel-base = 0.20; deceleration = (25 ft. per sec.)². *Solution.*—From the intersection E of the 40% line and line r = 0.20 for front wheels, lay off on the 40% line a distance EF = (25 ft. per sec.)², according to scale shown. At F erect a perpendicular to EF, intersecting r = 0.20 (front wheels) at G. Project G horizontally and read the new percentage of weight on front wheels as 55.5%. Percentage of weight on rear wheels = 100 − 55.5 = 44.5%. If the coefficient of friction between tires and road is such that (25 ft. per sec.)² is the maximum deceleration possible, the distribution of brake effort should be 55.5% front and 44.5% rear in order to obtain the maximum deceleration.

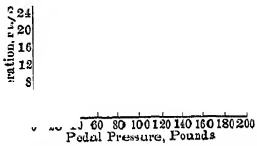

Fig. 39. Relation of Deceleration and Pedal Pressure

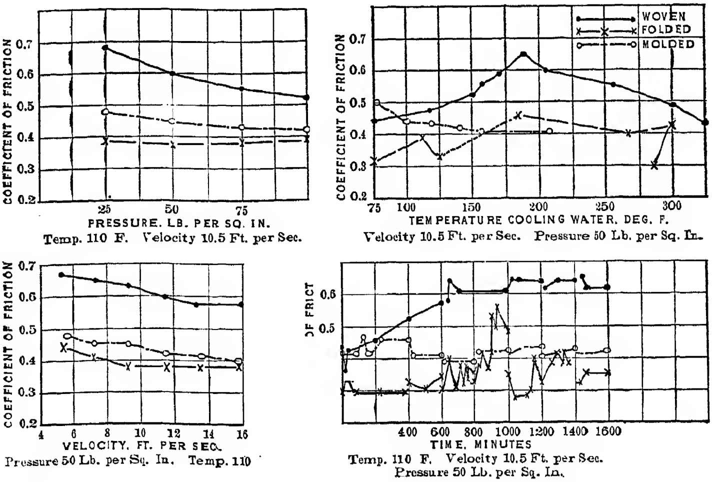

Fig. 40. Relation of Coefficient of Friction, Speed, Load and Temperature of Various Brake Linings

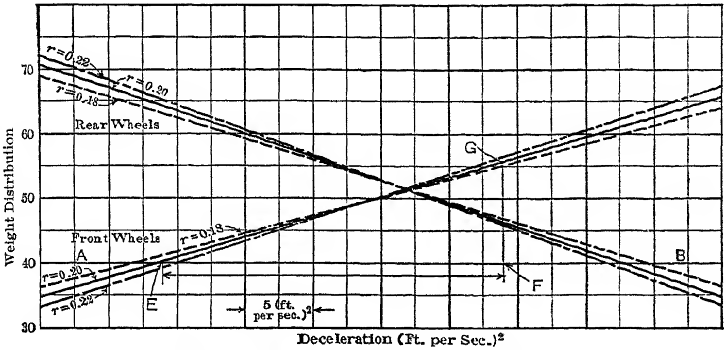

FIG. 41. Weight Transfer Due to Deceleration

The Internal Brake depends on self-actuation for part of the low pedal pressure necessary. The self-actuating brake produces a retarding force greater than the product of the normal pressure due to the applied force and the friction coefficient of the lining, due to a wedging action between shoe and drum. Variations in other parts of the brake limit self-actuation to about 50%.

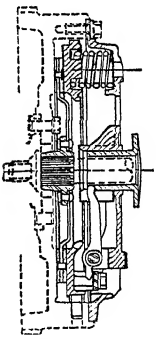

FIG. 42. Single Disc Clutch

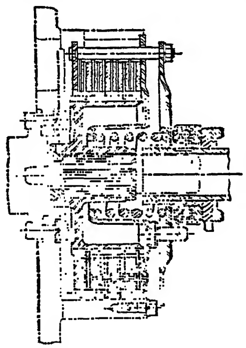

FIG. 43. Multiple Disc Clutch

Pedal Pressure is transmitted to brake shoes by either a mechanical or a hydraulic system. Both should have high efficiency to obtain low pedal pressure. Retardation should be proportional to pedal pressure, with an initial pressure of not over 25 lb. and preferably 10 to 15 lb. In the larger and heavier passenger cars, trucks and buses, a servo or auxiliary mechanism is sometimes desirable to obtain low pedal pressures. Compressed air, manifold vacuum or a mechanical device, driven from the engine or drive shaft, variously are used. The servo-brake should give proportionality of effort equivalent to a mechanical system, and should positively and accurately control the auxiliary power.

CLUTCHES.—Many types, including conical, internal expanding, band, single and multiple disc clutches have been used on automobiles; the last two almost universally are used (1935). For small and medium-size cars the single dry-disc clutch gives a simple design with few parts. Fig. 42 shows a typical design. For heavier cars, multiple disc clutches, Fig. 43, sometimes are used.

The torque-carrying capacity of a clutch is approxi-

where T = torque, in.-lb.; f = coefficient of friction; p = unit pressure between plates, lb. per sq. in.; A = area of contact, sq. in.; r_1 = outside diam. of disc, in.; r_2 = inside diam. of disc, in.

Fig. 44 shows the relation between torque carrying capacity and clutch pressure plate displacement of two different clutches.

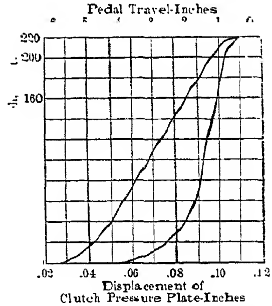

FIG. 44. Relation of Torque Carrying Capacity and Pressure Plate Displacement

PROPELLER SHAFT or drive shaft transmits engine torque from the transmission to the rear wheels. It usually is of plain carbon steel. In the torque tube drive, it is enclosed in the torque tube, and in the Hotchkiss drive it is open. Propeller shafts are made both solid and hollow. The exposed shaft in the Hotchkiss drive is usually a hollow drawn tube.

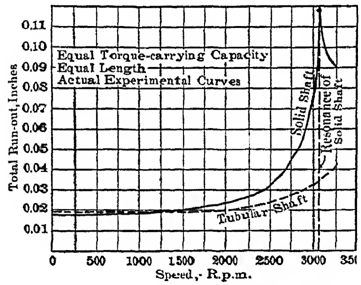

Fig. 45. Run-out of Tubular and Solid Propeller Shafts

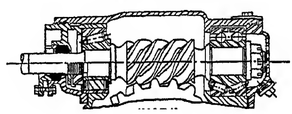
For calculating stresses in the shaft the following formula is used: $M_t = S_r I_p / r$, where M_t = torque, in.-lb.; S_r = shear stress, lb. per sq. in.; I_p = polar moment of inertia of shaft section; r = radius of shaft, in.

One of the greatest difficulties in propeller shafts is the tendency to whip and cause noise at high engine speeds. Whip is due to shaft unbalance, lack of rigidity and natural frequency of vibration. Hence, high rigidity in the shaft and good initial balance are necessary, together with a resonant speed above that of the engine operating speeds. The natural frequency of a shaft with hinged ends, *i.e.*, where universal joints are used, is $F = (\pi/2L^2)\sqrt{EIg/A\gamma}$, where F = natural frequency, cycles per sec.; L = length of shaft, in.; E = modulus of elasticity = 30×10^6 for steel; I = moment of inertia of the shaft section = $\pi d^4/64$ for solid round section; g = acceleration of gravity = 32.2; A = area of shaft section, sq. in.; γ = density of material, lb. per cu. in.

Since a tubular shaft is more rigid and has a higher natural frequency of vibration, the amplitude of vibration will be smaller and come at a higher engine speed. Fig. 45 shows the amplitude of vibration at the center of a shaft or the "run out" for a solid and tubular shaft used on the same car.



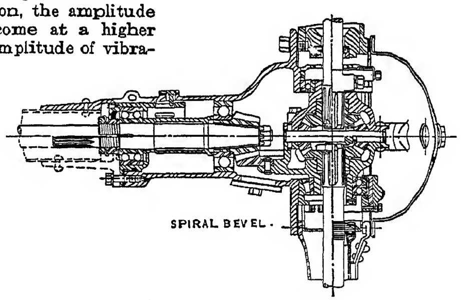


Fig. 46. Rear Axles

REAR AXLES.—The final drive is through a gear reduction which varies with the type and use of the vehicle. The most common type used (1935) is the spiral bevel gear. To lower the center of gravity, the worm and hypoid gear is used sometimes. Worm gears are used on trucks and buses, which also use double reduction units with internal gears or combined spiral and spur gears. Fig. 46 shows worm and spiral bevel types. Both hypoid and worm gears have much more sliding friction than spiral bevel gears, run hotter and require better lubrication. Fig. 46 also shows the application of roller, tapered roller, or ball bearings in the rear axle.

Table 10 gives comparative test results on three types of rear axles installed on the same chassis. A speed of 35 m.p.h. at road torque was used in all tests, with mineral oil lubricant.

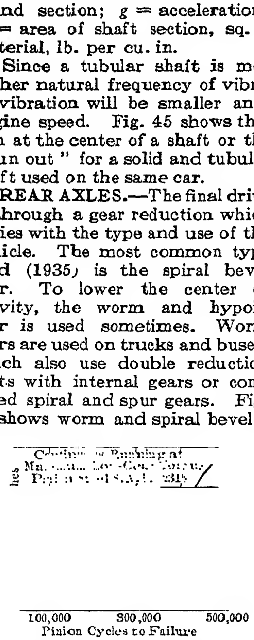

Fig. 47. Effect of Case Depth on Fatigue Resistance of Spiral Bevel Gears

Passenger cars mostly use spiral bevel gears. Pinion material is somewhat better than the gear material to withstand the greater stress. Heat treatment of gears materially affects fatigue strength. Fig. 47 shows results of tests on rear axle gears run under maximum low-gear torque. With an increase in case depth, resistance to fatigue failure increases, becoming less with the greater depths. This indicates that gear tooth durability depends

on a relatively thin surface layer. In gear design, fatigue strength, rather than static strength, should be considered. Fatigue strength of spiral bevel gears is affected by: 1. Bending stress (design elements of gear teeth, as circular pitch, tooth thickness, pressure angle and spiral angle); 2. Stiffness of carrier, bearings and gears; 3. Material and heat treatment; 4. Adjustment (position of total tooth contact area under load); 5. Machine accuracy and finish. The resistance to scoring and pitting is affected by these factors, and also by compressive stress, surface hardness, sliding velocities of teeth in contact, and physical and chemical properties of the lubricant. (See Gearing, Vol. 3 of this series.)

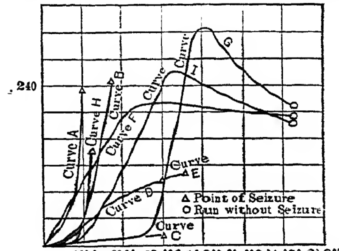

Fig. 48. Lubricant Tests. Mineral Oils: Curve *A*, viscosity, 48 sec. at 210° F.; curve *B*, 90 sec. at 210° F.; curve *C*, 200 sec. at 210° F. Mineral oils containing sulphur: Curve *F*, 40 sec. at 210° F.; curve *G*, 300 sec. at 210° F. Lard Oil: Curve D, 60 sec. at 210° F. Castor Oil: Curve *E*, 99 sec. at 210° F. Fluid Grease containing mineral oil and soap: Curve *H*, 500 sec. at 210° F., and 2500 sec. at 100° F. under 20 lb. per sq. in. Fluid Grease containing mineral oil, soap and sulphur: Curve *I*, 90 sec. at 210° F. and 1500 sec. at 100° F. under 20 lb. per sq. in.

Petroleum oils, free from excessive water, sediment, acid or other substances detrimental to proper performance, are used for rear axle lubrication. Fillers, as talc, pulp, cork, fuller's earth, graphite, mica or asbestos should not be used. The grade of oil is designated by S.A.E. viscosity numbers from 80 to 250. S.A.E. 80 and 90 are for extremely low temperatures. S.A.E. 250 is extra heavy for extremely high temperatures. S.A.E. 110 and 160 are for more normal temperatures.

In some rear axles what are known as E.P. (extreme pressure) lubricants are necessary. When loads are such as to cause a failure of fluid film lubrication, seizure and galling occur. A small percentage of some other material, as sulphur, will prevent seizure and permit carrying of loads two or three times heavier than can the mineral oil alone. Fig. 48 from Symposium on Developments in Automotive Materials, Regional Meeting A.S.T.M., Detroit, March, 1930, gives results of tests of a number of lubricants of varying viscosity and chemical composition.

TRANSMISSION.—Fig. 49 shows a typical 3-speed spur-gear transmission. Table 11 gives efficiencies of such a transmission. To make gear shifting easier for the driver, synchro-mesh transmission is used in the U. S. and England. In synchro-mesh transmission either two mating gears or dog clutches are brought up to an equal speed by a small cone clutch before they are engaged. A small differential in speed of the two mating members just before engagement insures that gear or clutch teeth will not meet end to end. In the constant-mesh type, helical gears may be used to give quiet operation. Synchronization between second and third, shifting up or down, is most used but synchronization on all speeds has been used.

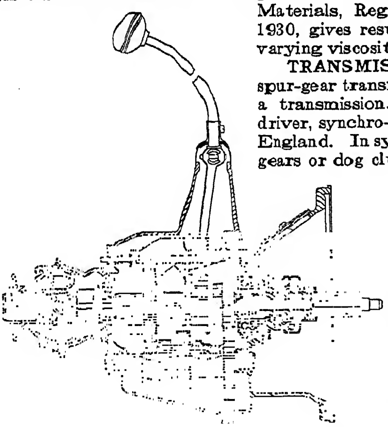

Fig. 49. Transmission and Hand Control

For ease of operation in shifting gears, a vacuum-operated clutch, Fig. 50, also is used. An interconnection between clutch and throttle engages or disengages the clutch. In the system shown, with the con-

trol button pressed down and the foot removed from the throttle, the clutch is disengaged, and gears can be shifted without depressing the clutch pedal, or the car can coast with the rear wheels disconnected from the engine. A free-wheeling device or over-running clutch also is used to obtain coaster action and easy shifting. Fig. 51 shows a roller type mechanism. When the engine is throttled and the car tends to go faster than the engine, the free-wheeling device disconnects them. A lock-out device prevents free-wheeling down hills and allows use of the engine as a brake.

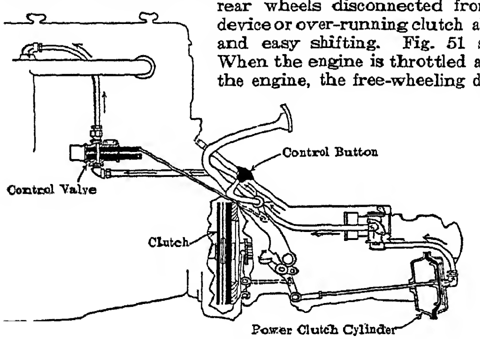

Fig. 50. Vacuum-operated Clutch

STEERING GEAR AND FRONT SUSPENSION.—Automobiles are steered by the divided axle or Ackerman system. The front wheels, suspended from the ends of the front axle, pivot around the king pins. The front axle must sustain the weight of the car and the braking torque. It usually is of I-section in the center, to carry the load, tapering to a circular section outside of the spring hangers to take the braking torque. Fig. 52 shows a typical steering system.

Independent Front Wheel Suspension improves riding quality and helps eliminate front wheel shimmy, wheel fight and tramp. Fig. 53 shows diagrams of various types.

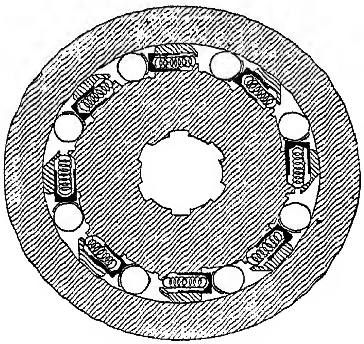

Fig. 51. Free Wheeling Unit

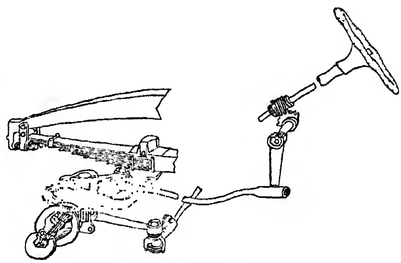

Fig. 52. Steering System

In the types used, a lower rate spring can be used in front than with the semi-elliptic type, resulting in better riding qualities. The spring parallelogram gives parallel wheel motion, but a change in tread. The spring and link type relieves springs of brake torque, but changes camber and track in proportion to the length of link. The link parallelogram type relieves springs of torque and allows proportioning length of links to obtain desired characteristics in camber and track changes. Swinging axles give large variations in

camber and track, but small lean of wheels on curves. Guided springs produce no changes in camber or track when vertical guides are used, but give hard steering.

The Geometry of the Front Wheels is chosen to give the best steering conditions on the steering system used. Wheels must be cambered, *i.e.*, the tops slightly further apart

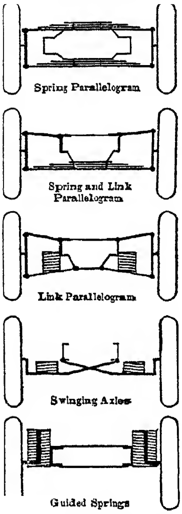

FIG. 53. Independent Front Wheel Suspensions

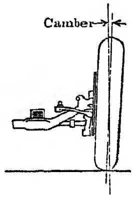

FIG. 54. Camber

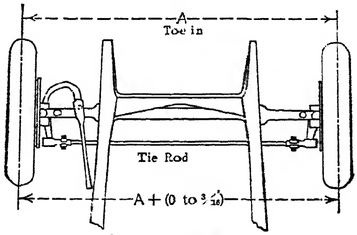

FIG. 55. Toe-in

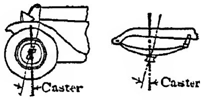

FIG. 56. Caster

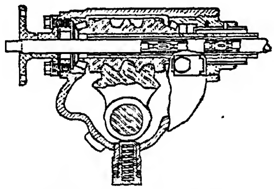

FIG. 57. Worm and Sector Steering Mechanism

than the bottoms (Fig. 54). The front of the wheels " toe-in," *i.e.*, are closer together than the rear (Fig. 55). The front axle and king pin is tilted backward (caster) so the bottom is further ahead than the top (Fig. 56). Toe-in varies from 0 to $^3/_{16}$ in. measured at the outer diameter of the wheels. The tie rod is adjustable to vary this factor. Camber is used to bring the contact points of tires and road directly under the center of the king pins to give easy steering. It is designed into the car by making the angle between king pin and the front axle end other than 90°. In practice, camber is measured as the angle between the king pin axis and the vertical axis of the wheel. Camber varies between 0.2° and 1.5°.

Tilting the front axle gives a caster effect by bringing the point of tire contact with the road at a point back of a line drawn through the center of the king pin. Caster varies from 1° to 4°, although a negative caster has been used.

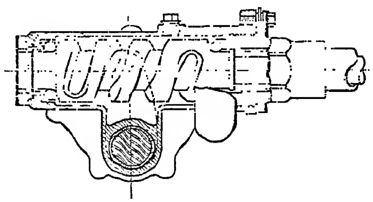

FIG. 58. Cam and Lever Steering Mechanism

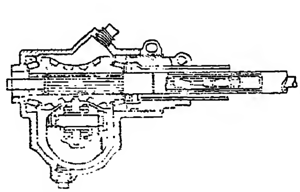

FIG. 59. Worm and Roller Steering Mechanism

Steering Mechanism.—The wheels are steered by a reduction mechanism. The most common types are: 1. Screw and nut; 2. Worm and sector (Fig. 57); 3. Cam and lever (Fig. 58); 4. Worm and roller (Fig. 59).

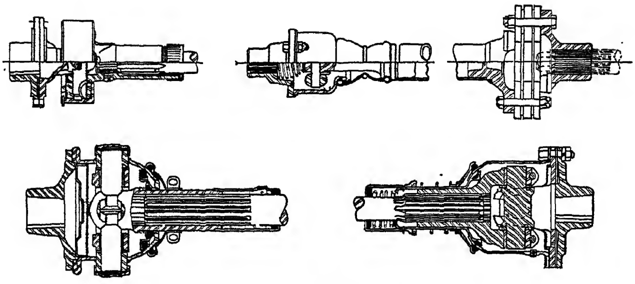

FIG. 60. Universal Joints

The ratio of the reduction unit ranges from 12 : 1 to 19 : 1; it is highest on large cars. From full left to full right, the arc of the steering wheel varies from 1000° to 1500° and the arc of the front wheels from 55° to 70°. The efficiency of the gear unit has much to do with the ease of steering. Factors affecting efficiency include type of unit, temperature, lubrication and use of anti-friction bearings. Average efficiencies for the various types of gear units are: Screw and nut, 20 to 40%; worm and sector, 40 to 50%; cam and lever, 40 to 65%; worm and roller, 60 to 70%. Under exceptionally good conditions, the efficiency of a worm and roller mechanism with anti-friction bearings may be as high as 85%.

UNIVERSAL JOINTS.—Where torque tube drive is used, only one mechanical universal joint is required. Where a Hotchkiss drive is used, a universal joint on both ends of the propeller shaft, either mechanical or fabric, is necessary Splines are used on the drive shaft end and a square section, key or spline on the transmission or rear axle end. Fig. 60 shows several types of universal joints.

8. ROAD TESTS

TYPES OF TESTS.—As yet, (1935) road tests have not been standardized by any society representing the automotive industry. Each manufacturer has developed his own procedure, and reported results of road tests are not comparative due to the wide variation in methods of conducting tests. Two distinct methods have been developed. One requires a specially built proving ground, where all conditions may be accurately controlled. The other depends on using public highways, with resulting interference from traffic. Highway tests sometimes are highly desirable, if test results demand conditions not easily duplicated at a proving ground. Two notable locations for special road work are: Uniontown Hill, in the mountains near Uniontown, Pa., often used when a long, almost even grade is required; Death Valley, Cal., 276 ft. below sea level, for road tests requiring extremely high temperatures, where for many successive days temperatures may be over 120° F., frequently reaching 130°.

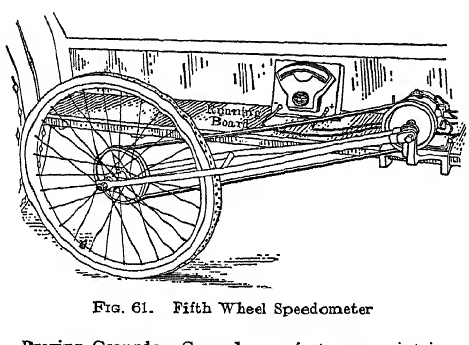

FIG. 61. Fifth Wheel Speedometer

Proving Grounds.—Several manufacturers maintain proving grounds where test conditions as well as procedure can be standardized exactly. To make results comparative, either the 2-door coach or 4-door 5-passenger sedan are used in all tests. These grounds are in a hilly district where various types of roads, including gravel, asphalt, concrete and dirt surfaces, may be built. Grades up to 30% are required. A straight stretch is necessary for acceleration, economy and speed tests. A speed loop is desirable where speeds in excess of 100 m.p.h. may be maintained. Proving grounds principally are used for comparative road tests of automobiles, and road tests of new models prior to production.

INSTRUMENTS AND EQUIPMENT FOR ROAD TESTS, in general, must be portable, not easily affected by rough usage, but equivalent in accuracy to laboratory instruments. Such conditions impose severe limitations on design and make instrumentation a subject of major importance.

The Fifth Wheel Speedometer (Fig. 61) gives accurate readings of speed in miles per hour. A bicycle wheel mounted in a frame clamped on the running board drives, through a web belt, a magneto whose open-circuit voltage is 6 at 1000 r.p.m., resistance, 100 ohms, and maximum speed 2000 r.p.m. The voltage is indicated on a voltmeter calibrated in m.p.h., one scale running from 0 to 50 m.p.h. and a second from 50 to 100 m.p.h. The connection between voltmeter and magneto is long enough to permit the meter to be held by the observer.

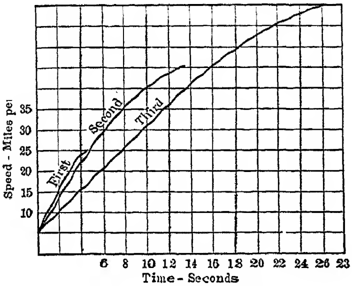

FIG. 62. Speed-Time Curve

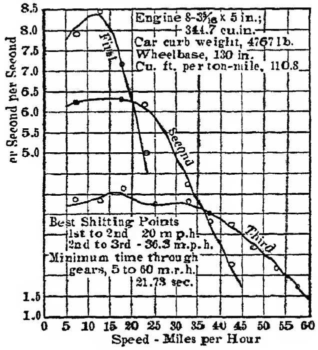

FIG. 63. Speed-Acceleration Curve

A variation of the above instrument incorporates a counter reading directly in feet traveled. A magnetic clutch operates the counter and a stop watch, to give simultaneous readings of speed in miles per hour, distance in feet and time in seconds. The maximum error in the distance covered was found to be 5 ft. in 1 mile; the average error was less than 2 ft. The data for the speed-acceleration curves, Figs. 62 and 63, in the three transmission ratios were obtained from the above instruments.

Fuel Economy Apparatus.—A good fuel economy measuring device consists of two 480 c.c. burettes, mounted side by side on a board and filled by an electric fuel pump mounted on the back of the board. A 2-way valve feeds gasoline from either burette to the carburetor directly, or to the fuel pump, depending on the fuel system used. This apparatus is used in connection with the distance recording device. Tests are run for one mile in opposite directions to average wind effect. Time (min. and sec.) and cu. cm. of fuel used are recorded. Readings start at 10 m.p.h., with 5 m.p.h. increments up to car speed. See Fig. 64.

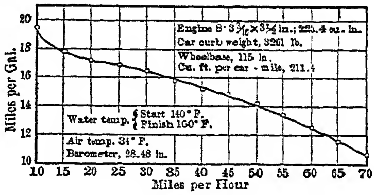

FIG. 64. Speed-Fuel-Consumption Curve

The Brake Decelerometer measures braking ability in terms of deceleration, ft. per sec. per sec., for a corresponding pedal pressure in pounds. Fig. 65 shows the essential parts; A is a 6-volt d.c. motor driving the recording paper; B is a fixed recording pen reading the zero position for pedal pressure pen C and deceleration pen D; E is the foot element for transmitting pedal pressure to spiral tube AA. Elements AA, F and E are filled with liquid. Pen D is so connected to an inverted pendulum that when the car slows down, and the pendulum moves forward, it moves across the paper in proportion to the deceleration rate. A device also is used to show the pedal travel in inches with deceleration.

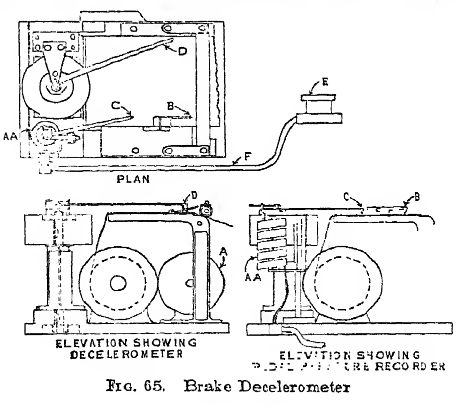

FIG. 65. Brake Decelerometer

Figs. 66 and 67 show results of tests under different conditions. Fig. 66 is the performance of a set of 4-wheel mechanical brakes when stopping from 50 m.p.h. with the brakes cold and hot. To heat the brakes prior to the test, they were applied with the throttle wide open, to reduce car speed to 20 m.p.h. Fig. 67 shows the result of stopping from 75 m.p.h. with a constant brake pressure.

Procedure for Obtaining Data on Road Tests

A driver and an observer are required for road tests. The tabulation (p. 14–83) shows the data and type of information most necessary for comparisons in road performance tests. These data usually are tabulated or plotted on curves. Instructions for each type of test follow.

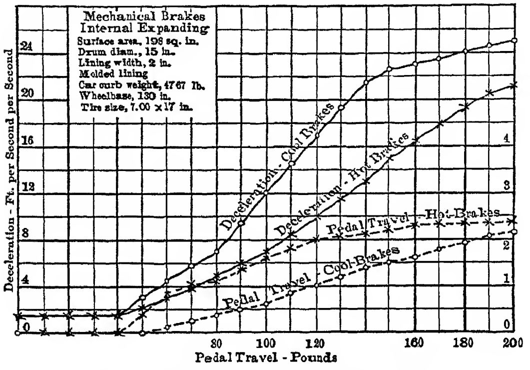

FIG. 66. Brake Curve at 50 Miles per Hour

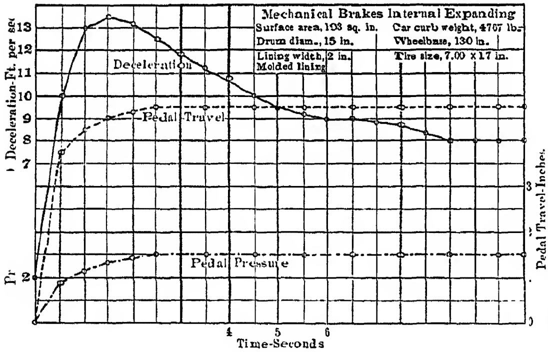

FIG. 67. Constant-pressure Brake Curve at 75 Miles per Hour

INSTRUCTIONS FOR OBTAINING GENERAL CAR DATA.—1. Obtain model number from instruction book or invoice, engine and serial number, tire size and make of car. 2. Bore and stroke will be obtained in garage. 3. Measure wheelbase from center to center of hub caps on each side. Obtain nominal wheel-base from instruction book. 4. Take curb weight with gas, oil and water to capacity; include tools and spare tire. This measurement is very important; care should be taken to get correct weight. Note weight of tools separately. 5. Oil capacity is quantity to fill to gage mark when oil has been drained through drain pet-cock. 6. Water capacity is capacity of block and radiator from level of drain-cock. 7. Obtain tire pressures from instruction book where possible, or compute from manufacturers' data. Computed pressures generally will be less than recommended pressures. 8. Turning diameter: Turn wheel hard over, and turn car around until it is traveling in a consistent circle; pour oil or water on tire tread to mark the ground, and measure diameter of resultant circle at center of tread. 9. Arc of steering wheel is angular travel from full right to full left, omitting lost motion at each end. 10. Number of feet for ten turns of the rear wheel—taken after inflating tires to correct pressure and loading car with 450 lb. weight. Take reading of rear tires on each side and record average. 11. Gear ratios: Obtain by jacking up *one* rear wheel and counting revolutions of distributor rotor while wheel is turned through 20 rev. Multiply readings by two and record. Count pinion and gear teeth and record. 12. Moment of inertia: Obtain by removing one front and one rear wheel, placing each separately on a standard disc of known moment of inertia and take at least two measurements of the time of 10 periods. Repeat for 10 periods for the standard disc alone. 13. Clearance data: Inflate tires to correct pressure. Put car on level surface and measure clearance of front and rear axle and fly-wheel housing. Measure distance from fly-wheel housing to center of front axle, from point on fly-wheel where clearance was measured. 14. Spring ride: Measure from bumper to bumper, *i.e.*, the maximum possible deflection is desired; measure length of springs from center to center of eyes. 15. Service and emergency brakes: Record whether they are 2-wheel, 4-wheel, transmission; whether hydraulic or mechanical; whether internal expanding or external contracting. Record

length and width of linings. If lining is in sections, record length of each section. Give drum diameter at point of contact. 16. Widest section of frame: Record measurements of channel section through the frame at its heaviest point.

DATA NECESSARY IN ROAD TESTS.—Information necessary for complete road tests is tabulated below.

DIMENSIONS

General Car Data
- Car manufacturer
- Body style
- Model No.
- Engine No.
- Serial No.
- Wheel-base—right and left, in.
- No. of cylinders
- Bore and stroke, in.
- Displacement, cu. in.
- Gas tank capacity, gal.
- Oil capacity, gal.
- Water capacity, gal.

Curb Weight, lb.
- Right front
- Left front
- Right rear
- Left rear
- Total

Tires
- Kind and size, in.
- Pressure, front and rear, lb. per sq. in.

- Rolling diameter, ft.
- Lb. per cu. in. displacement
- Lb. per in. of wheel-base

Gear Ratios
- First, second, third, fourth, reverse.
- Engine r.p.m. per m.p.h.
- Piston travel, ft. per car-mile
- Displacement, cu. ft. per ton-mile
- Displacement, cu. ft. per car-mile

Service Brakes
- Type
- Lining length, front and rear, in.
- Lining width, front and rear, in.
- Drum diam., front and rear, in.
- Braking surface, sq. in., front and rear

Emergency Brake
- Type
- Lining length, in.
- Lining width, in.
- Braking surface, sq. in.
- Minimum road clearance
- Front and rear axle, in.

Spring Ride
- Right front, in.
- Left front, in.
- Right rear, in.
- Left rear, in.

Front Spring
- Length and width, in.
- No. and thickness of leaves, in.

Rear Spring
- Length and width, in.
- No. and thickness of leaves, in.

- First speed, 5–25 m.p.h.

Hill climb on 7 to 11% grade; start at 10, 20, 30 m.p.h.
- Maximum speed, m.p.h.
- Speed at top of hill, m.p.h.
- Time, sec., to go over top

Fuel Consumption
- From 5 m.p.h. to max. speed, by 5 m.p.h. intervals

Procedure for Car Performance Tests

BEFORE LEAVING GARAGE.—1. Check oil, water and gas; see that oil is at proper level, and that radiator and gas tank are full. Check tire pressures, and inflate to standard pressure for car under test. See that brakes do not drag. 2. Install thermometer in water outlet from engine. 3. Attach fifth-wheel speedometer; load car with sufficient ballast to bring weight of instruments, passengers and ballast up to 450 lb. Observer should have a good 30-sec. single-hand stop-watch and performance data sheets.

Warm Up.—1. Drive large cars 8 or 10 miles at speed of 30 to 40 m.p.h., and small cars 25 to 35 m.p.h. to warm oil and reduce friction before starting tests.

On Straightaway.—1. Make several acceleration runs at from 10 to 25 m.p.h. at different temperatures, from cool to boiling, to find temperature of best performance; record best temperature on data sheet, and hold to it on subsequent runs within $\pm 10°$ F. 2. Run at least five consistent accelerations in each direction from 10 to 25 m.p.h. Car velocity should not exceed 8 m.p.h., preferably less, when accelerator is opened. If car is braked to reduce speed, it should roll for an instant before accelerating. Record time in seconds, beginning when fifth-wheel speedometer pointer passes 10 m.p.h. and ending when it passes 25 m.p.h. 3. Repeat (2) for 10–45, 5–60, 10–60, 20–60, 30–60 m.p.h. 4. Find and record minimum speed, in both directions, at which car will idle, *i.e.*, minimum speed with accelerator as far as possible from floorboard. 5. Find and record lowest speed in each direction from which car will accelerate smoothly without bucking. This speed generally is less than that found by (4); usually car must be braked to obtain it. Driver should brake car to speed desired by observer and note whether or not the get-away is good. Trials at different speeds usually will show a certain well-defined speed below which car will not accelerate; this speed is recorded.

Hill Climb.—Make three series of tests on a grade, starting at 10, 20 and 30 m.p.h., respectively. Take readings, in seconds, at each starting speed, of time to climb grade, maximum speed, and speed at end of grade.

Maximum Speed.—Return to straightaway and record maximum speed in each direction; run sufficient distance to maintain constant speed for 0.1 to 0.2 mi.

General Notes.—Record date, hour, temperature and speedometer mileage midway of test, and approximate direction and velocity of wind. In general, tests should not be made with wind stronger than moderate, except in cases of brake tests. Observers should sign all test sheets.

Procedure for Making Economy Tests

BEFORE LEAVING GARAGE.—Follow same procedure as for car performance test. Also install fuel measuring burettes and tank in car. Disconnect carburetor from gasoline pump; connect burettes to carburetor. Provide fuel economy data sheets.

On Straightaway.—1. Make at least four trips from end to end of straightaway to warm oil and reduce friction. Make final trip at speed at which first test run is to be made. 2. To start test, fill one burette to zero mark, engine running meanwhile on other burette. Bring car up to desired speed, and have it constant, before reaching starting post. On passing starting post, throw valve on lower 3-way cock to take fuel from first burette, and start stop-watch. On passing finish post reverse valve on lower 3-way cock and stop stop-watch; record time and cu. cm. of fuel used. 3. Length of course should be one mile. Start first test run at 10 m.p.h.; speed of succeeding test runs should increase by 5 m.p.h. increments unless otherwise instructed. Make two runs in each direction at each speed, to and including 35 m.p.h., and one run in each direction at a higher speed.

General.—In addition to time and fuel readings, data sheet should show: Car number, name and special features; weight of instruments and passengers; date, barometer, temperature, direction and approximate strength of wind; odometer.

Procedure for Brake Tests

BEFORE LEAVING GARAGE.—1. Run car on brake testing machine; adjust and properly equalize brakes to slide the wheels. Check on pavement outside of garage. 2. Install decelerometer and storage battery in car; attach pedal pressure element to brake pedal. See that decelerometer motor runs freely.

On Straightaway.—1. Level decelerometer; deceleration pen should read zero with car standing still. 2. To start test, bring car to speed, start decelerometer motor, declutch and apply brakes. 3. Take readings from zero pedal pressure to maximum; increments should be as uniform as possible. Make tests in both directions to eliminate effect of wind. About 20 properly spaced readings usually are sufficient, though more are better.

In Office.—1. Read data from rolls by celluloid template in conjunction with the fixed base pen of the decelerometer; take readings where deceleration and pedal pressure are approximately constant; average slight variations by a light average pencil line, and read from this line. 2. Plot points obtained and draw an average curve.

9. ENGINE TESTS

The procedure used in engine testing varies in the different laboratories. Since so many variables materially affect results, information obtained at different places is not at all comparative unless a standard procedure is used. The General Motors Corporation has adopted an engine test code which is used in the engineering departments of its divisions. An abstract of this code follows.

FIG. 68. Engine Test Log Sheet

GENERAL ENGINE INFORMATION.—Information on engine specifications, equipment and settings shall be obtained at the time the test is made and permanently attached to the test data. See Fig. 68.

VALVE LIFT DIAGRAMS.—Valve lift diagrams for a representative cylinder shall accompany data for any standard test. A special curve sheet (Fig. 69) is suitable for plotting full lift diagrams and exaggerated diagrams for the ramp portion of the lift curve.

REQUIRED ENGINE EQUIPMENT.—1. Transmission and clutch (omitted in dynamometer testing). 2. Intake system includes, when standard for the engine: *a*, Hot air pipe; *b*, air cleaner; *c*, carburetor; *d*, choke valve (in open position); *e*, riser (uptake or downtake); *f*, manifold heat

control system; *g*, intake manifold. Item *a* may be omitted, if necessary, for volumetric test. If air measuring equipment is used, it is noted on log sheets.

EXHAUST SYSTEM.—Tests are made with and without mufflers. For tests with muffler, the standard exhaust system includes: *a*, Exhaust manifold; *b*, automatic heat valve; *c*, exhaust pipe; *d*, tail-pipe. For tests without muffler, the manifold is connected directly to dynamometer exhaust system.

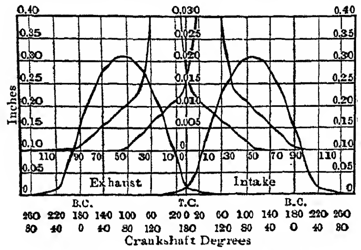

FIG. Valve Lift Diagrams

Cooling System.—The standard water pump is used, operated at normal speed; car radiator is omitted; standard cooling fan is used, driven at normal speed with normal belt tension. For the water heat-rejection test, direct cooling is required.

Ignition System.—Standard generator is used, operating at normal speed with leads grounded to eliminate charging; standard distributor and coil are used, even with manual control of spark.

Fuel System.—Standard fuel pump and carburetor are used.

Lubricating System.—Standard oil pump is used.

Engine Adjustments and Settings

Throttle.—Most tests are made at full throttle. For tests at part throttle, arbitrary standard road power data are used, simulating level-road driving requirements. See Fig. 70. The curves are based on the formula

$$\text{Hp.} = (0.017W + 0.018AV^2)(V/375)$$

W = car weight, lb. based on 15 lb. per cu. in.; A = projected frontal area, sq. ft.; V = road speed, m.p.h.; K and K_1 = constants. See Table 12 for values of K and K_1.

The curves, Fig. 70, give the power to be used in the road power tests. Torque may be calculated by the equation $Q = 5250\ \text{Hp.}/N$.

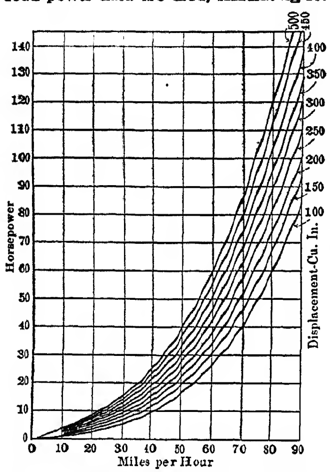

FIG. 70. Passenger Car Standard Road Power Data Based on Engine Displacement

Engine speed for a given road speed may be calculated from rear axle ratio and tire circumference, or assumed to be 50 r.p.m. per m.p.h., which is the average for passenger cars.

Carburetor.—The best compromise settings are determined and maintained constant throughout a series of tests. The following type adjustments are mentioned: *a*, Leanest for best torque, any condition; *b*, richest for best torque, any condition; *c*, combination of good idling at 200–300 r.p.m., and leanest for best torque at 1000 r.p.m.; *d*, variable fuel flow, any condition, to obtain the progressive effect of this variable over the range from best torque to best economy. Adjustment *c* is usually used.

Intake Manifold Heat Control where optional, is maintained in the *summer* position; where automatic, is so maintained.

Ignition Settings.—For all power tests, spark plug gaps and breaker clearances are adjusted standard.

Valve Lash is adjusted as specified by manufacturer. As the lash used in the car is not always suitable for dynamometer testing, it is necessary to check it under running conditions. Standard lash is used for the compression test.

Preliminary Engine Checking Procedure.—Prior to making any standard test: 1. Engine is

Table 12.—Values of K and K_1 in Horsepower Formula

500	7500	36.34	0.017	0.06541

thoroughly conditioned; 2. All engine equipment and settings are checked and recorded; 3. A performance check test is made.

FUELS AND LUBRICANTS. Fuels.—Special fuels are used for engines requiring them; normally, any good grade of fuel may be used. A fuel of given knock rating is not required, but knock rating must be stated.

Lubricants.—Any good grade of engine oil is used. It is required only that the viscosity be that recommended by the manufacturer for summer conditions.

ENGINE STABILITY.—Performance data are obtained under stabilized operating conditions. Sudden heat changes should be avoided. In any test, the series of runs should progress continuously. For any test run: 1. No data are taken until torque, speed and temperatures have been maintained without noticeable change for at least one minute; there should be no important change in these items during the test run; 2. No adjustments of engine settings are made during the run; 3. As an overall check, two separate torque readings are recorded, one before and one after recording all other data.

Torque, Speed and Power

TORQUE.—The electric cradle dynamometer is used. It should have absorption capacity and speed rating to permit testing under any simulated road condition.

SPEED.—Instrumentation. An accurately checked indicating tachometer is used for compression and friction tests. An accurately calibrated revolution counter operated from dynamometer or engine shaft and synchronized with a time measuring device is used for the power test.

Time.—The conventional stop watch is satisfactory. Time units operated from stabilized alternating-current circuits give a finer degree of precision.

A Speed Measurement Interval of at least 40 sec., preferably not less than 1 min., is used when measuring speed with the automatically synchronized counter-watch combinations; for hand operation, not less than 60 sec.

Limiting Speed is defined either by maximum car speed or by limitations of testing equipment.

Computations

Notations.—B.Hp., F.Hp., I.Hp. = brake, friction and indicated horsepower, respectively; L = average of two torque scale readings, lb.; N = r.p.m.; K = dynamometer constant; R, r = torque scale arm, ft. and in., respectively; D = engine displacement, cu. in.; P = M.E.P. = mean effective pressure, lb. per sq. in.; Q = torque, lb-ft.; B_c = carburetor air pressure, in. Hg, absolute; e = water vapor pressure, in. Hg, absolute; T_c = observed, and T_s = standard, carburetor air temperature, deg. F., absolute; E_m = mechanical efficiency.

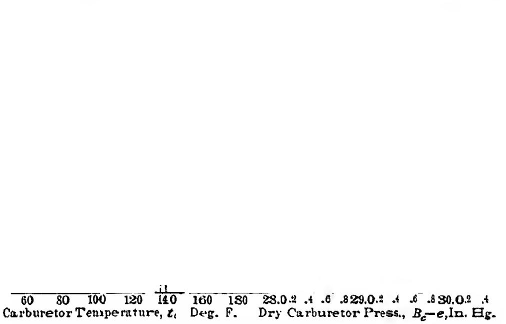

FIG. 71. Power Correction for Pressure, Humidity and Temperature

OBSERVED POWER.—B.Hp. = $N\,L/K$. $K = 5250/R = 63000/r$. K = 6000 for $r = 10.5$; 4000 for $r = 15.75$; 3000 for $r = 21$. For 4-stroke cycle engine, Hp. = $DPN/792{,}000$ = $0.0001903\,NQ$. Torque is computed directly from torque scale reading. $Q = LR$. For 4-stroke cycle engine, Q = 5250 Hp./N = $5250\,L/K$ = $DP/150.8$. Mean effective pressure is computed directly from torque scale reading. For 4-stroke cycle engine, $P = 150.8\,LR/D$ = $150.8\,Q/D$ = 792,000 Hp./DN = $792{,}000\,L/DK$. A curve is plotted of observed motoring F.Hp.* *vs.* speed. Values from this curve for the speed of the brake power test are added to brake power to obtain indicated power.

CORRECTED POWER.—Full-throttle power data, including power at borderline detonation, are corrected to standard conditions for carburetor air. Part-throttle data are not corrected. Standard pressure is 29.92 in. Hg; atmospheric water vapor pressure standard temperatures are 60° F., 103° F., 150° F. The standard for stock tests is 103° F.

Combined correction factor for indicated power = $F_{ci} = [29.42/(B_c - e)]\sqrt{T_c/T_s}$. See Table 13 and Fig. 71.

Combined correction factor for full throttle brake power = $F_{cb} = [29.42/(B_c - e)]\sqrt{(T_c/T_s)} + E_m$. See Table 14.

Mechanical Efficiency is based on corrected power.

SPARK TIMING.—The measured timing for a representative cylinder is sufficient; timing for all cylinders is often desirable. The spark control is rigged to permit maintenance of any

Table 14.—Full Throttle Brake Power Correction Factors for Pressure, Temperature and Humidity

(Based on $E_m = 0.85$. 103° F. Datum Temperature)

NOTE: These factors are to be applied directly to full throttle brake power or torque. They should not be used for part throttle power.

Carb. Temp., deg. F.	Dry Carburetor Pressure, in. of Mercury

desired manual setting of the distributor head. For automatic control, distributor head is clamped at required initial timing.

DETONATION.—Three arbitrary grades of intensity are used. 1. None (N); 2. Incipient or borderline (BL), which is that condition where detonation is barely perceptible in the most offensive cylinder; 3. Objectionable (OBJ) which is that condition where intensity is greater than incipiency in any cylinder.

Fuel

FUEL CONSUMPTION INSTRUMENTATION.—Either weight or volumetric method is used.

FUEL TEMPERATURE.—With volumetric method, fuel temperature is measured by a glass-stem thermometer at a point adjacent to the pipettes.

MINIMUM FUEL MEASUREMENT INTERVAL is the same as for speed measurement. Speed and fuel are measured during the same interval.

Computations

Notation.—w = weight of fuel, lb.; v = volume of pipette, c.c.; sp.gr. = specific gravity of fuel at pipette temperature; W = fuel rate, lb. per hr.; t = measuring interval, sec.; D_s, D_o = standard and observed moist-air carburetor density, respectively, lb. per cu. ft.; F_s = specific fuel consumption, lb. per Hp.-hr; Q = torque. lb.-ft.; L = torque scale reading, lb.; n = engine revolutions for w lb. of fuel.

Fuel rate is expressed in lb. per hr. With the volumetric method, weight of fuel in pipette = $w = v \times$ (sp. gr.)/453.6. $W = 7.94\ v \times$ (sp. gr.)$/t$. Specific gravity of commercial gasolines is about 0.74 at 60° F.; the rate of decrease is about 0.00033 per deg. F. increase in temperature. Observed hourly fuel rates may be presented with corrected power data, but should be so designated. The correction factor to standard carburetor air conditions = $\sqrt{D_s/D_O}$. D_s for 60° F. = 0.07581; for 103° F. = 0.07002; for 150° F. = 0.06462. $F_s = W/\text{Hp.} = 315{,}000\ w/Qn$ = (for 21-in. dynamometer torque arm) $180{,}000\ w/Ln$; = (for 15.75-in. torque arm) $240{,}000\ w/Ln$. Observed specific fuel may be presented with corrected power data, but should be so designated. Corrected data may be obtained by correcting the observed rate and dividing by corrected power.

Air Consumption

INSTRUMENTATION.—Standard intake system is used. Air meter is connected to an air-tight box surrounding carburetor. Satisfactory instruments are the gasometer, smooth approach orifices or thin-plate, sharp-edged orifices of the Durley type. Restoration of atmospheric pressure at carburetor may be obtained by a motor-driven blower between orifice tank and carburetor. To reduce pulsations it is customary to use a large-volume surge tank between engine and air meter.

Computations

Notation.— D = density, lb. per cu. ft.; B_C = corrected barometer, in. Hg, absolute; T = temperature, deg. F., absolute; e = water vapor pressure, in. Hg, absolute; V = volume flow, cu. ft. per min.; W = weight rate, lb. per hr.; d = orifice diam., in.; C = orifice discharge coefficient; p = orifice depression, in. of water; A_s = specific air consumption, lb. per Hp.-hr.; E_v = volumetric efficiency; S = engine displacement, cu. in.; N = engine r.p.m.; A/F = air-fuel ratio.

DENSITY.—For dry air, $D = 1.326\ B_C/T$; for moist air $D = 1.326\ (B_C - 0.378e)/T$; weight of dry air in 1 cu. ft. of moist air = $1.326(B_C - e)/T$. Neglecting moisture gives density values higher than actual. Where absolute pressure differs but slightly from barometer, vapor pressure e is assumed equal to atmospheric pressure e.

AIR RATE.—For a displacement meter, volume flow of moist air at meter intake density is obtained directly; weight flow of moist air = $W = 79.56\ V(B_C - 0.378\ e)/T$. This is used to determine volume flow at carburetor density. The weight flow of dry air = $W = 79.56\ V(B_C - e)/T$. For orifice meters, volume flow of moist air = $V = 5.98\ dC\sqrt{p/D}$; using moist-air density at meter intake, $V = 5.195\ d^2C\sqrt{PT/(B_C - 0.378\ e)}$. Weight flow of moist air = $W = 60\ VD$. Computations are simplified by use of charts. Observed data may be presented with corrected power data, if so designated. Corrected data are obtained by correcting observed air rate, using the correction factor for indicated power.

Specific air consumption should be based on dry air rate. If so designated, however, moist air rate may be used. Specific consumption = $A_s = W/\text{Hp}$.

AIR-FUEL RATIO is based on the ratio of weight rates of air and fuel. Dry-air weight rate should be used, but moist-air weight rate may be used. Observed A/F data may be presented with corrected power data if so designated.

VOLUMETRIC EFFICIENCY is based on volume flow of moist air at carburetor moist-air density. E_v (for 4-stroke cycle engine) = $3456\ V/SN$. Observed E_v may be presented with corrected power data if so designated. Corrected E_v = observed $E_v\sqrt{T_s/T}$, where T_s = standard, and T = observed, carburetor temperature.

Temperatures

GENERAL INSTRUMENTATION.—Recommended equipment for measuring important temperatures includes: Mercury or alcohol glass-stem thermometers, thermocouple-potentiometer units, and constant-voltage, electric-resistance thermometers. Vapor or liquid-filled, distance-reading type thermometers are not recommended. Temperatures are measured in deg. F. The thermometer is shielded from radiant heat.

CARBURETOR AIR.—Reading usually is taken immediately inside air cleaner in the air stream, and used to compute power correction factors and volumetric efficiency. Standard car-

buretor air temperatures are 60° F., 103° F., and 150° F. The value 60° F. is retained for comparisons with published data corrected to this datum. The values 150 ° F. and 103° F. represent, respectively, approximate temperatures for V-type engines with carburetor in the V, and other engines. The odd value, 103 ° F. facilitates conversion of corrected data to and from the intermediate datum by adding or subtracting 4% for indicated power and 4.7% for brake power. The datum 103° F. is used for the stock test.

MIXTURE is measured at a representative point in intake manifold.

WATER TEMPERATURE.—Outlet temperature is measured near the point where water leaves the engine. Standard water outlet temperature is 165° F. for power and friction tests.

SUMP OIL preferably is measured at some point between entrance to oil pump suction pipe and the first pressure-fed bearing. For all standard tests under power, an adequate oil cooler is used to limit the temperature to 195 ± 5° F. Standard temperature is 165 ± 5° F. for the motoring friction test. See p. 14–94. For the motoring compression test it is required only that the temperature be above 100° F.

Pressures

GENERAL INSTRUMENTATION.—Glass-tube manometers usually are used for small differential pressures; calibrated Bourdon gages for the higher differentials. Single-leg inclined manometers, with compensated scale, are suitable for more exact measurements. Mercury is used for differentials greater than 1 in. Hg; for smaller differentials, a lighter liquid is used. For mercury, the top of the meniscus is read; for other liquids, the bottom.

SPECIFIC PRESSURES.—Barometer measurement at a central location is sufficient. A high-grade adjustable-reservoir mercury barometer is used. True pressure is obtained by correcting observed readings to standard temperature of 28.5° F. See Fig. 72. The standard for total pressure (dry air plus water vapor) is 29.92 in. Hg.

Carburetor Air Pressure usually equals barometric pressure. Water vapor pressure at carburetor is assumed equal to that measured in the atmosphere. Dry carburetor pressure is used in computing power correction factors; total carburetor pressure (dry air + water vapor) is used in correcting compression and computing moist air density. The standard for total carburetor pressure is 29.92 in. Hg.

Intake Manifold pressure is measured at a representative point in the manifold as determined for each engine, using a mercury U-tube manometer, suitably damped.

Exhaust Manifold pressure is measured at point in exhaust manifold near exhaust pipe flange, using a mercury U-tube manometer, with suitable damping and a water-condensing reservoir.

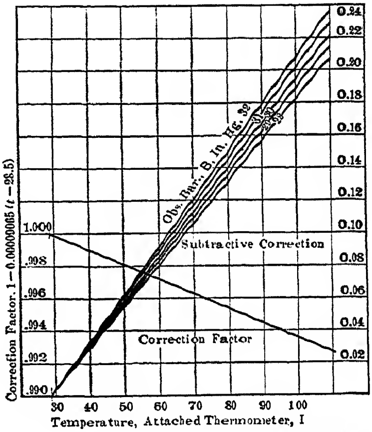

FIG. 72. Barometer Correction for Temperature

Humidity

INSTRUMENTATION.—A stationary wet-and-dry-bulb psychrometer, having a fixed-position fan giving a ventilation velocity of 10 ft. per sec., or more, past the wet bulb, is recommended.

COMPUTATIONS.—Water vapor pressure may be determined from the psychrometric chart (see p. 11–52) and equations on p. 1–08, using observed psychrometer temperatures. Vapor pressure is used in computing air density and power correction factors.

Water Heat Rejection and Circulation Rate

INSTRUMENTATION.—Direct cooling is required. The recommended set-up includes: Lagged water piping between engine and a lagged water reservoir, the latter suitably baffled to intimately mix make-up and circulation water; open-scale thermometers to measure water out, water in, make-up and overflow water temperatures; make-up water line leading to the reservoir, fitted with a fine control valve; overflow pipe for leading overflow water either to weighing-pan or drain; weighing-pan and scale. The *temperature method* (see below) of determining circulation rate is recommended.

Computations

Notation.—Heat rejection is expressed in B.t.u. per min.; specific heat rejection, in B.t.u. per Hp.-min.; w = overflow water rate, lb. per min.; t_1 and t_2 = respectively, overflow and make-up water temperatures, deg. F.; t_3 and t_4 = respectively, engine water out and in temperatures, deg. F.

Water heat rejection = $w\,(t_1 - t_2)$; specific heat rejection = $w\,(t_1 - t_2)/\text{B.Hp.}$ observed; flow rate through engine = lb. per min. = $w\,(t_1 - t_2)/(t_3 - t_4)$. Fuel heat is based on lower heating value = 18,500 B.t.u. per lb. 1 Hp. = 42.42 B.t.u. per min. When overflow water is measured by volume, density of water is considered. Pure water weighs 62.428 lb. per cu. ft. at 39.3° F.; 1 gal. weighs 8.345 lb. at 39.3° F.; 8.153 lb. at 160° F.; 7.995 lb. at 212° F. Observed data on

water heat may be presented with corrected power data when so designated. Heat removed by an external oil cooler is classified under radiation and exhaust losses.

Motoring Friction

TEST CONDITIONS. — Motoring the engine by an electric dynanometer and measuring input power determines friction power. Motoring friction tests are made with: 1. Full throttle; 2. Dry carburetor; 3. Muffler and tailpipe off; 4. Water and oil temperatures at 165 ± 5° F.

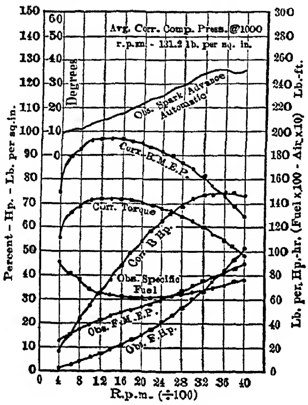

FIG. 73. Power and Economy Test Curves. Full Throttle

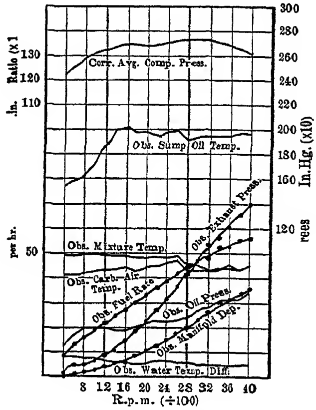

FIG. 74. Standard Engine Test, Full Throttle, Temperatures and Pressures

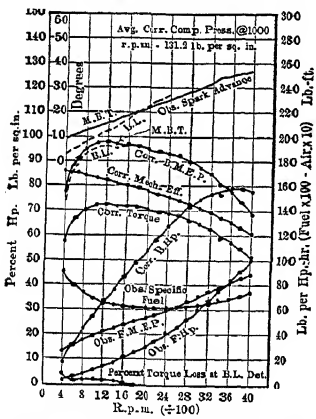

FIG. 75. Standard Engine Test (No. 2) Maximum Power and Economy

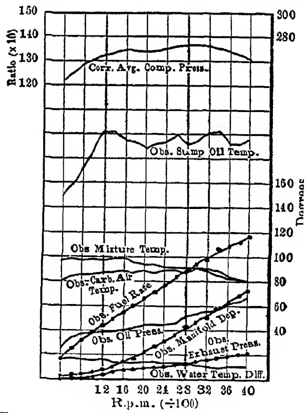

FIG. 76. Standard Engine Test (No. 2) Maximum Power and Detonation

Required temperatures are maintained by operating under power for the interval needed to restore them. Test is made in continuous progression, independent of power test, from 400 r.p.m. to limiting speed in 200-r.p.m. increments.

Motoring Compression

INSTRUMENTATION.—A suitable compression gage, reading maximum pressure, is recommended. Check valve is located, if possible, flush with inside wall of cylinder.

TEST CONDITIONS. — Motoring tests are made with: 1. Full throttle; 2. Dry carburetor; 3. Water and oil temperatures above 100° F.; 4. Muffler off; 5. Ignition off. When measurement is made at one speed, 1000 r.p.m. is standard.

Computations

Notation.—P_c = total carburetor pressure (dry air + vapor pressure); B_c = true barometric pressure, in. Hg. Standard datum pressure for compression is 29.92 in. Hg. Correction factor = $29.92/P_c$. Usually $P_c = B_c$.

TEST 1. FULL THROTTLE AS INSTALLED. Purpose.—This test gives representative full throttle performance over the speed range of engine as installed in car. It should not be used for purposes other than this. See Figs. 73, 74.

Procedure.—Stabilize on 400 r.p.m. and make test run; proceed, making test runs under stabilized conditions every 200 r.p.m. to limiting speed.

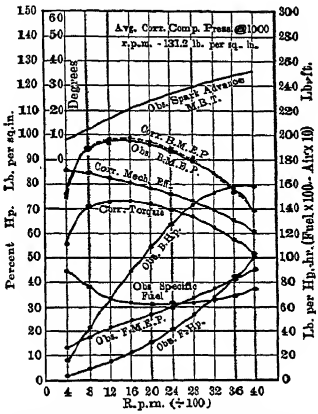

Fig. 77. Standard Engine Test (No. 3) Power and Economy

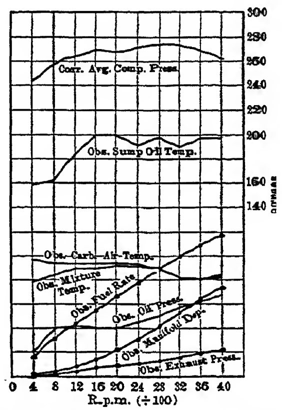

Fig. 78. Standard Engine Test (No. 3) Temperatures and Pressures

Engine Equipment, Adjustments and Settings.—Muffler and tailpipe on; throttle, full; carburetor, fixed standard or adjustment *c*; see p. 14–86; ignition, automatic, adjustment as recommended by manufacturer, using and recording standard initial setting.

TEST 2. MAXIMUM POWER AND DETONATION. Purpose.—This test is used as a check on fundamental design. It gives both maximum power performance and engine detonation charactertistics. See Figs. 75, 76.

Procedure.—Stabilize on 400 r.p.m. with spark retarded to eliminate detonation; advance spark to BL detonation (see p. 14–92) and note spark timing; advance 2° or until a definite increase in detonation intensity occurs; reset on original BL timing, and if original impressions are checked, record timing and torque. Next adjust spark timing to MBT as outlined in Test 3; stabilize and make complete test run; repeat procedure at 200-r.p.m. increments to that speed where overadvance for BL detonation causes 1% torque loss from MBT spark; at higher speeds make test at MBT spark only.

Engine Equipment, Adjustments and Settings.—Standard exhaust pipe, muffler and tailpipe off; throttle, full; carburetor, fixed standard or adjustment *c*; ignition, manual; adjustments as noted above, or adjustments *b* and *c*.

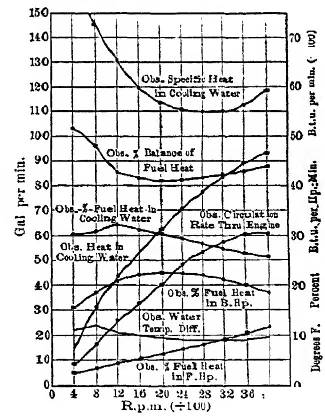

Fig. 79. Standard Engine Test (No. 3) Heat Distribution

TEST 3. HEAT DISTRIBUTION. Purpose.—These tests involve making: 1. A water heat-rejection test; 2. A motoring friction test. As it usually is of no interest to separate exhaust, radiation and oil heat, fuel heat need be divided into only: 1. Brake power; 2. Friction power; 3. Heat to cooling water; 4. Balance. The rate of water circulation through engine is determined from water heat-rejection data. In a heat-rejection test to ascertain radiator requirements in the car, the standard engine exhaust system is used, and also a standard radiator to simulate water flow restriction. See Figs. 77, 78, 79.

Procedure.—Stabilize at 400 r.p.m. using MBT spark setting; make complete test run and proceed in 400-r.p.m. increments to limiting speed.

Engine Equipment, Adjustments and Settings.—Standard exhaust pipe, muffler and tailpipe off; throttle, full; carburetor, fixed standard or adjustment *c*; ignition, manual, adjustment *b*.

TEST 4. VOLUMETRIC EFFICIENCY. Purpose.—This test, used to determine full-throttle volumetric efficiency, is made separately. Power and economy are of secondary importance, but all engine data are recorded with the air consumption data. See Figs. 80, 81.

Procedure depends on type of air measuring equipment used.

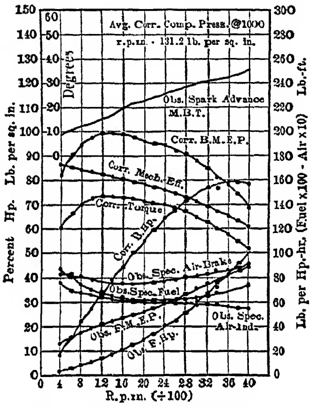

Fig. 80. Standard Engine Test (No. 4) Power and Economy. Volumetric Efficiency

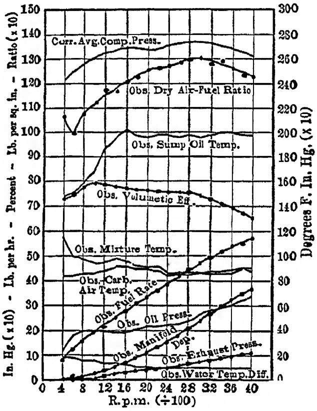

Fig. 81. Standard Engine Test (No. 4) Volumetric Efficiency. Temperatures and Pressures

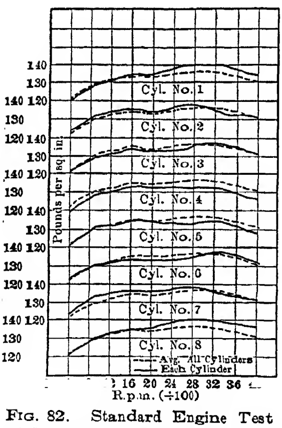

Fig. 82. Standard Engine Test (No. 6) Motoring Compression

Engine Equipment, Adjustments and Settings.—Standard exhaust pipe, muffler and tailpipe off; throttle, full; carburetor, fixed standard or adjustment *c*; ignition, manual, adjustment *b*.

TEST 5. MOTORING FRICTION. Purpose is to obtain an estimate of engine friction loss. Comparative results obtained by several methods justify use of full throttle motoring method. See Friction Hp. curves, Figs. 73, 75, 77, 80.

Procedure.—Test is made in 200-r.p.m. increments from 400 r.p.m. to limiting speed.

Engine Equipment, Adjustments and Settings. — Standard exhaust pipe, muffler and tailpipe off; throttle, full; carburetor, fuel off; ignition, off.

TEST 6. MOTORING COMPRESSION. Purpose is to show relative air charge distribution among cylinders and to indicate ram effects. See Fig. 82.

Procedure.—With compression gage in first cylinder, motor at 400 r.p.m. and read gage; proceed in 200-r.p.m. increments to limiting speed without interruption; repeat for all cylinders; make check test on first cylinder.

Engine Equipment, Adjustments and Settings.—Standard exhaust pipe, muffler and tailpipe off; throttle, full; carburetor, fuel off; ignition, off.

TEST 7. ROAD POWER AS INSTALLED. Purpose is to obtain fuel economy of engine as installed in car. Standard road power curves (see p. 14–86) are used and torque is adjusted for existing conditions. Interest in fuel consumption at high road speeds make test desirable at engine speeds approaching maximum car speed. See Figs. 83, 84.

Procedure.—Stabilize on 400 r.p.m. with corresponding standard road torque and make complete test run; proceed in 200-r.p.m. increments, with corresponding loads, to limiting speed.

Engine Equipment, Adjustments and Settings.—Standard exhaust pipe, muffler and tailpipe on; throttle, adjusted at each speed to standard road power; carburetor, fixed standard or adjustment *c*; ignition, adjustment *a*, or manual adjustment *b*, for engines with non-automatic distributors.

Power Correction Factors for Pressure, Humidity and Temperature

Table 13 gives factors for application to indicated power, for the standard datum temperature of 103° F. Table 14 gives similar factors for full throttle brake power based on an assumed average mechanical efficiency of 85%. Fig. 71 extends the range of pressures and temperatures of the tables.

Tables and charts are based on: 1. Datum pressure (total), 29.92 in. Hg; 2. Datum water vapor pressure = 0.5 in. Hg; 3. Datum temperatures of 60°, 103° and 150° F.; 103° F. is datum temperature for stock engine test. Datum air pressure thus is (29.92 – 0.5) = 29.42 in. Hg.

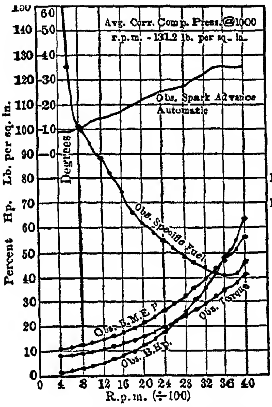

FIG. 83. Standard Engine Test (No. 7) Power and Economy. Road Power as Installed

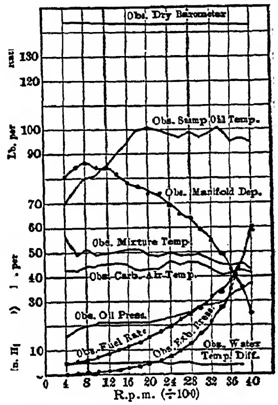

FIG. 84. Standard Engine Test (No. 7) Road Power

The combined correction factor is based on the assumption that indicated power varies; *a*, proportionally with dry air pressure at carburetor; *b*, inversely as the square root of absolute carburetor air temperature. The formula for the indicated power correction factor is:

$$F_{ci} = \frac{29.42}{\text{Dry carburetor press., in. Hg}} \times \sqrt{\frac{\text{Observed carburetor temp., deg. F., abs.}}{\text{Datum carburetor temp., deg. F., abs.}}}$$

Correction factors for full throttle brake power are based on the assumptions: *a*, no change in motoring friction when passing from observed to corrected air conditions; *b*, an average mechanical efficiency of 85%. The formula for brake power correction factor is: $F_{cb} = (F_{ci} + E_m \text{ observed} - 1)/E_m$ observed. Substituting 0.85 for E_m observed, $F_{cb} = (F_{ci} - 0.15)/0.85$. E_m = mechanical efficiency.

AERONAUTICS

By Edward P. Warner and S. Paul Johnston

DEFINITIONS AND CLASSIFICATIONS.—Machines for aerial navigation fall into two general categories.

Lighter-than-air craft are those which displace a mass of air whose weight is greater than their total weight, and which, therefore, can float in the atmosphere buoyed up by aerostatic forces.

Heavier-than-air craft do not displace enough air to achieve buoyancy, but derive their lift by the relative motion of air passing over appropriately designed surfaces. The sustaining forces are aerodynamic.

FORMS OF AIR CRAFT.—Lighter-than-air craft assume two general forms, *viz.*, balloons and airships.

Balloons consist of containers for a suitable gas whose density is less than that of the atmosphere (heated air, hydrogen, helium, etc.), are usually without means of directional control, and always without means for mechanical propulsion.

Airships differ from balloons in that they have means for mechanical propulsion and apparatus for directional control. They consist of single or multiple containers for the supporting gases and the necessary structures to house the personnel, and to support the power plants and controlling surfaces. Structurally, they fall into three classes:

1. *Non-rigid*, in which the gas container maintains its shape solely by reason of the internal gas pressure; 2. *Semi-rigid*, in which the shape of the gas container is partially maintained by means of a structural keel, or backbone; 3. *Rigid*, in which appropriate structural members completely surround and are independent of the gas containers.

Heavier-than-air Craft, so far given practical acceptance, divide into 4 general classes: 1. ***Airplanes***, fixed-wing, mechanically-driven aircraft, supported by the dynamic action of the air. 2. *Gliders*, airplanes without power plants, which utilize the forces of gravity to produce the required propulsive action. 3. *Helicopters*, machines designed to ascend vertically, due to the upward thrust of power-driven rotating airfoils or propellers. 4. *Autogiros*, in which the fixed wings of the airplane are replaced by rotating airfoils revolving under aerodynamic forces only. In spite of a superficial resemblance, an autogiro is not a helicopter, as the engine is not directly connected to the rotor when in flight.

AIRPLANES

1. CLASSIFICATION OF AIRPLANES

Airplanes consist of 5 principal elements which may be combined in a variety of ways. These are: 1. Main supporting surfaces (wings). 2. Auxiliary surfaces for stabilization and control (horizontal stabilizer, fin elevators, rudders and ailerons). 3. Housing for the personnel, power-plants and cargo (body, fuselage, nacelles, or hull). 4. Undercarriage or landing gear (wheels, tail skids, floats or hull). 5. Power-plant (engines, propellers, fuel, oil, cooling system and controls). Airplanes may be classified under four major considerations, all of which are inter-related: *a.* Structural arrangement. *b.* The nature of their terrestrial base of operations. *c.* Materials used. *d.* Power-plant arrangement.

CLASSIFICATION BY STRUCTURAL ARRANGEMENT.—Airplanes are either **monoplanes, biplanes,** or **triplanes**, depending upon whether they have one, two, or three main supporting surfaces. Biplanes in which the area of one wing is very small as compared with the other sometimes are referred to as **sesqui-planes.** Almost without exception the ailerons, or lateral control surfaces are mounted at or near the tips of the main wings, and the other auxiliary surfaces are combined into a single tail unit or *empennage*, supported some distance aft of the main wing. Tailless and "tail-first," or *canard*, designs so far have had limited practical use. With respect to landing gear, airplanes are grouped as landplanes, seaplanes, or amphibians.

Landplanes are fitted with an undercarriage, usually of three wheels, connected to the body through suitable shock-absorbing devices. Water types take two practical forms:

the float seaplane, essentially a land type in which the wheels of the undercarriage are replaced by one or more suitably designed floats, and the **flying boat**, in which the main body of the airplane is a water-tight hull, with a bottom suitably shaped to give good take-off and landing characteristics, which not only encloses the personnel but furnishes points of attachment for wings, auxiliary surfaces and power plants. An **amphibian** is a composite type designed to operate either from water or land.

Monoplanes may be of the parasol, the high-, the mid-, or the low-wing type, depending on whether the wing is carried on struts above the fuselage or is attached to the upper, the middle, or the lower part of the fuselage. Also, these wings may be of the *full cantilever* variety, in which the structure is totally enclosed within the wing contour, or they may be either *strut-* or *wire-braced* to some suitable part of the fuselage or undercarriage.

Biplanes may be either *orthogonal*, or *staggered*, depending on whether the top wing is placed directly over the bottom, or whether it is located forward or aft of the bottom wing. Either monoplane or biplane wings may be tapered in section or in plan or in both, or they may be swept back, that is, they may make an angle rearward with respect to the plane of symmetry of the craft of less than 90°.

CLASSIFICATION BY MATERIALS.—The principal structural materials used in aircraft are: wood, chiefly spruce; fabrics, chiefly cotton; and metals, chiefly steel and aluminum-alloy. For many years *composite* construction has been employed, using wood, fabrics and metals in various combinations. For military and transport aircraft, the all-metal machine is now (1935) rapidly replacing the composite.

CLASSIFICATION BY POWER PLANT ARRANGEMENT.—Modern aircraft are propelled by 2-, 3-, or 4-bladed wooden or metal propellers driven by air- or water-cooled internal combustion engines. Propellers may be arranged either as *tractors* or as *pushers*, depending on whether the propeller is ahead of or behind the engine. Airplanes may be equipped with single or multiple power plants, arranged either as pusher or tractor, or in combinations of both. Power plants may be mounted within the fuselage proper, or may be housed in nacelles supported by the fuselage and mounted either directly in or above or below or between the wing or wings. There is a tendency, as the overall dimensions of airplanes increase, to enclose engines completely within wing structures to reduce the parasite drag.

2. AERODYNAMICS

THE ATMOSPHERE.—The layer of air which surrounds the earth is a non-homogeneous fluid whose density varies inversely with the distance above sea-level. The density at 20,000 ft. is approximately one-half and at 40,000 ft. about one-quarter the sea-level density. As with any gas, a very definite relationship exists among temperature, pressure and density. The absolute values may vary considerably in any given locality, due to local meteorological conditions. To have a basis for comparison of airplane performance or calibration of instruments, a purely fictitious *standard atmosphere* has been assumed, roughly corresponding to average conditions, and defined by known altitude-temperature-pressure relations. See The Standard Atmosphere, W. S. Diehl, Nat. Advisory Comm. for Aeronautics Report No. 218. In selecting bases for the standard atmosphere, international standards have been followed. The basic data are: Standard sea-level pressure, p_0, $= 29.921$ in. Hg (2116 lb. per sq. ft.); standard temperature, $t_0 = 59.0°$ F.; standard specific weight of air, $g\rho = 0.07651$ lb. per cu. ft.; standard temperature gradient, $a = 0.003566°$ F. per ft. of altitude (1° F. per 280 ft.).

Based on the above assumption, properties of the standard atmosphere at intervals up to 25,000 ft. are given in Table 1. Up to an altitude h of about 35,000 ft. the density ratio is given correctly within $2\ ^1/_2\%$ by the formula

$$\rho/\rho_0 = 1 - 0.03\,[(h/1000) - (h/10{,}000)^2] \qquad [1]$$

FLUID RESISTANCE.—Since atmospheric air is not a perfect fluid, any solid body passing through it at any speed is opposed by a certain fluid resistance, which depends

Table 1. Standard Atmosphere—English Units

on the density of the fluid, the dimensions and form of the body, and its velocity. That is

$$R = C_R(\rho/2)SV^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

where R = total resistance or resultant force; C_R = a coefficient depending on the form of the body and its attitude with respect to the motion of the fluid (nearly enough constant for most purposes, though to be exact C_R varies somewhat with the absolute dimensions of the body and the relative velocity between body and fluid); ρ = density of air ($\rho/2$ is used in the equation, because $(\rho/2)V^2$ has a physical significance as the pressure which results from a complete conversion of the kinetic energy of moving air into its pressure equivalent); S = projected area of body; V = velocity of motion. See also discussion of coefficients in formulas [3] and [4].

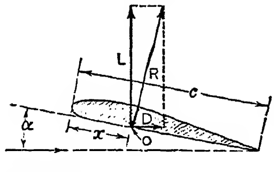

Fig. 1. Resolution of Aerodynamic Forces Acting on a Typical Airfoil

AIRFOILS are winglike surfaces, with cross-sections designed to develop a useful dynamic reaction when relative motion is set up between them and the surrounding air. Fig. 1 is a typical airfoil cross-section, and indicates the location and direction of the resultant force. For a given angle of attack α, the resultant R intersects the chord c of the airfoil at the center of pressure O at a distance x from the leading edge. For convenience, it is customary to resolve the resultant force into the lift component L, and the drag D, respectively normal and parallel to the relative wind. Since the components of any force vary in accordance with the same laws that govern the force itself, fundamental equations may be written for the lift and drag, *viz.*:

$$L = L_c SV^2 \quad . \quad . \quad . \quad . \quad . \quad [3]; \qquad D = D_c SV^2 \quad . \quad . \quad . \quad . \quad . \quad [4]$$

where L_c and D_c are lift and drag coefficients, and are functions of the angle of attack α.

The coefficients of the above formulas are of the so-called engineering type, and yield values of lift or drag in pounds when S is in square feet, and V is in miles per hour. To give dimensionally correct equations, the density factors must be introduced to put the coefficients in the so-called absolute form. The absolute coefficients of lift and drag C_L and C_D, adopted by the N.A.C.A. are designed to fit into the relations

$$L = C_L(\rho SV^2/2) \quad . \quad . \quad . \quad [5]; \qquad D = C_D(\rho SV^2/2) \quad . \quad . \quad . \quad [6]$$

The relation between the engineering and N.A.C.A. absolute coefficients, therefore, is

Engineering		N.A.C.A Absolute	
$L_c = L/SV^2$	or	$C_L = 2L/\rho SV^2$	[7]
$D_c = D/SV^2$	or	$C_D = 2D/\rho SV^2$	[8]

ρ must be in mass units. In foot-second units $\rho/2 = 0.00118$ under standard sea level conditions. To transpose coefficients from N.A.C.A. absolute units to engineering units, multiply by 0.00255; to change engineering coefficients to the absolute form, multiply by 392.

In dealing with lift and drag coefficients of wings, the area S involved is the area of the wing in plan; fundamentally, the product of span and chord, sq. ft. In applying these

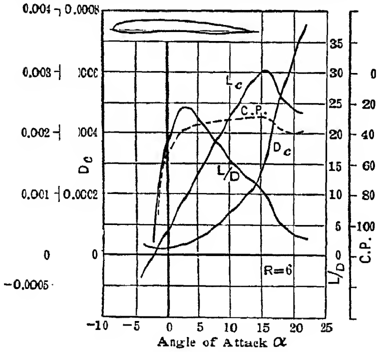

Fig. 2. Characteristics of a Relatively Thin Airfoil with Concave Lower Surface

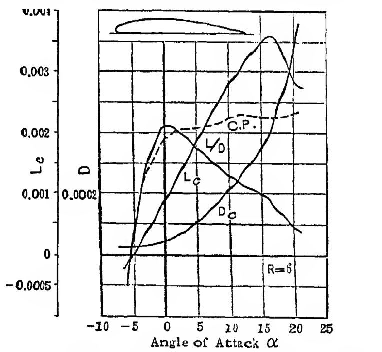

Fig. 3. Characteristics of Medium Thick Airfoil with Flat Lower Surface

equations to the calculation of parasite resistance of solid bodies, the area considered is the area of the body projected on a plane normal to the direction of relative motion.

Center of Pressure Travel and Moment Coefficient.—The location of the vector of resultant force on an airfoil can be indicated either by specifying the distance from the leading edge to the intersection of the vector with the chord (called the center of pressure), or by giving the moment of the resultant force about some convenient axis. The first method has the clearer physical significance and is valuable for purposes of illustration and instruction; the second is more convenient for calculation. The usual moment axis is a point on the chord 25% of its length back from the leading edge, as the moment about that point for a given airfoil is substantially independent of the angle of attack.

The location of the center of pressure on an airfoil is a function of its section, planform and angle of attack. For most common airfoils, as the angle of attack is increased from zero to the angle of maximum lift, the center of pressure tends to move forward from a point about 50% of the chord to a point from 30 to 35% of the chord from the leading edge. Decreasing the angle of attack to very small values causes a very rapid rearward movement of the center of pressure for most airfoils. In fact, for angles within two or three degrees of that where the lift becomes zero, the center of pressure actually may pass behind the leading edge. As the angle decreases, the center of pressure moves to make it decrease still more. Thus most airfoils are markedly unstable in pitch, and the addition of some form of auxiliary surface, usually a tail, is necessary to maintain equilibrium in flight. Airfoils whose bottom surfaces are substantially convex, and those in which the trailing edge is slightly reflexed upward, ordinarily exhibit a lower rate of center of pressure travel than non-symmetrical, positively-cambered sections. The rate of center of pressure travel depends principally on the angle which a line bisecting the angle between the upper and lower surfaces of the airfoil at the trailing edge makes with the chord. When this angle is zero, the center of pressure of that particular section will be found very nearly in a constant position for all angles of attack.

The center of pressure coefficient C_p for an airfoil is the ratio of the distance from the leading edge to center of pressure to the chord length, or

$$C_p = x/c \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [9]$$

Interpreting the foregoing in terms of moments, an airfoil will be found to be stable when the moment about a point 25% of the distance back on the chord is positive (of such sign as to tend to increase the angle of attack); unstable when that moment is negative. The larger the negative value of the moment, the more unstable the airfoil becomes and the more tail surface will be required to stabilize it.

Selection of Airfoils.—A vast number of airfoil sections have been tested in aerodynamic laboratories, but only a few of them are in common use. A few of the best sections in 1935 design practice are given and their properties plotted and tabulated in Figs. 2 to 5. In selecting an airfoil for a particular purpose, the following properties are, in general, and for various reasons, sought by the designers: 1. High maximum lift coefficient. 2. Low drag for the values of the lift coefficient that cover the normal working range of the aircraft, generally from 0.0003 to 0.0005 for maximum speed, from 0.0004 to 0.0007 for normal cruising, from 0.0012 to 0.0018 for best take-off and quickest climb.

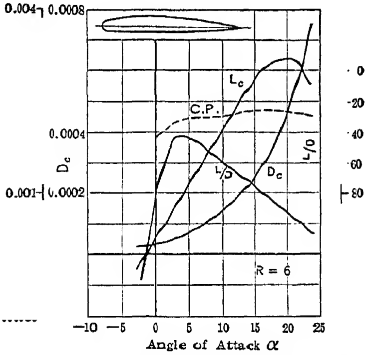

FIG. 4. Characteristics of Medium Thick Airfoil with Convex Lower Surface

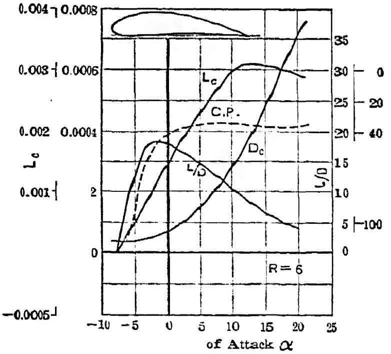

FIG. 5. Characteristics of Relatively Thick Airfoil with Slightly Concave Lower Surface

3. Minimum center of pressure travel. 4. Suitable structural characteristics, *i.e.*, thick enough to permit installation of deep spars.

Pressure Distribution Around Airfoil.—The distribution of pressure along the chord of an airfoil varies with the shape of the section, the angle of attack, and the position of the section in the span. A typical distribution for an average airfoil of medium thickness toward the center of a span of rectangular planform is shown in Fig. 6. The curves represent the condition at approximately 0° and at +15° angle of attack. Typical pressure distributions along the span of rectangular and tapered airfoils are shown in Fig. 7. Note that for angles within the ordinary flying range the span-loading is approximately elliptical. At high angles of attack, unusually high pressures tend to develop around the tips of a rectangular wing, which is undesirable from a structural standpoint. The average effects of tapering a wing in plan are indicated by the dotted lines in Fig. 7.

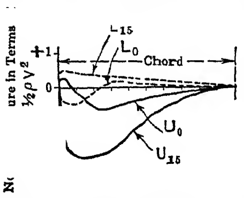

FIG. 6. Typical Pressure Distribution along Chord of Typical Airfoil at Low and High Angles of Attack

The above indicates that the shape of the wing tip influences the pressure distribution of the wing. Rectangular, or positively raked, *i.e.*, leading edge shorter than trailing edge, wings are to be avoided. Negative rake, *i.e.*, leading edge longer than trailing edge, shows a decided improvement in this respect. A distorted semi-elliptical tip, as shown in Fig. 8, is favored in 1935 designs.

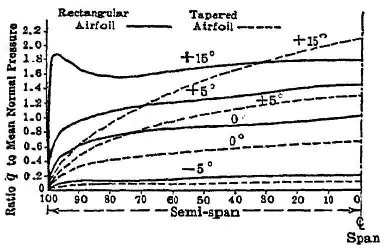

FIG. 7. Pressure Distribution along the Span of Typical Airfoils, Rectangular and Tapered

INDUCED DRAG AND ASPECT RATIO CORRECTION.—For ordinary engineering purposes, lift and drag are referred to the direction of the relative wind at some point well outside the zone of influence of the airfoil. See Fig. 1. Actually the lines of flow immediately surrounding the airfoil are deflected downward. Thus a more exact axis of reference is found by bisecting the angle at which the air flows on to the section and the angle at which it leaves, as in Fig. 9. The components of the resultant force, taken with respect to the mean relative wind, are called the *profile lift*, L_O, and the *profile drag*, D_O. In this case the ordinary lift and drag components are indicated by L_a and D_a, and may be found by taking components of the profile lift and drag parallel to the ordinary relative wind direction. Since profile drag is much smaller than profile lift, its component parallel to the lift axis may be neglected, and the profile lift may be assumed equal to the lift as ordinarily measured. The component of the profile lift along the drag axis, however, may have considerable magnitude, and is called the *induced drag*. The total drag thus is made up of two elements, profile drag and induced drag. Profile drag only depends on the shape of the section and its angle of attack. The induced drag, however, is purely a function of the *aspect ratio*, *i.e.*, ratio of span to chord, and the lift coefficient. It is independent of the individual section considered. It can be shown that the coefficient of induced drag D_{ci} may be expressed in engineering units by

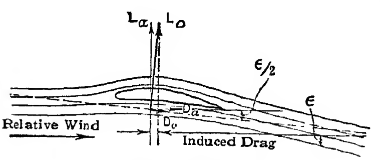

FIG. 9. Graphical Representation of Induced Drag

$$D_{ci} = 125\, L_c^2/R \quad [10]$$

corresponding relation in N.A.C.A. absolute units is

. . . . [11]

where R = aspect ratio. Thus the total drag coefficient for a given lift coefficient steadily decreases with increasing aspect ratio.

ASPECT RATIO, as usually defined, is simply span divided by chord. For tapered, or other irregular planforms, this definition cannot apply. A more general relation is

$$R = b^2/S \qquad [12]$$

where R = aspect ratio; b = extreme span, ft.; S = area, sq. ft.

From a standpoint of aerodynamic efficiency alone, high values of R are to be preferred. The average range of aspect ratio for 1935 airplanes is: Powered monoplanes, 5 to 7 1/2; powered biplanes, 6 to 9; soaring gliders, −13 to 19. The maximum L/D generally increases by about 8% of its value at R = 6 for each unit by which the aspect ratio is increased.

BIPLANES.—Due to interference effects, the efficiency of a combination of two or more airfoils working in close proximity is not as great as that of either of the individual airfoils as a monoplane. Fig. 10 shows a typical case for an unstaggered biplane of equal spans and equal chords with a gap-chord ratio of unity. The general effect of putting two wings together as a biplane is qualitatively the same as reducing the aspect ratio of a monoplane wing, and a similar theory can be applied. The basic biplane, as compared with the monoplane, shows a loss of maximum lift from 3 to 9%; a reduction in maximum L/D of from 15 to 25%; and an increase in minimum drag of from 7 to 20%. Based on the induced drag theory, it can be shown that the relation between biplane aspect ratios (where gap/chord = 1) and the equivalent monoplane aspect ratios are approximately:

Biplane Aspect Ratio	5	6	7	8	10
Equivalent Monoplane Aspect Ratio	3.4	3.9	4.5	5.0	6.1

For a gap-chord ratio of 0.6, reduce the monoplane aspect ratios approximately 8%; for a gap-chord ratio of 1.4, increase equivalent monoplane aspect ratios by approximately 6%.

Even though dimensionally and geometrically similar, the two wings of a biplane generally carry unequal portions of the total load. Except at very low angles of attack, or for combinations with negative stagger (upper wing set behind the lower), the upper wing usually carries the major portion. For unstaggered cellules over the greater part of the normal range of lift coefficients, the ratio of unit load on the upper wing to that on the lower wing is approximately 1.1. With 30° positive stagger the ratio may go as high as 1.6 at low angles of attack, scaling down to approximately 1.2 as the condition of maximum lift is approached. For accurate calculation the relative efficiency must be corrected for span and chord ratios, gap ratios, and stagger.

SLOTS AND FLAPS.—The two devices most commonly used to increase the speed range of airplanes are: 1. Trailing-edge flaps. 2. Fixed or variable slots in the leading edge. 3. Combinations of both.

The general effect of moving trailing-edge flaps downward is to increase the concavity of

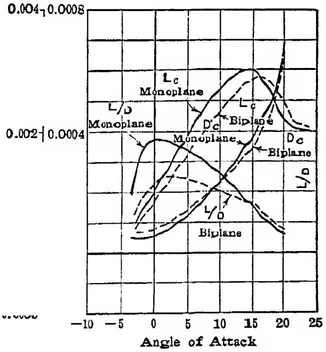

FIG. 10. Comparative Characteristics of a Typical Airfoil as a Monoplane and as a Biplane without Stagger with Gap/Chord = 1 (Clark Y — A.R. = 6)

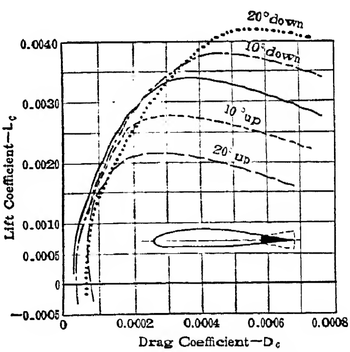

FIG. 11. Effect of Trailing Edge Flap on Lift and Drag. (N.A.C.A. M–6 Airfoil with Flap Chord 20% of Total Wing Chord)

the lower surface of the section and thus to increase the lift. Using trailing edge flaps whose chord is approximately 20 to 25% of the chord of the basic airfoil, monoplane airfoils show an increase in maximum lift to about 40% with a flap setting of 45 to 60°. In practice, however, the maximum flap travel usually is limited to about 30°, under which conditions anywhere from 50 to 70% of the maximum possible increase in lift may be realized. The general effect of a trailing edge flap on the lift and drag is shown in Fig. 11. Flaps may be either simple, the whole trailing-edge section of the wing being pulled down as a unit, or split, the lower part of the trailing edge being depressed while the upper part is left rigid and the form of the upper surface of the wing remains undisturbed. The split type is somewhat the more efficient of the two but the difference is not great.

FIG. 12. Proportions of Typical Leading Edge Slots

Fixed or variable leading-edge slots commonly are used only in that portion of the wing ahead of the ailerons, although some designs use slots over the full span. Proportions for typical installations are shown in Fig. 12, and the effect on the lift and drag of the airplane at full scale is shown in Fig. 13. The effect of the slots is to prevent "burbling" and maintain smooth air flow, with consequent increase in lift, at very large angles of attack. The maximum improvement in lift coefficient is obtained by a combined use of leading edge slots and trailing edge flaps. Some of the combinations that have been tried, all of them based on the same airfoil, are shown in Fig. 14. The maximum L_c obtained is recorded beside the sketch in each case.

SCALE EFFECTS AND REYNOLDS NUMBER.—The simple variation of resultant air force with density, area and velocity, of equation [1], is not strictly true for all cases. It can be shown that the simple coefficients R_c, L_c, and D_c are not simple numbers, but functions of Vl/ν, where V is the velocity, l is some lineal dimension of the body moving in the fluid, and ν is the kinematic viscosity, or the viscosity per unit density of the fluid. The factor Vl/ν usually is called the Reynolds Number. In most cases the variation of the coefficients with scale is a secondary factor, but it becomes an important one when predicting full-scale aerodynamic characteristics from wind tunnel tests on models.

As a general rule, the maximum lift coefficient for a comparatively thin airfoil section tends to increase slightly with increase in Reynolds Number. A test made on a small model of a Clark Y airfoil at about 30 mi. per hr. gave a maximum lift coefficient of 0.00315, and a test made at approximately full scale and flight speed yielded a coefficient of 0.00350. On the other hand, thick sections, which have a relatively high value of maximum lift coefficient, tend to show a decrease as full-scale conditions are approached. The U.S.A. 35, shows an absolute coefficient of 0.00375 under model-test conditions, and 0.00308 at full scale. Induced drag does not change with Reynolds Number, but the effect on profile drag may be marked. The general effect, regardless of section, is to show a decrease in drag as full-scale conditions are approached. This is connected intimately with the change of skin friction. See below. The reduction in drag usually is greatest for the thicker sections. Center of pressure travel virtually is unaffected by changes in Reynolds Number.

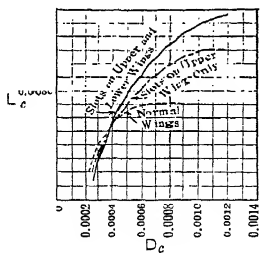

FIG. 13. Effect of Handley-Page Wing Slots at Full Scale on Bristol Fighter

3. PARASITE RESISTANCE

PARASITE DRAG is the air resistance of all parts of an aircraft except the wings. Drag arises from two sources: 1. Skin friction. 2. Turbulence. The latter, which arises from the breakdown in the smooth flow of air around the body and the subsequent formation of eddies, is usually much more important.

SKIN FRICTION may be determined by either of two formulas. The choice between the two depends on the conditions existing in the layer of air immediately adjacent to the

NOTES.—1. In comparing properties of modified sections with the plain basic section, the coefficients used in each case were obtained under similar test conditions. Drag coefficients were taken with slot closed (if movable) and with flap neutral.

2. A low value of L/D at maximum lift indicates a steep glide angle and consequently a short landing. An L/D of 8 corresponds to a gliding angle of approximately 7 deg., and a value of 3.5 means about 16 deg. (T.R. 428).

3. Based on total wing area; lift increasing device extended and projected on original chord line. Actually this area is structural area necessary and forms the basis for the comparison with the simple flap.

4. With slot and flap retracted the airfoil is not perfect, having a drag coefficient of 0.0182 compared with 0.0156 for the plain airfoil.

5. Based on contracted area.

FIG. 14.—Characteristics of High Lift Devices Applied to the Clark Y Wing (*Aviation*) (The Reynolds Number for all tests is 609,000 which corresponds to about one-third that for an ordinary small airplane at landing speed)

frictional surface. The effect of viscosity of fluid on the flow of air is confined to a *boundary layer*, within which the velocity gradient is exceedingly steep. The thickness of the boundary layer seldom exceeds 1/2 in. in practice, except on the hulls of airships, and at a distance of 2 ft. from the leading edge of a flat plate at 200 mi. per hr. it is about 3/16 in.

At low Reynolds Numbers the flow in the boundary layer is smooth and laminar, and the friction is determined by the formulas

$$D_f = D_{cf}\, S_e V^2 \quad . \; . \; . \quad [13]; \qquad D_{cf} = 0.0034/\sqrt{N} \quad . \; . \quad [14]$$

where N = Reynolds Number; S_e = total surface exposed to the air. In the case of a wing or flat plate, S_e would be twice the area as ordinarily defined. At very high Reynolds Numbers the boundary-layer flow becomes turbulent. The friction then is much higher and varies according to a different law, following the formula

$$D_{cf} = 0.00019/\sqrt[5]{N} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [15]$$

At intermediate values of N the motion is laminar on the forward part of the surface, turbulent on the after part, and the friction has an intermediate value. The transition

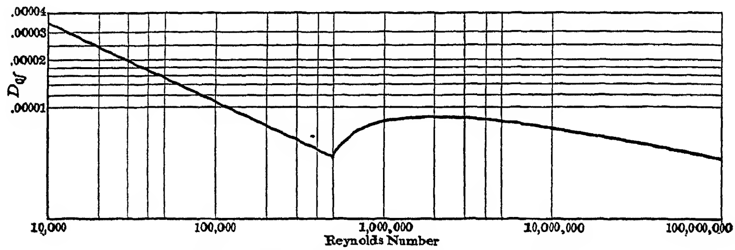

FIG. 15. Scale Effect on Skin Friction Coefficient

from laminar to turbulent motion is governed in part by the degree of roughness of the frictional surface, and in part by the general conditions existing in the stream. On the average it occurs at about N_x = 500,000. $N_x = Vx/\nu$, where x is distance from leading edge of the surface to the point under examination, and the other symbols have the same meaning as in the general definition of Reynolds Number. Fig. 15 is a typical curve of frictional coefficient against Reynolds Number showing the two distinct zones and the transition between them.

SPHERES AND HEMISPHERES.—The resistance of a sphere varies through a wide range with Reynolds Number. At Reynolds Number 500,000, corresponding to a sphere 1 ft. diam. and an air velocity of 45 mi. per hr. under the atmospheric conditions standard at sea-level, D_c = 0.0002; at 1,000,000, D_c = 0.0003; at 4,000,000, D_c = 0.00037.

Eiffel found that if he attached a solid cone, whose base diameter was that of the sphere, and whose conning angle was 20°, to the downwind face of a hemisphere with convex side toward the wind, the total drag was approximately 50% of that of a complete sphere of the same diameter.

STREAMLINE BODIES.—The resistance of a number of typical streamline bodies is shown in Fig. 16. The fineness ratio, or the maximum length divided by maximum diameter, of a streamlined body influences the total drag. In general, well-shaped streamlined bodies exhibit the best resistance values at fineness ratios of from 2 to 3. The very best streamline forms have a disc ratio, or ratio of their own resistance to that of a normal flat plate of area equal to the projected cross-section area of the body, as low as 1/40.

Good streamlined shapes are very sensitive to the effect of minor projections or slight surface discontinuities which disturb the smooth air flow. For example, the wrapping of a single turn of a thread 0.014 in. diam. around a section 1 in. from the nose of a smooth streamline body 8 in. diam. and 24 in. long has proved sufficient to increase the total drag approximately 67%. Seven sets of similar thread rings placed at 1-in. intervals from the nose practically doubled the drag of the bare body.

STRUTS.—The relative drag of struts of several cross-sections is shown in Fig. 17. Minimum drag for struts is associated with fineness ratios of 3 to 3 1/2. The drag coefficients for the best struts are about twice as high as for the best streamline bodies, due to the substitution of two-dimensional for three-dimensional flow.

Minimum strut resistance is obtained with the axis of the strut parallel to the relative wind. Yawing the average strut 7° increases the drag by 50%; 8°, approximately 100%. Round members may be used as struts without fairing if their axes lie at less than 45° to the relative wind, as the section around which the air flows has then become elliptical.

FLAT PLATES NORMAL TO WIND.—For a rectangular plate, of aspect ratio = 1, the drag coefficient D_c is 0.00328. With increase of aspect ratio, the drag coefficient must be increased by a factor, as follows:

Aspect Ratio....................	2	4	6	10	14	18
Coefficient Correction Factor......	1.05	1.08	1.10	1.15	1.24	1.30

WIRES AND CABLES.—The resistance coefficient for a single strand of round wire, cable, or streamlined wire is given in Table 2. The streamlined wire mentioned in the table actually is rolled to a roughly lenticular section, with a major axis about 2 1/2 times the minor one. When round or streamlined wires are used in pairs, the resistance of the combination usually is below that of the total for the two wires singly, the saving by interference depending on the spacing between wires. The relative drag of wires in combination is shown in Fig. 18. The drag of each exposed turnbuckle is figured equivalent to approximately 2 ft. of additional length of wire or cable. Each exposed streamlined-wire end fitting should be considered equivalent to 3 ft. of wire.

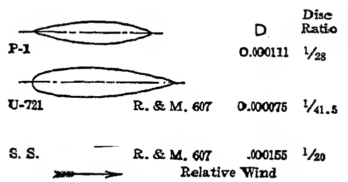

FIG. 16. Typical Streamline Bodies, their Resistance Coefficients and their Relative Resistance to a Flat Disc of Equal Diameter

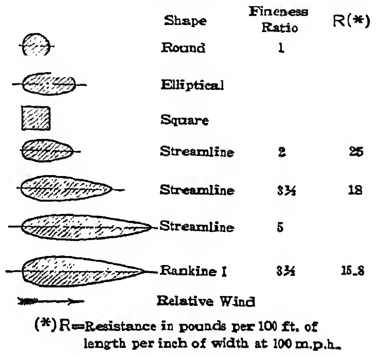

FIG. 17. Relative Drag of Struts

LANDING WHEELS.—The drag of standard wire-spoke wheels with high-pressure tires is shown in Table 3. By adding streamlined housings or "pants" to a high-pressure type wheel, the drag of the combination may be reduced to approximately 40% below that of the wheel with its ordinary disc fairings. A recent test indicated the drag of two large semi-low-pressure tires as follows:

Tire size, in..................	40 × 10	15.00 – 16
Drag, lb. at 100 mi. per hr....	28.9	33.6

Partially enclosing the tire in a streamlined housing reduced the drag 40% on the average. In both cases the axle and landing gear struts were in place, so that the results include a certain amount of interference effect from these members.

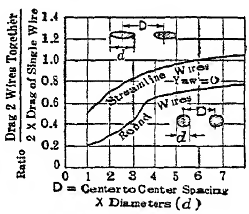

FIG. 18. Drag of Adjacent Wires and Cables

FUSELAGES.—Drag coefficients for a series of fuselage models are listed in Table 4. In all cases the fuselages were tested without landing gear, wings, or tail surfaces, but with the modifications indicated in each case. These tests were made at relatively low Reynolds Numbers. The coefficients are given in the usual form, based on cross-sectional

....	....	....	....	1/2–20	.1530

area. In typical practice, the disc ratio for fuselages, either with air-cooled or liquid cooled engines, usually ranges between 1/4 and 1/8.

Cowling for Air-cooled Engines.—Mounting an air-cooled engine in the nose of a fuselage ordinarily increases the total drag, at full scale, about 200 to 400%. The N.A.C.A. in America, and Townend in England, have developed forms of annular engine cowling which offset from one-half to two-thirds of this increase. Fig. 19 shows the N.A.C.A. cowling applied to a cabin and to an open cockpit fuselage. Table 5 shows the drag in pounds for various combinations at 100 miles per hour. An application of this cowling to a standard airplane usually increases the top speed by from 10 to 15%. Roughly, the cowl reduces the additional resistance due to the engine by some 45 to 70%.

The Townend, or ring, cowling is similar to the N.A.C.A. type in principle but, as indicated in Fig. 20, it is considerably shorter and has less curvature. In both cases the cowl acts to reestablish a normal smooth flow of air along the sides of the fuselage, preventing a turbulent divergence of the air directly disturbed by passing over the engine.

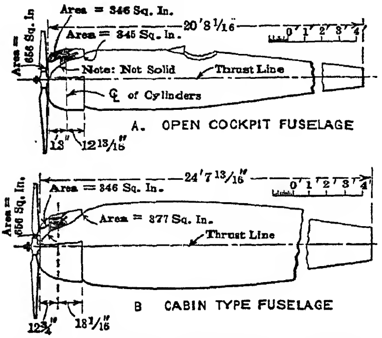

Fig. 19. Application of N.A.C.A. Cowling to Typical Fuselages

NACELLES.—The N.A.C.A. cowling has been applied to engine nacelles to reduce the drag of an air-cooled engine. Fig. 21 shows the so-called conventional, and N.A.C.A.

nacelles, both for a 300-Hp., 9-cylinder engine. The relative drag of the various combinations at 100 mi. per hr. is shown in Table 6.

INTERFERENCE DRAG.—The total drag of airplane components in close proximity to one another, for example, fuselage and wings, or fuselage and landing gear, always is considerably greater than the sum of the resistances of the individual units, due to mutual interference. In general, no members should intersect at sharp angles, but generous fairings or fillets should be provided. The relation between wings and fuselages has been studied for many cases, and the importance of careful filleting has been established. In one high-wing monoplane, studied at full scale, a simple 12-in. radius fillet at the intersection of the under-surface of the wing and cabin effected a reduction in the total resistance of the combination of almost 2%. Research has indicated that the longitudinal rate of change of the radius of the fillet is important, and that the radius at the trailing edge of the wing should be much larger than at the leading edge. Fig. 22 shows the lines for the optimum fillet for a low-wing monoplane.

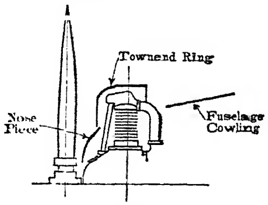

FIG. 20. Engine Fitted Cowling Ring of Townend Type

The location of an outboard engine nacelle with respect to a wing has an important bearing on interference effect and propulsive efficiency. Studies made by the N.A.C.A. indicate that all nacelles should be completely cowled. In general, nacelles placed above a wing show much greater interference effect than those placed below. Nacelles placed closer than approximately one nacelle diameter below the lower surface of a wing should be completely faired into the wing, but in no case should the engine cowling hood be faired into the wing. The best location for a completely cowled nacelle for minimum drag and for greatest propulsive efficiency is with the propeller hub in line with, and about 25% ahead of the leading edge of the wing. The location and fairing of nacelles have a great effect on top speeds, but little influence on climbing powers.

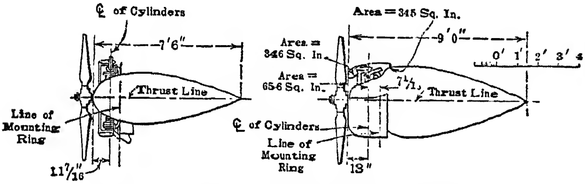

FIG. 21. Conventional and N.A.C.A. Nacelles

FLOATS AND HULLS.—Wind tunnel tests on various groups of floats and hulls yielded the range of drag coefficients, in terms of square feet of maximum cross section, given in Table 7. In most cases the minimum drag occurs at 0° pitch of the deck line, and on an average the drag is doubled at a pitch angle of 10°, and multiplied by five at about 18°. Floats and hulls at positive pitch angles yield considerable lift. In most cases the lift-drag ratio has a maximum value of 2.2 to 2.5 at a pitch angle of 12 or 14°.

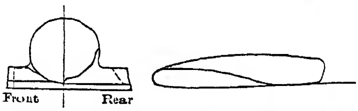

FIG. 22. Optimum Fillet for Low-wing Monoplane (Klein)

Table 6.—Drag of Engine and Nacelles

Form	Drag, lb. at 100 mi. per hr.	Percent Reduction from Bare Engine
Bare engine	178	0
Engine in conventional nacelle	155	12.9
Engine in N.A.C.A. nacelle	43	75.9

Table 7.—Drag of Floats and Hulls

Type	No. of Tests	Drag Coefficient, D_c		
		Maximum	Minimum	Average
Seaplane floats	8	0.000855	0.000651	0.000728
Flying boat hulls	15	.000366	.000267	.000307
Wing-tip floats	....	.000800	.000400	.000600

TOTAL AIRPLANE DRAG.—The distribution of the total drag for complete airplanes of several types at full scale is indicated in Table 8.

The total structural drag of any airplane may be conveniently expressed in terms of the flat-plate area having equivalent drag. The equivalent flat-plate area of an airplane of good modern design, with a retractable or a very carefully streamlined landing-gear, can be kept at low as 1 sq. ft. for every 1000 lb. of gross weight or, especially in machines of large size, even as low as 0.40 sq. ft. in exceptional cases.

Table 8.—Percentage Drag Distribution of Typical Airplanes

	Air-cooled Cabin Monoplane	Prestone-cooled Monoplane	Prestone-cooled Sesqui-plane	Air-cooled Open Biplane
Fuselage and engine	32.3	17.2	17.9	27.8
Radiator	....	7.4	7.2	....
Landing gear	13.4	12.4	12.5	10.1
Tail surfaces	4.7	10.9	9.9	8.3
Wings and struts	49.6	52.1	52.5	53.8

4. PERFORMANCE CALCULATION

All performance calculations are based on the relation between power required for flight and power available under the given condition. The power required, P, is a direct function of the total drag, *i.e.*, wing drag + parasite drag.

$$P = DV/375 \qquad [16]$$

where D = total drag, lb.; V = speed, mi. per hr.

SLIP STREAM EFFECT.—In calculating total parasite drag at a given speed of flight, allowance must be made for slip-stream effect. The slip-stream of the propeller is taken roughly as a hollow cylinder, concentric with the thrust axis, whose inside diameter is 0.2 × propeller diameter, and whose outside diameter is from 0.8 to 0.9 × propeller diameter. The parasitic drag of all objects which lie within the slip stream must be calculated on the basis of slip stream velocity, which always is greater than the speed of normal horizontal flight. Its value is

$$V_s = V\sqrt{1 + (490\,T/D^2V^2)} \qquad [17]$$

where V_s = slip stream velocity, mi. per hr.; V = speed of flight, mi. per hr.; T = propeller thrust, lb.; D = propeller diam., ft. The propeller thrust for use in formula [17] is

$$T = 375\,P\eta/V \qquad [18]$$

where η = propeller efficiency, percent; other notation as before. For propeller efficiency see p. 14–112. The power available under any set of conditions equals the horsepower developed by the engine under those conditions, multiplied by propeller efficiency.

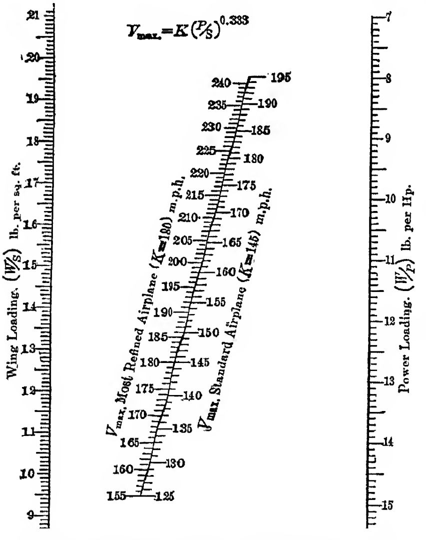

FIG. 23. Nomograph for Estimating Maximum Speed of Airplanes Based on Equation 21. (*Aviation*)

EFFECT OF ALTITUDE ON PERFORMANCE.—Increase in altitude is accompanied by a reduction in density of the air, with consequent reduction of power output for an unsupercharged engine. See Standard Atmosphere, p. 14–99. The general relation between power output, P, at constant r.p.m., and density ρ, based on average curves of a number of tests is

$$P = P_0(\rho/\rho_0)^{1.2} \qquad [19]$$

where the subscript o indicates sea-level conditions. With a controllable-pitch propeller

the power available for propulsion will follow the same formula. When the propeller is of the fixed-pitch type there is a further loss due to decrease of r.p.m. at higher altitudes, and the effective propulsive power is more nearly proportional to $\rho^{1.3}$

For all practical purposes, the total drag at any given angle of attack may be considered as independent of air density, and the power required for straight horizontal flight, P_r, is given by

$$P_r = P_{ro}(\rho_o/\rho)^{1/2}, \quad . \quad . \quad . \quad [20]$$

since the speed of flight at a given angle of attack varies inversely as the square root of the air density. The subscript o indicates sea-level conditions.

Where engines are supercharged, sea-level output may be maintained to considerable altitudes. The power output at any given altitude then must be obtained from performance curves of the engine in question. It is common practice in 1935 to supply engines supercharged to maintain as much power up to an altitude of 5000 to 10,000 ft. as it is safe to draw from them continuously at any altitude. Maximum speed will increase with altitude until the critical altitude is reached, and the airplane may be as much as 10% faster at 10,000 ft. than it is at sea-level.

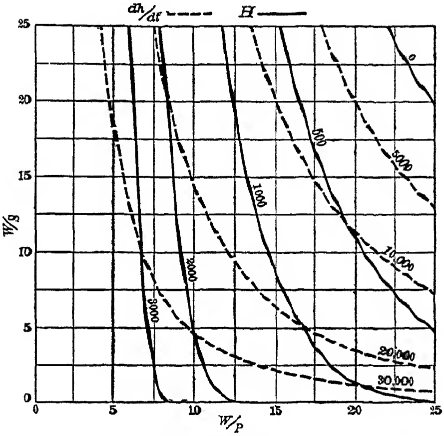

FIG. 24. Chart for Estimation Rate of Climb at Sea Level, and Ceiling

MINIMUM OR STALLING SPEED for horizontal flight is

$$V_{min} = \sqrt{W/L_{c\,max}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [21]$$

where W = gross weight, lb.; S = effective wing area, sq. ft. On the average, for airplanes without flaps or slots,

$$V_{min} = 17\sqrt{W/S} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [22]$$

Where flaps and slots are used, the constant ranges from 12 to 15.

MAXIMUM HORIZONTAL SPEED.—An empirical formula for maximum speed, based on actual performance of a large number of airplanes is

$$V_{max} = K(P/S)^{1/3} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [23]$$

where P = nominal horsepower; S = wing area, sq. ft.; K = a constant. For ordinary airplanes, K = 145; for exceptionally well "cleaned-up" machines, K = 150 to 183. The best transport and bombing planes of 1935 show K = 175 to 183; pursuit planes, K = 160 to 175; racing planes, K = 155 to 165. Formula [23] gives a close approximation for monoplanes and biplanes of all types. With a little experience in estimating K, it can be used to predict the maximum speed of a new machine within a percentage error that should not exceed 4. Fig. 23 gives maximum speed in terms of horsepower per square foot of wing area for machines of average quality and for exceptionally clean ones.

RATE OF CLIMB.—The rate of climb, dh/dt, at sea-level depends on the reserve of engine power, in excess of that required for level flight, available for doing work against gravity. It is approximated by

$$(dh/dt) = \{(25{,}000\,P/W) - 225\sqrt{W/S}\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [24]$$

Fig. 24 is a chart based on formulas [24] and [27], showing the relationship between rate of climb at sea-level, ceiling, wing loading, and power loading. Both ceiling and rate of climb formulas are predicated on the use of controllable-pitch propellers. This virtually is universal practice with all machines on which performance is a serious objective

CEILING CALCULATION.—An airplane reaches its absolute ceiling when the power available for flight exactly equals the power required. It can be shown that the ceiling, H, with an unsupercharged engine, can be expressed in terms of power available, P_{ao}, and power required P_{ro}, at sea-level, by

$$H = 40{,}000\log_{10}(P_{ao}/P_{ro}) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [25]$$

An empirical formula, based on the performance of a large number of unsupercharged airplanes, is

$$H = 40{,}000 \log_{10}\{120/(W/P)\sqrt{W/S}\} \quad [26]$$

W = gross weight, lb.; P = nominal horsepower; S = wing area, sq. ft. See Fig. 23.

Where the engine is supercharged to produce a constant power up to a certain altitude, and to fall off in accordance with the normal rule after that, the formula becomes

$$H = 0.75\, h_c + 40{,}000 \log_{10} [120/(W/P)\sqrt{W/S}] \quad [27]$$

where h_c = critical altitude.

A RANGE OF FLIGHT, x, in miles may be approximated by

$$x = 12{,}500 \log_{10} (W_1/W_2) \quad [28]$$

or more accurately by

$$x = 8000 \log_{10} (W_1/W_2) + 2400\{(W_1 - W_2)/W_1\} \quad [29]$$

where W_1 = initial gross weight, lb., and W_2 = final gross weight. $(W_1 - W_2)$ is the weight of fuel and oil consumed during the flight. For a very "clean" machine the constants in the formula may be increased as much as 25%. The range of flight, in accordance with the formula is given in Table 9.

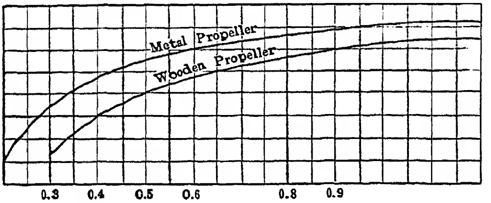

Fig. 25. Average Propeller Efficiencies. (Air Corps Data)

TAKE-OFF DISTANCE.— An empirical formula for the take-off distance x, in feet, from an ordinary field in a dead calm with a controllable-pitch propeller, but without the use of flaps or slots to reduce take-off speed, is given by

$$x = 200(W/S)/[\{110/(W/P)\} - 1] \quad [30]$$

With a propeller of fixed pitch, the coefficient of the first term in the denominator should be reduced to 85. With flaps and slots judiciously used, the run may be reduced by as much as a third of the figure given by the formula, the exact reduction depending on the particular variable-lift device selected. Taking off into the wind shortens the run. For a typical military or commercial plane, facing a 20-mile wind reduces the run about 50%.

5. POWER PLANTS

PROPELLERS.—Propeller characteristics usually are expressed in terms of the function V/ND, where V is speed of flight, N the r.p.m. and D the diameter. General propeller efficiency curves in terms of this function are given in Fig. 25. Engine power and propeller efficiency vary with airplane speeds. For most practical purposes the relationship between air speed and propeller revolutions per minute can be obtained from Fig. 26.

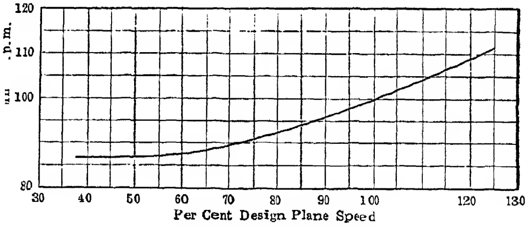

Fig. 26. Full Throttle R.P.M. at Various Speeds. (Air Corps Data)

SELECTION OF METAL PROPELLERS.—Reference should be made to N.A.C.A. Technical Report No. 350, Working Charts for the Selection of Aluminum-Alloy Propellers, by F. E. Weick, for complete charts and tables

Table 9.—Flight Range and Initial Fuel and Oil Load

(Average airplanes)

Approximate range, miles	1260	1960	2740	3610	4620

for the selection of metal propellers for a wide range of fuselage shapes and conditions. Fig. 27 is a typical chart.

PROPELLER DIAMETER.—A general formula for the calculation of propeller diameter is $D =$

$K \sqrt{(\frac{\ }{100}}$

where D = propeller diam., ft.; V = maximum speed, mi. per hr.; N = rev. per min.; K = a constant = 9.6 for a 2-bladed, and 9 for a 3-bladed propeller. The weight of fixed-pitch aluminum-alloy propellers can be calculated approximately by the formula

W : . . . [32]

where W = weight, lb.; P = nominal engine horsepower. Controllable-pitch types run about 30% heavier. Average weights of 2- and 3-bladed metal fixed- and controllable-pitch (aluminum-alloy blades in steel hubs) are given in Table 10.

ENGINES. — The general characteristics of a number of well-known American engines, which are commercially available are given in Table 11.

6. BALANCE, STABILITY AND CONTROL

Stability, balance, control and maneuvrability are closely related. The service for which any machine is intended dictates the predominant characteristic. A high degree of inherent stability is desirable in certain types intended particularly for the use of amateur pilots of limited skill, and great maneuvrability at the expense of stability is paramount for fighters.

LONGITUDINAL STABILITY AND BALANCE.—The longitudinal stability of an airplane is measured in terms of its pitching moments. These depend principally on the location of the center of pressure on the mean aerodynamic chord of the wing cellule, on the relationship between the center of pressure and the center of gravity of the airplane, and upon the size, location, and setting of the horizontal tail surfaces. For most machines the center of gravity lies in a vertical plane that intersects the mean aerody-

A = air cooled; W = liquid cooled; Rad. = radial; Id = inverted; L = in-line; V = vee type.

namic chord at a point about 30% of the chord from the leading edge. It seldom intersects further forward than 28% of the chord, or further aft than 33%. The longitudinal stability is steadily decreased by moving the center of gravity back along the wing chord, and most machines will become positively unstable with the center of gravity approximately at the 35% point.

HORIZONTAL TAIL AREA AND LONGITUDINAL STABILITY.—As a general rule, the total horizontal tail surface, *i.e.*, stabilizer plus elevators, for biplanes ranges from 11 to 14% of the total wing area, and for monoplanes from 13 to 16%. The distribution of horizontal area between fixed stabilizer and elevators varies, in percent of elevator area to total area, from about 38 to 55. The larger the tail surfaces in proportion to the wings, the further back the center of gravity can be placed along the wing chord, without causing instability.

VERTICAL TAIL AREA.—The total vertical tail area for biplanes ranges from 5.0 to 5.5% of the total wing area. Monoplanes run slightly higher, averaging about 6.5%.

For most landplanes the proportion of the total vertical area in the rudder varies from 60% to 70%. On seaplanes (float type), the ratio is 50 to 55%, and for flying boats, 40 to 45%. Seaplanes and flying boats require a greater percentage in fixed fin area to offset the keel plane area of the floats or hulls forward of the center of gravity.

AILERONS.—The total area of ailerons ranges from 7 to 12% of the wing area, with average values in the neighborhood of 9 to 10%. Aileron chords range from 15 to 25% of the wing chord, a good average being about 20%. Spans for ailerons range from 35 to 60% of the wing semi-span, averaging about 50%. These figures apply best to monoplanes. For biplanes with ailerons on the upper wing only, the span and chord average slightly above the figures given.

7. STRUCTURAL LOADS AND LOAD FACTORS

Most airplane structures are somewhat specialized space frameworks. They may be analyzed by applying the ordinary principles of mechanics, once the magnitude and location of the loads are known. The structural elements must be designed to withstand the worst of an infinite variety of combinations of loads which may be imposed while the machine is in flight under various conditions, or when approaching or leaving the ground.

CRITICAL LOADING CONDITIONS.—The external forces which act on an airplane are: 1. The air reactions, *i.e.*, lift, drag, etc. 2. Propeller thrust and torque. 3. Ground reaction, *i.e.*, landing and take-off. 4. Weight and inertia of the structure and its contents. A number of loading conditions have been determined to be critical, and always are investigated. These may be classified as: 1. *Main Loading Condition.* *a.* High angle of attack (as in violent maneuvers). *b.* Nose-diving. *c.* Low angle of attack (maximum flight speed). *d.* Inverted flight. 2. *Landing Conditions.* *a.* Three-point landing (wheels and tail-skid). *b.* Level landing (2-point). *c.* Drifted landing (side loading). 3. *Minor Loading Conditions.* *a.* Maximum fin and rudder load. *b.* Maximum stabilizer and elevator loads. *c.* Maximum aileron load. *d.* Nosing over on the ground. *e.* One-wheel landing. *f.* Braked-landing. For detailed rules as to method of analysis for the various conditions, see Aeronautics Bulletin No. 7A, U. S. Dept. of Commerce, Airworthiness Requirements of Air Commerce Regulations for Aircraft.

LOAD FACTORS.—To take care of accelerations in flight and in landing, structures must be analyzed not on the basis of actual weight, but on gross weight, increased by certain factors whose magnitude depends on the service for which the airplane is intended. Thus, U. S. Army specifications (1935) require a factor of 12.0 to be used in analyzing pursuit types for the high angle of attack condition. Factors for commercial aircraft, which are not called upon to do violent acrobatics, fall below these limits. The load factors required by the Department of Commerce for the wing truss at a high angle of attack (customarily the most severe condition) are determined approximately by

$$n = 1.5 + \{V/(3W/S)\}\{4/(3 + 6/R)\} \quad [33]$$

$$n = 1.5 + \{3.75 + 156{,}000/(W + 9200)\}/(W/P)^{0.435} \quad [34]$$

where n = ultimate load factor that must be sustained before failure; W = gross weight, lb.; W/S = wing loading; W/P = power loading; R = aspect ratio; V = maximum speed, mi. per hr. In any particular case, the load factor used is the higher of the two resulting from the separate application of the two formulas. The Department of Commerce rule for load factors in the landing gear and fuselage in landing is

$$n = 4.2 + 13{,}500/(W + 4000) \quad [35]$$

The loads, for which other parts of the structure must be designed, are similarly indicated by formulas especially derived for the conditions there prevailing.

Table 12 lists the approximate range of weights of a variety of airplane materials and accessories. Table 13 lists unit weights for several commonly used materials. Table 14 has been condensed from a study of weights of a number of typical existing airplanes.

LIGHTER-THAN-AIR CRAFT

Balloons and airships derive their lift from simple displacement of the air. A certain degree of dynamic lift may be developed from the forward motion of a power-driven streamlined airship envelope, but, in general, equilibrium conditions are reached at an altitude where the displaced volume of air equals the weight of the aerostat. The absolute altitude of equilibrium varies with atmospheric conditions. (See page 14–98 for definitions and classification of airship types.)

AIRSHIP CHARACTERISTICS.—The external shape of an airship envelope is dictated by structural economics and considerations of parasite drag and of control. Practically, pure streamline shapes of optimum dimensions cannot be used, as it is necessary

(Continued on p. 14–118)

Table 12.—Weights of Miscellaneous Aircraft Parts and Accessories

Low-voltage generators (15–50 amperes)	15–32 lb.
Double-voltage radio generators	21–34 lb.
Dynamotors (including control switch)	6–30 lb.
Generator control boxes	3–5 lb.
Storage batteries (6 volt–65 amperes)	65–70 lb.
Landing lights (per pair)	15–20 lb.
Running lights (set of three)	1 lb.
Transport radio-beacon receiving sets (total installed weight including dynamotor, but excluding battery)	30 lb.
Transport radio, 50-watt, 2-way transmitting and receiving equipment (average installed weight excluding storage batteries)	100–110 lb.
Transport radio-antenna and miscellaneous wiring (extra)	10–15 lb.
Two-way radio for private ships, including dynamotors	45–48 lb.
Starters, hand-inertia	20–30 lb.
" , electric-inertia	27–39 lb.
" , direct cranking electric	16–33 lb.
" , injection type	28–30 lb.
Instruments, common navigation or engine types, complete (each)	1–2 lb.
" , magnetic compasses	2–4 1/2 lb.
" , magneto or earth-inductor compasses	11–12 lb.
" , Sperry (Horizon, Directional Gyro, each)	3 1/2–4 lb.
" , Sperry Gyropilot (installed)	60–75 lb.
Parachute flares, large, with brackets	22 lb.
Shock absorber struts, static loads 1000–7500 lb., each	10–50 lb.
Adjustable airplane chairs, single	12–15 lb.
Washroom equipment, basins, complete	3–5 lb.
" " , 2-3 gal. tanks	4 1/2–5 1/2 lb.
" " , chemical closets	10 lb.
Parachutes (all types)	17–23 lb.

Seaplane floats: Weight $= 0.10 \times (\text{submerged displacement})^{0.92}$

Attachment structure for twin float installation: Weight $= 0.09 \times (\text{gross wt. of seaplane})^{0.85}$

* Retracting landing gear, includes weight of retracting mechanism.

to modify the structure to attach control cars, power-plant housings, control surfaces, etc. For most practical purposes, the volume of the average airship envelope may be estimated from $V = \frac{1}{2}LD^2$, where V = volume, L = length, and D = maximum diameter. Under standard atmospheric conditions at sea-level, buoyancy may be taken as 64 lb. per 1000 cu. ft. for hydrogen and 58 lb. per 1000 cu. ft. for helium. In a rigid ship, with a multiplicity of gas cells, the gas volume is usually about 5% less than the volume enclosed by the outer cover.

For rigid types the fineness ratio (length/max. diam.) is tending downward. Early ships exhibited ratios of $8\frac{1}{2}$ or 9; present practice (1935), as indicated by the Akron-Macon class, reduces the ratio to 6. On non-rigid ships, structural factors favor a lower fineness ratio; it ranges between 3 and 5. Comparative statistics of three of the best known rigid airships of recent design are given in Table 1.

Table 1.—Characteristics of Typical Rigid Airships

	Los Angeles	Graf Zeppelin	Akron and Macon
Overall length, ft.	658	776	785
Maximum diameter, ft. .	91	100	133
Gas volume, cu. ft.	2,470,000	3,700,000	6,500,000
Gross lift, lb.	153,000	258,000	403,000
Total Hp.	2,000	2,750	4,480
Maximum speed, m.p.h. .	73	80	84

AIRSHIP PERFORMANCE.—The maximum speed of an airship depends simply upon its coefficient of aerodynamic resistance, complete with tail surfaces and cars. The coefficient commonly is stated in terms of the resistance per unit of volume of the airship envelope, rather than in terms of frontal area, as with airplane parts. Total resistance varies as the two-thirds power of the volume. Thus, $R = Cv^{2/3}V^2$, v being the volume of the envelope, cu. ft., and V the velocity, mi. per hr. Using the customary mi.-per-hr. and sq. ft. units, the value of C for the best rigid airship forms falls as low as 0.000035 for the bare envelope, or 0.00006 for a complete ship. Knowing the propeller efficiency, the power required for a given speed can be calculated and a maximum-speed formula obtained in the form $V_{max} = K\sqrt[3]{P/v^{2/3}} = K\sqrt[3]{P/v}(v^{1/9})$, where P = engine power and v = the volume. K attains a maximum value of approximately 165, and can be taken as 165 for large rigid airships of good design, and as 125 for typical non-rigid ships. Unlike airplanes, airships show an inherent increase in performance with increasing size. If the power and volume and lift all be doubled the maximum speed will, other things being equal, be increased by 8%.

The ceiling attainable with an airship depends almost solely on the relation between the minimum fixed, or non-disposable, weight of the ship and the total lift that would exist at sea-level if all the gas cells were filled to the limit. In attaining high altitudes the airship acts as a free balloon, and its altitude performance follows free-balloon laws. The ship will rise until the gas in the partly-filled cells has expanded to fill them completely, and then continue to rise until the density of the surrounding air has decreased to a point where the ascensional force, or difference between the weight of air displaced by the ship and the weight of the gas doing the displacing, is barely equal to the solid weight of the ship at that moment. The altitude that can be attained is given approximately, including an allowance of 1000 ft. for the effect of dynamic lift in carrying the ship above the level of static equilibrium, by $H = 29{,}000(1.75 - \sqrt{4(W_2/W_1) - 1})$, where W_1 = maximum lift of airship at sea-level with gas cells full; W_2 = total weight that has to be carried to the highest altitude.

The range of an airship in still air increases steadily with declining speed, the lowest speed always being the most economical under that condition. Other things being equal it increases, like maximum speed, with increasing size. An approximate range formula, for ships using liquid fuel exclusively and inflated with helium, is

$$X = 21{,}000(W_f/W_1) \times \{\sqrt[3]{(v \times 10^{-6})}/(V/50)^2\}$$

where X = range, miles; W = maximum lift, lb. at sea-level; W_f = weight of fuel carried, lb.; and V = cruising speed mi. per hr. For a hydrogen-filled ship the constant is increased to 24,000, but W_f/W_1 also is increased, as the extra lift of the lighter gas can all be put into extra fuel. The final result of replacing helium with hydrogen is likely to be an increase of range at a given speed approximately 40%.

Section 15

ELECTRIC POWER

By E. S. Dibble

TABLE OF CONTENTS

ELECTRIC POWER

By E. S. Dibble

PURCHASED POWER

The factors influencing choice of electric current for industrial applications are summarized below.

ALTERNATING CURRENT (A.C.) can be transmitted economically over long distances and utilized by transformation of its voltage. A.C. motors and generators are available for practically all types of work, and are less expensive and of simpler construction than D.C. machines. Purchased power usually is alternating current, and conversion or local generating equipment is necessary if direct current is needed. Alternating current is generated at 25, 50 and 60 cycles. The latter is the most common as it is satisfactory for lighting, and higher speed motors may be used than with 25- or 50-cycle current. Equipment generally is standardized on 60 cycles.

DIRECT CURRENT (D.C.) is required in large amounts for some processes, as electrolytic, certain types of welding, and a few motor applications, such as variable speed drives with fine speed adjustment. Some driven machines have torque characteristics that are met only by D.C. motors. The character of plant load and relative amount of direct current needed determine whether it shall be generated as direct current or converted from alternating current at the point of use. If the amount of direct current is relatively small, the latter course generally is advisable.

1. PLANT POWER SUPPLY

The usual sources of power supply for an industrial plant are: 1. Purchased power; 2. Private generating plant; 3. Private generating plant supplementing purchased power.

PURCHASED POWER.—Rates will vary in different localities, and with the amount of power used. In a given locality, a group of consumers usually will have lower rates than a single consumer. Factors influencing low rates are: Large energy consumption; proximity to distribution lines; constant load; high power factor.

Reliability.—Efficiency of large generating stations is higher than that of the smaller stations of average industrial plants. Duplicate power lines and extensive interconnection of high-voltage distribution systems make remote the chances of serious interruption of power.

Isolated Locations.—Rates will be high and reliability low when relatively small amounts of power are transmitted over a single long line to one or a group of industries. Duplicate lines would increase reliability but would also increase cost. A private generating station, under such conditions, may be warranted, especially for continuous-process industries where reliability is of first importance.

PRIVATE GENERATING STATIONS.—**Low-pressure Process Steam** is required by textile, sugar and paper mills, glue factories, dye works, chemical plants and other industries. A complete steam plant is necessary, which can, by minor changes in design, produce the same weight of steam at a pressure sufficient to operate turbo-generators, the exhaust being used as process steam. With boiler and exhaust pressures of 250 lb., gage, and 15 lb., gage, respectively, about 1 kw.-hr. may be obtained per 30 lb. of steam. That is, process steam requirements of 30,000 lb. per hour would make available 1000 kw. of electricity, at a fuel cost equal to the difference in fuel required to produce equal weights of steam at 250 lb. and 15 lb., gage.

Waste Heat or Waste Fuel may be available as by-products in such industries as smelting and refining. Electricity generated from such by-products, either by means of steam produced in waste heat boilers, or by using the fuel in Diesel or gas engines, has little or no fuel cost chargeable to it. The total cost of boilers, etc., however, must be included in the cost of electrical equipment.

2. SUBSTATIONS

THE MAIN SUBSTATION reduces transmission line voltage to a voltage suitable for industrial plant use. Common public utility line voltages are 13,200, 11,000, 6600, 4000, and 2300 volts. Usual industrial plant voltages for motors are 220, 440, and 550, and for lighting, 115 to 120 volts. Some large industries, with extensive distribution within the plant, may take current at 6600 volts. The substation also may include conversion equipment to provide D.C. power or A.C. power of a different frequency.

Ownership of the Substation usually rests with the public utility, which operates and maintains it.

Location of the Substation depends on the relative location of the customer and the public utility transmission lines. On high-voltage lines, it probably will be located at the point where the lines are tapped. For a short extension of an existing line operating at 22,000 volts or lower, the sub-station would be placed at the receiving end of the extension.

INDOOR AND OUTDOOR SUBSTATIONS.—Outdoor substations are used where conditions permit. They have the following advantages: Reduced fire hazard from oil-filled transformers and circuit breakers; easier and less expensive separation of high-voltage bus structures; small difference in cost of outdoor and indoor equipment above 15,000 volts. Most industrial substations are simply transformer stations with static equipment only, located outdoors on the consumer's premises. In congested areas, substation equipment must be indoors. It may be placed in a room or corner of an existing building, if Code requirements are met.

Substation Capacity must be sufficient to carry peak load without excessive voltage variation. Transformer ratings or the ratings of rotating conversion equipment will be governed by the load characteristics.

Demand Factor is the ratio (actual maximum demand/connected load). It is used in determining capacity of equipment, and in fixing rates for power supplied by public utilities. Demand factors, determined by actual measurement with maximum demand meters, have been tabulated by public utilities for different classes of industries.

Example.—The demand factor for industries working sheet metal is about 70%. The probable maximum demand of a sheet metal manufacturer, whose connected load is 1000 kw., would be 1000 × 0.70 = 700 kw. Substation equipment would be installed on this basis. The time interval over which measurement has been taken should be specified.

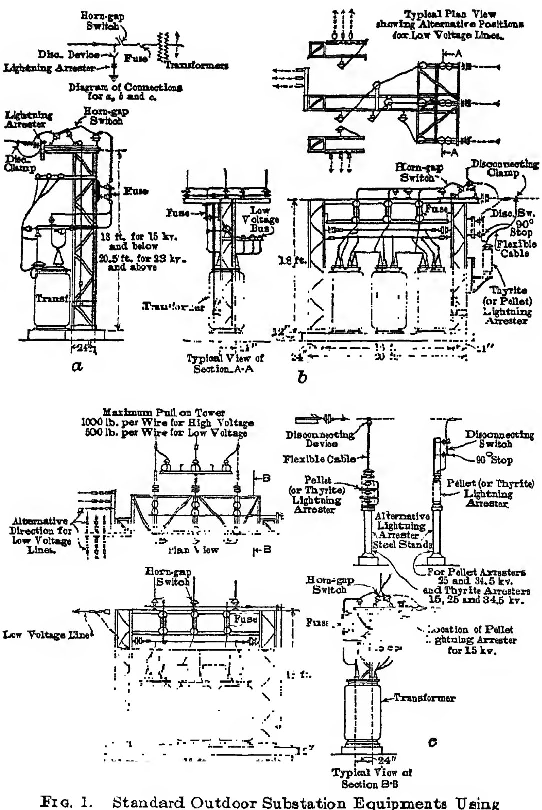

Fig. 1. Standard Outdoor Substation Equipments Using High-voltage Fuses

Load Factor is the ratio (average power ÷ peak power). It also is used in fixing rates, and in determining capacity of equipment. The interval of maximum load must be specified, and also the period over which load is averaged, as a 15-min. monthly, or a 30-min. yearly load factor. Continuous-rated equipment is installed when load factor is at or near unity. Overload capacity is relied on to carry peak loads of short duration, occurring only occasionally.

Switching Arrangements and Number of Circuits in the substation depend on the nature of the service and probability of system disturbance. Power interruptions of short duration, causing only loss in production and labor are not serious, but they are serious in industries using batch or continuous processes. In the latter case insurance of the continuity of service will warrant considerable expense.

MAIN SUBSTATION EQUIPMENT is essentially the same for outdoor substations served by an overhead line, or indoor substations served by underground cable. Fig. 1 shows typical standard substation equipment for outdoor use. The range of capacities of the arrangements shown are as follows:

Fig. No.	1*a*	1*b*, 1*c*
Transformer capacity, kva.	75–1500	150–1500
Maximum primary voltage	34,500	,
Secondary volts, up to 450 kva.	440 or 2300	440 or 2300
Secondary volts, over 450 kva.	2300	2300

A single equipment includes: One each of galvanized steel structure, galvanized steel bracket for distribution-type arresters for 23,000 to 34,500 volts; horn gap switch with manual operating mechanism; three each of fuse disconnecting switches, disconnecting clamps for isolating distribution-type arresters, or disconnecting switches for isolating station-type arresters, distribution-type or station-type lightning arresters.

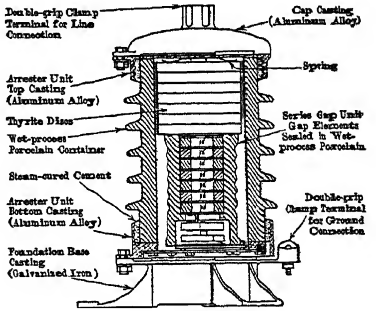

Fig. 2. Thyrite Arrester Unit

Substation Metering Equipment comprises current and potential transformers connected on the high- or low-voltage side of the transformer bank, depending on who is to be charged with transformer losses, and metering instruments. The latter comprise arresters, voltmeter, watt-hour meter and reactive-volt-ampere-hour meter, located either outdoors or on an incoming line panel.

Horn-gap Switches will interrupt the magnetizing current of the transformer bank, and, in emergencies, may interrupt load current. They are not recommended for load-break switches or for breaking heavy line charging current. For such purposes, an oil circuit breaker would be used with disconnecting switches.

3. LIGHTNING ARRESTERS

Lightning arresters are necessary only for exposed lines, and should be placed close to the equipment to be protected. Distribution-type arresters are used for transformer banks up to 1000 kva., and station-type arresters for banks over 1000 kva.

THYRITE ARRESTERS.—Station-type Arresters consist of stacks of arrester units, the number depending on the voltage of the circuit. Table 1 shows the maximum and minimum arrester voltage ratings and the corresponding rated circuit voltages at which these arresters should be used.

Table 1.—Thyrite Station-type Lightning Arrester Ratings

Rated circuit voltage	2300	4600	6900	11,500	13,800	23,000
Rated arrester voltage	1000*	3000*	6000*	9,000*	9,000*	23,000
Max. arrester voltage	3000	6000	9000	15,000	15,000	25,000

* Minimum voltage rating.

Thyrite Unit Arresters comprise discs of thyrite material, assembled as in Fig. 2. Thyrite is an insulator at one voltage and a conductor at a higher voltage, its resistance being a function of voltage only. Doubling the applied voltage will increase a given current I to about $12.5\ I$.

Thyrite Bushing Arresters are mounted inside the bushings of pole-type, 2400- and 4800-volt distribution transformers, rated up to 100 kva. The arresters are so connected that they shunt the high-voltage and low-voltage insulations. Lightning discharges are dissipated through ground on the low-voltage side, or to the transformer tank. Protection is obtained at a saving of 40 to 60 percent in cost, as compared with externally mounted arresters. Fig. 3 shows single-phase connections.

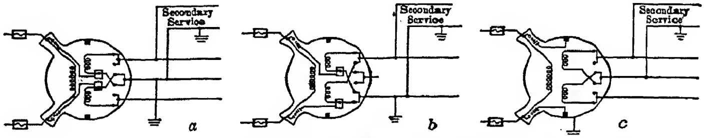

FIG. 3. Connections for Bushing Arresters for Distribution Transformers

DISTRIBUTION LIGHTNING ARRESTERS.—**Pellet-type Arresters** are used to protect distribution transformers, medium-size substations, and cable terminals. Fig. 4 shows construction for voltages up to 15,000 kva. Fig. 5 illustrates typical connections for protecting distribution circuits and transformers. An installation is shown in Fig. 7.

Diagram *a* shows 3-phase and single-phase applications to 3-phase ungrounded-neutral systems or systems with the neutral grounded through resistance or reactance. The rating of the arresters is selected on the basis of line-to-line voltage. Diagram *b* shows 3-phase and single-phase applications to 3-phase, 3-wire, solidly grounded neutral systems. Diagram *c* shows 3-phase and single-phase applications to 3-phase, 4-wire, solidly grounded neutral system with the neutral wire carried out. The rating of the arresters, on the main circuit wires in *b* and *c*, can be less than line-to-line voltage, usually of the next lower rating to that used on delta or ungrounded neutral systems. The maximum rating of the arrester on the neutral of *c* is equal to, or higher than, the potential from neutral to ground due to any phase unbalancing. The ground on the neutral at the power source does not in any way reduce the lightning potentials occurring on the neutral wire out on the circuit. It is just as important to apply arresters to the neutral as to the phase wires, where the neutral is connected to the apparatus.

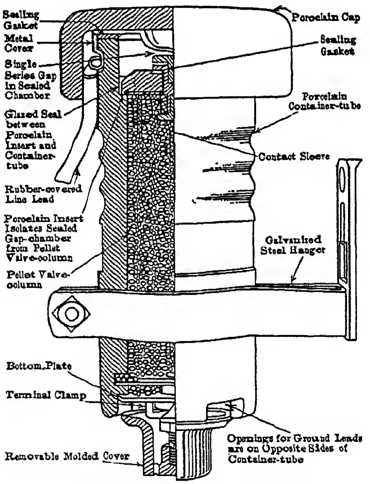

FIG. 4. Pellet-type Lightning Arrester

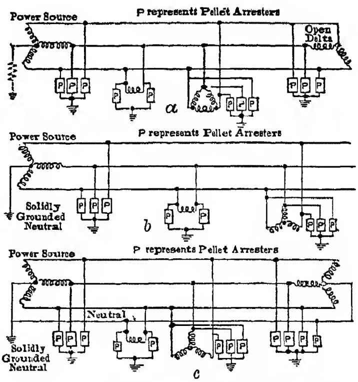

FIG. 5. Application of Lightning Arresters

Compression Chamber Arresters can be used on A.C. circuits up to 750 volts, which includes secondary lighting and power circuits.

4. DISCONNECTING EQUIPMENT

DISCONNECTING SWITCHES are used for isolating equipment, for bus sectionalizing, for transfer switching and for line sectionalizing. Standard sizes of indoor types are 200, 400, 600, 1200, 2000 and 3000 amperes, mounted on insulating bases for 5000-volt circuits, and on insulators for higher voltage. They are made single-throw, double-throw, front- or rear-connected, as required by the installation. Fig. 6 shows a typical outdoor switch with manual operating mechanism.

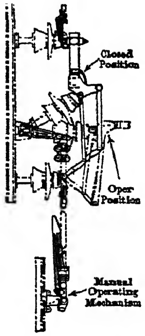

FIG. 6. Typical Outdoor Disconnecting Switch

SUBSTATION CIRCUIT BREAKERS.—For small industrial plants a substation may consist of a distribution transformer and its protective equipment. See Fig. 7. Usual voltage transformation for this type of station is 2300 to 220/440 volts. Fuse cutouts give full protection against short circuits and oil switches are unnecessary. However, automatic switching and interruptions of circuits under load require oil circuit breakers. Duplicate lines feeding the substation require oil circuit breakers to provide selective switching to clear faults and insure continuity of service.

OIL CIRCUIT BREAKERS are designed to interrupt circuits under load and provide protection against short circuit currents by making and breaking contacts under oil. Rating is based on normal continuous current in the circuit, maximum current that can be carried for a short time without mechanical failure and maximum current that can be interrupted on short circuit.

Classification.—1. Service, indoor or outdoor. 2. Operating method, manual or electric. 3. Method of mounting. *a.* On back of panel; manual operation recommended if voltage does not exceed 5000 volts between lines. *b.* Alone on panel frame to match and line up with existing installation. *c.* Remotely on frame, either manually or electrically operated. *d.* In cubicles, for increased safety and decreased fire hazard.

Manual Operation of large breakers is not feasible because of the excessive thrust required. Small and medium size breakers usually are operated by a lever on the front of the panel.

Electrical Operation is used for breakers remotely located, or too heavy for manual operation. Either a solenoid or a motor can be used. Coils of standard solenoid-operated mechanisms are wound for 48, 125 and 250 volts. Low-voltage operating coils are not recommended for large breakers.

Methods of Tripping.—1. Over-current trip coils, operated from current transformers, will meet requirements of most industrial plants. For large industrial plants, with more complicated systems of control, and those generating their own power, relays will insure more accurate tripping. 2. Circuit opening relays, operated from current transformers, giving more accurate time delay in tripping on over-current, which opens contacts and permits current to flow in trip coils. Relays which close the trip circuit will give under-voltage or over-voltage tripping.

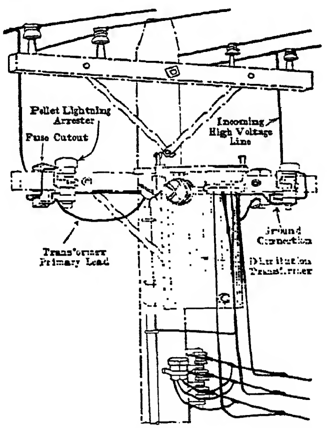

FIG. 7. Typical Distribution Substation for Small Power Users

SELECTION OF OIL CIRCUIT BREAKERS depends on: 1. Normal voltage of circuit in which breaker is to operate, defined as highest rated voltage of the secondary of transformers supplying the system. 2. Normal root-mean-square current of the circuit. 3. Magnitude of short circuits to which breaker will be subjected. 4. Root-mean-square value of short circuit currents. 5. Operating time of relaying devices and breaker-operating mechanisms, determining the interrupting duty under a given condition. 6. Altitude at which breaker is to operate, guiding proper selection of high-voltage bushings, the amount of insulation required varying with altitude. 7. Lowest temperature to which breaker is subjected, enabling proper selection of oil.

OIL CIRCUIT BREAKER RATINGS.—**Interrupting Rating** is determined by the highest root-mean-square amperes that the breaker successfully will interrupt at any specified voltage and for a specified duty cycle. See Table 2.

Short Time Rating is determined by the highest root-mean-square amperes that breaker will carry for a specified time without damage.

‡ The duty cycle on which standard interrupting ratings of oil circuit breakers are based assumes that the breakers will interrupt a circuit under the conditions imposed by two unit operations. Each unit operation consists of closing the circuit breaker, followed immediately by its opening without purposely delayed action. The standard duty cycle of oil circuit breakers is based on two unit operations with 15 seconds interval, except for non-oil-tight breakers of 50,000 kva. rating and below, which have a standard duty cycle consisting of two unit operations with a two minute interval. For example, OCO is a unit operation. Beginning with the breaker open, it is closed and opened, and after a two minute time interval the unit operation is repeated.

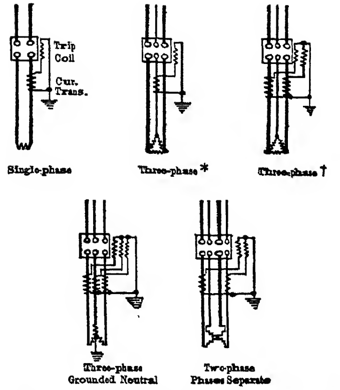

FIG. 8. Circuit Breaker Tripping Connections with Tripping Coils Operating in Secondary of Current Transformers ‡

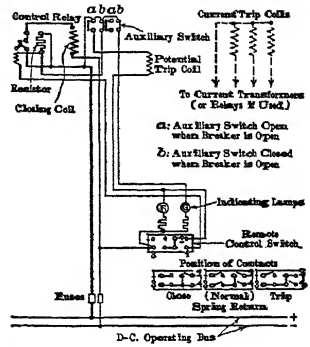

FIG. 10. Typical Control Connections for Remote-control D.C. Solenoid Circuit Breaker Operating Mechanisms

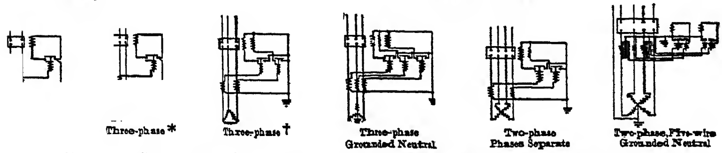

FIG. 9. Circuit Breaker Tripping Connections Using Overcurrent Relays ‡

COST OF OIL CIRCUIT BREAKERS depends on operating voltage, current rating, method of operation, and system short-circuit values. Accurate estimates of costs cannot be made until these factors have been investigated. See Table 2 for typical ratings. Manufacturers should be consulted in regard to circuit breakers to meet specific conditions.

CIRCUIT BREAKER CONNECTIONS.—Figs. 8, 9, 10 show recommended connections for trip coils operating with current transformers, relays or other tripping devices. Power storage batteries are advised for complicated relaying in connection with oil circuit

* Used for railway service only, to protect A.C. motors, synchronous converters, transformers or incoming lines.

† Always provide three over-current coils if circuit is served by transformers whose primaries are connected in Y with neutral not connected to system or grounded.

‡ For incoming service lines, where Underwriters' rules apply, an over-current unit must be provided in each ungrounded conductor.

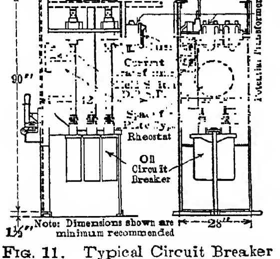

FIG. 11. Typical Circuit Breaker Installation for Circuits up to 2500 Volts

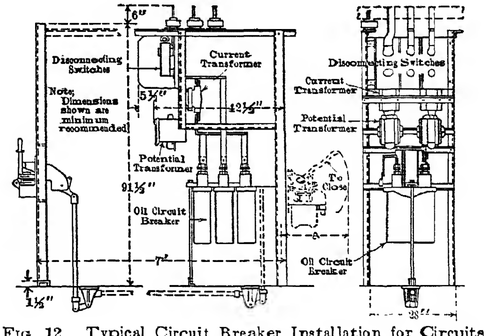

FIG. 12. Typical Circuit Breaker Installation for Circuits up to 5000 Volts

breakers using a separate D.C. source of tripping. Suggested arrangements for indoor type circuit breakers for maximum values of 2500 and 5000 volts respectively are shown in Figs. 11 and 12.

5. TRANSFORMERS

A transformer consists essentially of two insulated coils assembled on an iron core, and immersed in oil in a tank. In small sizes, coil and core may be exposed directly to the air. The coils are designated primary and secondary, or high-voltage and low-voltage. Sometimes more than two windings are involved. A.C. voltage, applied to one coil, will induce in the other coil a voltage which will be in the same ratio to the primary voltage as the ratio of the numbers of turns in the two windings. Thus, if 1000 volts be applied to the high-voltage coil of a transformer in which the ratio of high- and low-voltage turns is 10 : 1, voltage induced in the low-voltage coil will be $1000 \times (1/10) = 100$ volts. The function of a transformer is to receive power at one voltage and deliver it at another.

POWER TRANSFORMERS comprise ratings above 500 kva., 25 and 60 cycles. See Table 3. Standard voltage ratings conform to preferred ratings as covered by N.E.L.A. and N.E.M.A. publications, April, 1930. Tables 4 and 5 cover power transformers for substation and general use.

Notes for Tables 4, 5, 6 and 7

Note 1.—Voltages marked * are preferred for new undertakings, and indicate suggested trend for future practice.

Note 2.—Where two voltages are given, the first figure indicates the line to line voltage on the high voltage side when transformers are connected single-phase or three are delta-connected; the second figure indicates the line to line voltage that may obtain, without exceeding the individual high voltage rating as indicated by the first figure, of three transformers Y-connected.

Note 3.—Full rated secondary voltage will be obtained with high voltages lower than rated high voltages as shown by two columns, when transformer is connected to corresponding taps. These taps provide leeway for variation in system voltage.

Note 4.—Nominal low voltage is voltage at point of use, and is that at which motor performance, etc., is guaranteed. Rated low voltages are those that will be delivered by the transformer and provide for line drop between transformer and current-using apparatus.

Note 5.—Transformers will deliver continuously full rated kva. output at rated voltage and at 5% above rated voltage without exceeding guaranteed temperature rise. They are suitable for operation at 5% below rated voltage, but may not conform to performance standards for operation under rated conditions.

Note 6.—Transformers with low-voltage rating 115/230 and 120/240 volts, 200 kva. and smaller are suitable for series multiple or 3-wire service; sizes 250–500 kva. inclusive are suitable for 3-wire service only. Transformers with low voltage rating 230/460 and 240/480 volts are suitable for series or multiple service only.

Standard transformers have a guaranteed temperature rise of 55° C. for continuous operation, referred to room temperature for self-cooled, and inlet water temperature for water-cooled transformers. The usual temperature limits specified are: room, 40° C.; inlet water, 25° C. Temperature rise is not affected by room or water temperature, but actual temperature is the sum of reference temperature and rise. The A.I.E.E. rules limit the observable temperatures after continuous load to 95° and 80° C. respectively, for self- and water-cooled transformers with insulations commonly used.

Power Transformer Construction.—Single-phase transformers usually are built on 2-legged cores and 3-phase transformers on 3-legged cores. Fig. 13 shows a typical single-phase construction with circular winding. Circular coils are produced in three ways: Assembled disc coils stacked over a Herkolite cylinder and connected; continuous disc coils wound directly on the Herkolite cylinder; helical coils with rectangular strands of the conductor wound in parallel over a Herkolite cylinder. Disc coils and continuous disc coils are used for high and medium voltage transformer ratings, and helical coils for low voltage and high current transformer ratings. High-voltage, 2-winding transformers usually have the low voltage winding over the core leg and the high voltage winding concentrically outside.

Cost of Power Transformers.—Figs. 14 and 15 show approximate 1935 prices per kva., of self-cooled step-up or step-down power transformers.

DISTRIBUTION TRANSFORMERS include ratings of 500 kva. and less, single and 3-phase, 25 and 60 cycles, for primary voltages up to 66,000 volts. The average industrial user is concerned only with primary distribution voltages of 2600 to 6600 volts. The following are standard kva. ratings of distribution transformers in sizes up to 500 kva.:

Single-phase, kva.....1.5, 2.5, 3, 5, 7.5, 10, 15, 25, 37.5, 50, 75, 100, 150, 200, 250, 333, 500
Three-phase, kva.....................10, 15, 25, 37.5, 50, 75, 100, 150, 200, 300, 450

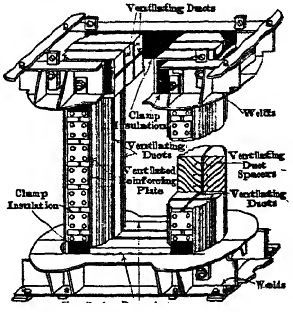
Table 6 covers the range of voltage ratings for single-phase, and Table 7 the range for 3-phase transformers.

Distribution Transformer Construction varies with differences in rating, either as to capacity or voltage. Differing heat-radiating requirements, mechanical forces, and voltage stresses are best met by changes in the core, coil, insulation or tank construction. See Table 8 for construction of single-phase transformers. Three-phase distribution transformers have core type construction.

Tank construction varies with kva. rating, a plain tank being sufficient for a small transformer. As kva. capacity increases, heat increases in proportion to volume of core and coils, but heat dissipating ability increases only as tank surface. Surface is increased by adding corrugations or tubes. Tanks are built of copper-bearing steel with parts welded together.

Self-contained lightning protection is available, in sizes of 100 kva. and smaller, for 2400/4160 and 4800/8320 grounded Y circuits. See Fig. 3 for connections as applied to single-phase units.

Cost of Distribution Transformers.—Figs. 16 and 17 show approximate 1935 prices per kva. of self-cooled 60-cycle distribution transformers. 25-cycle transformers range from 20 to 60% higher, depending on voltage and kva. rating.



Assembly of Two-legged Split Core

FIG. 13. Typical Power Transformer Core Construction

INSTRUMENT TRANSFORMERS are interposed between high-voltage circuits and meters and instruments. They are classed as potential transformers and current transformers.

Potential Transformers, built both for indoor and outdoor service, are used to obtain

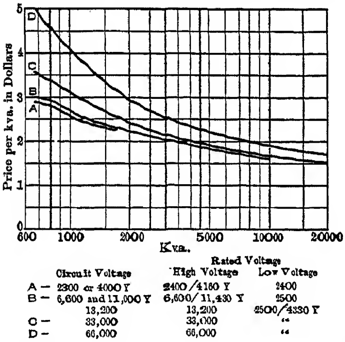


FIG. 14. Self-cooled, 60-cycle, Single-phas Power Transformers

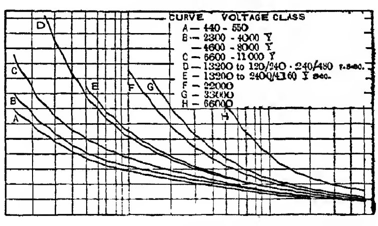

FIG. 17. Self-cooled, Single-phase, 60-cycle Distribution Transformers

Approximate 1935 Transformer Prices

voltage measurements when it is necessary to insulate switchboard appliances from line voltage on A.C. circuits. Indoor construction is built for voltages up to 13,800; outdoor

construction is used for both outdoor and indoor service with higher voltages. The accuracy of the average transformer will be within 1% of the name-plate ratio within the volt-ampere ratings. At low outputs, the phase angle will not exceed 15 min. Special transformers are designed for higher accuracy. See Table 11 for volt-ampere ratings.

Potential transformers are available with fuses mounted on the cases, or separately mounted. Current-limiting resistors are recommended on all circuits above 550 volts where primary fuses are used.

Current Transformers, built for indoor or outdoor service, are used where current measurements are taken and it is necessary to insulate against high voltage, or where circuit current is too high to be read directly. See Table 12.

Table 8.—Index to Construction of Standard 60-cycle, Single-phase Distribution Transformers

High-voltage Class	Kva. Range	Type	High-voltage Class	Kva. Range	Type

TRANSFORMER CONNECTIONS FOR VOLTAGE TRANSFORMATION, 3-PHASE are the delta-delta, Fig. 18; star-star, Fig. 19; star-delta, Fig. 20; delta-star, Fig. 21; open-delta, Fig. 22. The relative advantages and disadvantages are as follows:

Delta-delta.—*Advantages.* Most economical connection for large output at low voltage; a 3-phase bank can operate in open-delta for 58% output if one unit or phase fails; third harmonic

voltages are eliminated; easy to phase in for parallel operation; heavily unbalanced 3-wire loads can be supplied without serious voltage unbalance. *Disadvantages.* Copper cross-section of both primary and secondary windings is a minimum while number of turns and insulation per phase is a maximum, resulting in a low copper factor and least sturdy winding; neutral point of windings not available; insulation stresses higher than in a star connection.

Transformer Connections

Star-star, used mostly for 3-phase, core-type transformers for small power loads. *Advantages.* Copper cross-section is maximum, number of turns in insulation per phase is a minimum resulting in high copper factor and mechanically strong winding; able to withstand heavy external short circuits; most economical for small output at high voltages; both neutrals available for grounding or for balanced 4-wire supply; easy to phase in for parallel operations; two-phases can be operated for single-phase at 58% output. *Disadvantages.* Neutral points are inherently unstable unless solidly grounded, and unbalanced 4-wire load cannot be supplied unless primary and secondary neutral points are tied together for shell-type or banks of single-phase transformers; a fault on one phase renders a 3-phase bank or unit inoperative for 3-phase output; third harmonic voltages exist but can be eliminated if transformer has a tertiary winding, connected delta, which supplies a short-circuited path for third harmonic currents. This delta winding also can supply loads, and if connected to a synchronous motor or condenser improves power factor.

Star-delta connection is considered best for high voltage transmission. Its chief application is a balanced 3-phase load, such as motors. *Advantages.* Third harmonic voltages eliminated by delta-connected secondary; primary can be grounded; most desirable for step-down transformers; secondary delta connection stabilizes the primary neutral. *Disadvantages.* No secondary neutral available for grounding or for 3-phase, 4-wire supply; a fault on one phase renders a 3-phase unit or bank inoperative.

Delta-star connection is used chiefly for step-down transformers, 4-wire distribution, supplying motor and lighting loads, balanced or unbalanced, and also for stepping-up voltage for power transmission. *Advantages.* No third harmonic; secondary neutral available for grounding or for 3-phase, 4-wire supply; suitable for unbalanced 4-wire load, resulting unbalanced voltage being relatively small; balanced and unbalanced loads may be applied simultaneously. *Disadvantages.* No primary neutral available for grounding; a fault in one phase makes 3-phase unit or bank inoperative.

Open-Delta.—*Advantages.* A 3-phase, shell-type transformer can operate in open-delta with one damaged phase; a transformer bank consisting of three single-phase units can be operated in an open-delta, since a damaged single-phase unit can be removed entirely. *Disadvantages.* A 3-phase, core-type unit usually cannot be operated open-delta because all three phases are magnetically interlinked; with delta-connected 3-phase, shell-type transformers, a damaged phase must be disconnected and short circuited on itself to prevent voltage being induced by the good phases; to

operate a 3-phase, core-type transformer in open-delta, the damaged phase must remain open circuited and yet be capable of withstanding normal voltage induced in it from the other phase windings; when connected open-delta, current in each transformer is 30° out of phase with voltage and transformer operates at 86.6% power factor if load is non-inductive. Capacity of a 3-phase transformer, or of a 3-phase bank, connected open-delta, with the damaged phase cut out is $0.86 \times 0.666 = 0.58$, or 58% of the bank rating.

CONNECTIONS FOR PHASE TRANSFORMATION.—Two- or Three-phase to Single-phase.—It is practically impossible to transform from polyphase to single phase with transformers and obtain balanced conditions. The best method is to simply connect the transformer across one phase of a polyphase system. If resulting unbalance is serious, a polyphase motor, driving a single-phase generator, should be used.

Two-phase to Six-phase.—Fig. 23 shows the double-T connection usually used to operate a 6-phase synchronous converter from a 2-phase supply. The cost of a standard 6-phase converter so connected may be less than 2-phase transformers and special 2-phase converters.

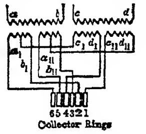

FIG. 23. 2-phase to 6-phase

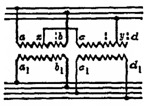

FIG. 24. 3-phase to 2-phase. (Scott Connection)

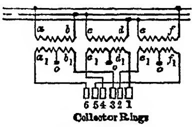

FIG. 25. 3-phase to 6-phase for Synchronous Converters

Transformer Connections

The T-connection requires two special transformers of equal impedance, each with two low-voltage windings so connected as to be displaced 180°, giving the 6-phase relation. Each transformer must have a capacity 15% greater than half the input required by the converter. Starting taps and a neutral tap complicate connections considerably.

Three-phase to Two-phase.—The most common connection is the Scott-connection, Fig. 24, using two transformers, T-connected on the 3-phase side, consisting of main and teaser windings. The teaser has 86.6% of the number of turns in the main winding. On the 2-phase side, both windings are identical and independent for supplying the 2-phase, 4-wire system.

Usually main and teaser transformers are identical. The 3-phase winding of each has a 50% and 86.6% tap. When used as a teaser, one unit will have 13.4% of its winding idle. The Scott-connection thus requires 6.7% more copper than single-phase transformers delivering the same power.

Three-phase to Six-phase transformation is required for standard 6-phase synchronous converters. Four different transformer connections can be used. The most common is the **diametrical,** which requires only one low-voltage winding on each transformer. See Fig. 25. The two leads of each secondary winding are connected to diametrically opposite points on the converter armature. See Fig. 26. With this connection it is possible to operate the 6-phase converter at reduced output with one transformer out of service.

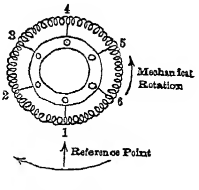

FIG. 26. Phase Rotation in 6-phase Synchronous Converter

PARALLEL OPERATION OF TRANSFORMERS.—Two transformers having the same ratio, and proper impedance, can be connected in parallel if polarity, phase rotation and angular displacement are the same. Delta-delta and star-star transformers have correct angular displacement, when the polarity and the phase rotation are correct. With delta-star or star-delta transformers, correct adjustment can be made by proper sequence of leads. If voltage diagrams are available for the transformers to be paralleled, it is only necessary that these diagrams coincide and that corresponding terminals be connected together. Leads which are to be connected will be at the same potential, which is the basic requirement for parallel operation. When voltage diagrams coincide, polarity and phase rotation must agree. When transformer leads are marked in accordance with the N.E.L.A. and A.I.E.E. standard markings, it is only necessary to connect similarly lettered leads together.

Three-phase transformers can be grouped according to their angular displacements. See Fig. 27. To operate in parallel transformers must belong to the same group. One group cannot be changed to another by interchange of external leads. For instance, two delta-delta transformers, one of group 1 and the other of group 2, cannot be operated in parallel. Table 13 shows operative and inoperative connection.

Effect of Ratio on Parallel Operation.—Circulating currents will flow in the winding of parallel-connected transformers of unequal ratios of high and low voltage windings.

Table 13.—Operative and Inoperative Parallel Connections for Transformers

	Operative Parallel Connections				Inoperative Parallel Connections			
	Low-voltage Side		High-voltage Side		Low-voltage Side		High-voltage Side	
	Bank A	Bank B	Bank A	Bank B	Bank A	Bank B	Bank A	Bank B
1	Delta	Delta	Delta	Delta	Delta	Delta	Delta	Star
2	Star	Star	Star	Star	Delta	Delta	Star	Delta
3	Delta	Star	Delta	Star	Star	Star	Delta	Star
4	Star	Delta	Star	Delta	Star	Star	Star	Delta
5	Delta	Delta	Star	Star	.....	.....	.....	.....
6	Delta	Star	Star	Delta	.....	.....	.....	.....
7	Star	Star	Delta	Delta	.....	.....	.....	.....
8	Star	Delta	Delta	Star	.....	.....	.....	.....

This current is equal to the difference of the two secondary voltages, divided by the sum of the impedances, Z_1 and Z_2, expressed in ohms or percent, of the two transformers. That is, $I_c = (e_1 - e_2)/(Z_1 + Z_2)$

EXAMPLE.—Assume a voltage difference of 2% and an impedance of 4% in each transformer. Percent of circulating current, I_c, then will be

$$I_c = 2 \times 100/(4 + 4) = 25\%.$$

The circulating current therefore is 25% of normal in both windings of the transformers. It adds to the load current in the transformer having the higher voltage and subtracts from the load current in the other.

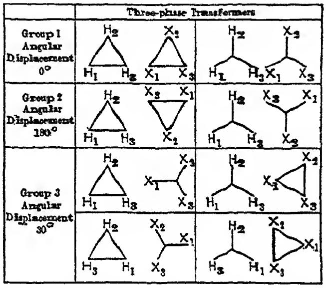

FIG. 27. Three-phase Transformer Connections According to Angular Displacement

The A.I.E.E. standards give the voltage ratio of a transformer as the ratio of root-mean-square primary terminal voltage to the root-mean-square secondary terminal voltage under specified conditions of load.

Effect of Impedance on Parallel Operation.—Impedance of a transformer is the voltage drop at normal load in percent of normal voltage. It is the resultant of the two components, resistance drop in phase with current, and the reactance drop 90° out of phase with current. For successful parallel operation, the ohmic impedance of transformers must be in inverse proportion to the load which they are to carry, so that voltage drop from no load to full load is the same in all units, both in magnitude and phase. Generally, total resistance is small as compared with reactance.

POLARITY OF TRANSFORMERS refers to voltage vector relations of transformer leads as brought outside the tank, both high and low voltage leads being in the same order. See Fig. 28. Polarity is the relative direction of induced voltage from H_1 to . as compared with that from . to X_2, both being in the same order with respect to the tank. Polarity can be additive or subtractive, as indicated, and depends on direction of winding.

A.I.E.E. standards provide that transformer lead designations also shall indicate polarity. When leads are so marked, polarity of transformers is subtractive when H_1 and X_1 are adjacent, and additive when H_1 is diagonally opposite X_1.

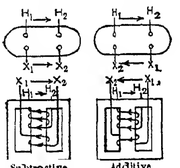

FIG. 28. Transformer Polarity

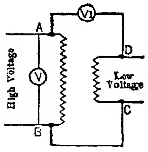

FIG. 29. Connections for Testing Transformer Polarity

Test for Polarity.—See Fig. 29. Connect one high voltage lead to the opposite low voltage lead, B to C. Apply voltage at AB and measure voltage between A and B and A and D. If V_1 is greater than V, polarity is additive; if less it is subtractive.

AUTO-TRANSFORMERS have parts of a winding in common in the primary and secondary circuits. For a given service, the advantages of auto-transformers are lower cost, greater efficiency, better regulation, smaller size, smaller exciting current.

An auto-transformer transforms only a part of the total kva., the rest flowing directly to the load circuit. Percent transformation is the same as percent voltage transformation, based on high voltage. For example, if voltage is raised 10% only 10% of the kva. supplied to the load is transformed. Therefore, physical capacity of the auto-transformer need be only 10% of the total load kva. Capacity/output = $(1 - E_2)/E_1$, where E_1 and

E_2 = respectively, high and low line voltage. See Fig. 30 for comparison of voltage and current relations of an auto-transformer and a transformer.

Disadvantages of Auto-transformers are: *a*. High stresses due to external short circuits because of the low percentage impedance. Thus, if the ratio of equivalent capacity to output is 10%, the short circuit current will be ten times as large and the short circuit stress 100 times as large as for a transformer whose line voltage is constant. *b*. Because of metallic connection between high and low voltage circuits, a disturbance in either circuit affects the other; thus a ground on the high voltage side may subject the low voltage circuit and its connected apparatus to high-voltage line voltage.

AIR-COOLED AUTO-TRANSFORMERS can be used profitably with voltages of 600 or less for both power and lighting as follows:

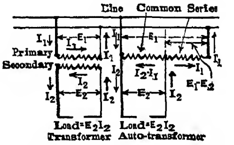

Fig. 30. Voltage and Current Relations in Transformer and Auto-transformers

Lighting.—1. To insulate lighting circuits from power circuits. 2. To boost low line voltage. 3. To operate low-voltage portable lamps in damp locations, where 32 volts may be advisable. 4. Where permitted, to step-down a power circuit voltage for light, thus eliminating separate lighting circuits. 5. To operate low-voltage lamps where concentrated illumination is desired, and where lights are subject to vibration.

Power.—1. To step-down power distribution voltages from 460 to 575 volts, to supply lighting or other 115 volt circuits, with resultant lower line losses, reduced copper cost and improved voltage regulation. 2. To operate low-voltage portable tools from power circuits instead of lighting circuits, giving the advantage of low power rates. 3. To operate 32-volt portable tools in packing plants, mines, tank cars, etc. 4. To balance the voltage on a single-phase, 3-wire system, and prevent under-voltages which would result in unsatisfactory operation of equipment. 5. Boosting or bucking the voltage of single- or 3-phase circuits, in order to operate equipment requiring more or less than the distribution voltage. 6. When phase change is made on a power system, to transform from 3- to 2-phase, in order to permit use of equipment that otherwise would be discarded.

Ratings.—Standard air-cooled transformers are available for frequencies of 25, 50, and 60 cycles in sizes of from 0.05 to 50 kva., single-phase; of from 1 to 250 kva., 3-phase, 60-cycle, for boosting voltage; and from 1 to 50 kva., 60-cycle, for changing 3-phase to 2-phase, or 2-phase to 3-phase.

Typical connections are shown in Figs. 31, 32, and 33.

Price.—Approximate 1935 prices per kva. of single-phase, 60-cycle units are shown in Fig. 34. 50-cycle transformers will cost from 5% to 10% more, and 25-cycle units approximately 40% more than 60-cycle units.

Fig. 31. Typical Winding Diagram for Air-cooled Transformer

Fig. 32. Winding Diagram of Three Single-phase, Air-cooled Auto-transformer Units Connected as a 3-phase Bank

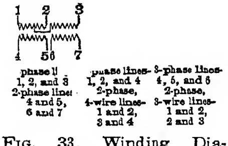

Fig. 33. Winding Diagrams for Phase-changing Transformers and Auto-transformers

Transformer Connections

Limitations.—Air-cooled auto-transformers should not be used where isolation must be maintained between phases in phase transformation. They can be used only on those two-phase systems in which phases are otherwise isolated, or in which the connection between phases, of any of its connected apparatus, corresponds precisely to that of the auto-transformer.

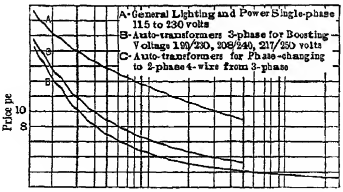

Fig. 34. Approximate 1935 Prices of Standard Air-cooled 60-cycle Transformers and Auto-transformers

TRANSFORMER COOLING INSULATING LIQUID.—Mineral oils have reached a high standard of quality, but are inflammable. The codes require oil-cooled transformers to be placed either out of doors or in fireproof vaults. This limits installations as regards location.

Pyranol now available as a cooling and insulating fluid for transformers is non-inflammable. The 1935 revision of the National Electrical Code permits installation of pyranol-filled transformers indoors, with many restrictions applying to oil-insulated transformer installations eliminated. The advantages of pyranol transformers are: 1. Can be installed indoors without expense of fireproof vaults. 2. All gases derived from the insulating fluid are non-inflammable and non-explosive. 3. Can be installed directly at load centers, providing improved voltage regulation and efficiency.

GENERATED POWER

1. CAPACITY REQUIRED

In comparing cost of generated power with that of purchased power the analysis must consider: 1. Fixed charges on initial investment, including cost of space, building and equipment; these charges cover interest, taxes, insurance, depreciation and obsolescence. 2. Cost of operation including labor, maintenance, fuel and supplies. 3. Present trend toward lower rates for purchased power. 4. Future power requirements.

REQUIRED GENERATING PLANT CAPACITY depends on the amount and character of load and the proportions of total connected load that will come on the generators at any one time. It is determined by multiplying the connected load in each department by its demand factor and dividing the result by the diversity factor.

Demand Factor is the ratio (actual maximum demand ÷ connected load). See p. 15–04.

Demand of an Installation or System is (A.I.E.E. standards) the load which is drawn from the source of supply at the receiving terminals, averaged over a suitable and specified interval of time. It is expressed in kw., kva., amperes or other suitable units. Maximum demand is the greatest of all demands which have occurred during a given period, as determined by measurement with a maximum demand meter. The most common intervals of time used are 15 and 30 min.

Diversity Factor takes account of the number of maximum demands of departmental loads that are likely to occur at the same time. Diversity factor is the ratio (sum of maximum demand of departmental loads ÷ maximum demand of total load). Table 1, from E. W. Lloyd, shows demand and load factors of typical industries in the Chicago district.

Table 1.—Demand and Load Factors of Chicago Consumers, Combined Power and Light.

Kind of Business	Load Factor, percent of 8760-hr. Year	Demand Factor, Ratio of Actual Maximum to Connected Load, percent	Kind of Business	Load Factor, percent of 8760-hr. Year	Demand Factor, Ratio of Actual Maximum to Connected Load, percent

Laundries	25	70			

Example.—Determine generator capacity for two load groups fed by separate radial feeders from the generator bus. Connected load on feeder No. 1, 1000 kva., demand factor, 0.7. Connected load on feeder No. 2, 500 kva., demand factor, 0.5. Maximum demand on feeder No. 1, $0.7 \times 1000 = 700$ kva.; on feeder No. 2, $0.5 \times 500 = 250$ kva. Assume the diversity factor to be 1.4. Maximum demand of total load then is $(250 + 700)/1.4 = 680$ kva., which is the required generator capacity.

Reserve Capacity equal to the largest generating unit in the power plant should be provided in order to carry maximum loads with one unit shut down. The degree of reliability required largely determines reserve capacity. With interconnected plants, reserve capacity can be a much smaller percentage of total generating capacity than with independent plants. From 10 to 25% often is sufficient when several sources of power are available.

Size of Generating Units.—The character of the load as shown by the load factor, and average daily load curves which would apply to the plant under consideration, determine the most economical sizes of individual generating units.

Load Factor is the ratio (average load ÷ peak load) for a specified period of time. Peak load on the generator will be determined over a period of 30 min. or 1 hr. Average load would be taken as for one day, month, or year. Power plant operating costs per unit of energy used decrease with increase of load factor. Operating expense will vary with the size of generating unit. The efficiency of large units operating below rated load is low. Operating charges such as fuel and labor do not decrease in proportion to the load.

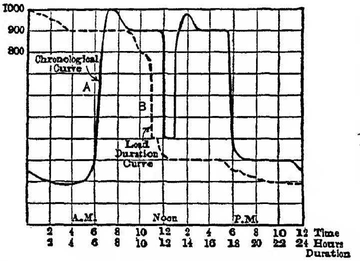

FIG. 1. Typical Industrial Plant Load Curves for Average Day of Year

LOAD CURVES are plotted with kw. load for any time interval as ordinates and the time intervals (usually 1 hr.) as abscissas. The curve is made daily. Such a curve is useful for plant analysis and for predicting magnitude and character of load on the power plant. It will include characteristics of all departmental loads, which will be well established in existing manufacturing plants. In determining power requirements for a new enterprise, predictions can be made on the basis of machinery to be installed. A study of existing plants using the same type of machinery is a good guide in applying correct diversity and demand factors to individual machines and load groups.

Fig. 1 shows a typical daily load curve of an industrial plant load. An approximate daily load curve can be obtained by averaging daily curves for two typical months. The area under the curve is the total output required in kw.-hr. for a typical day.

In Fig. 1, *A* is a chronological curve showing amount of load and time at which it occurs. *B* is the *load-duration curve* derived from *A*. In *B*, the magnitude of the load is plotted against the number of hours it exists. For any load-ordinate of the duration curve, the abscissa shows the total number of hours during the day that the load has been on the generator. To prepare the load-duration curve from the daily load curve, tabulate the load for each hour according to magnitude. Then plot these loads as ordinates, beginning with the maximum at the left and the time accumulating along the abscissas. When plant load curve is established, size and number of generating units can be fixed.

LARGE vs. SMALL GENERATING UNITS.—Generally, for small power plants, with low load factor, the most economical installation is several small generating units. For large plants, with high load factor, fewer units of larger size probably will be best.

In Fig. 1, the load-duration curve shows that for 24 hr. per day the load is 190 kw. or more; for 22 hr., 200 kw. or more; for 18 1/2 hr., 250 kw. or more; for 17 hr., 300 kw. or more; for 11 hr., 400 kw. or more; for 10 hr., 800 kw. or more; and for 9 hr. the load is between 900 and 1000 kw. Five 250-kw. units would meet the needs, and provide a spare 250-kw. unit for the initial load. Four 300-kw. units would fit the curve well, with one unit in use at night at not less than approximately 65% load. This would provide 200 kw. spare capacity, and if one unit is shut down, the other three units can carry the peak load. Future requirements, however, may dictate three 500-kw. units.

Future Growth must be considered in power plant design, in order to provide initially sufficient space for additional generating equipment. Size of individual units and reserve capacity must be determined on the basis of probable future loads. Thus, if the plant load of Fig. 1 should double in a few years, nine 250-kw. units would be poor economy, and five 500-kw. units would be better.

2. ALTERNATING-CURRENT GENERATORS

Electric generators generally are classified as alternating current (A.C.) and direct current (D.C.).

ALTERNATING CURRENT GENERATORS generate a voltage, which in an external circuit causes current to flow alternately in opposite directions. This current builds up to maximum, returns to zero, and builds up to maximum in the reverse direction according

to $i = I_m \sin \theta$, where i = current at any instant; I_m = maximum current; θ = angular position of field pole with respect to armature conductor, expressed in electrical degrees.

Frequency is the number of current reversals per second. If speed of generator is given in r.p.m., and the frequency f in cycles per second, $f = pn/2$, where p = number of poles, and n = r.p.m./60.

Construction.—Generators larger than 25 kva. have revolving fields with salient poles on the rotor for slow speed and medium speed design. High-speed turbine-driven generators have field coils wound in slots on the rotor. Armature windings are stationary. D.C. excitation is applied to the field coils through collector rings on the rotor shaft. Below 25 kva., both revolving armatures and revolving fields are used.

Excitation of alternating current generators is at either 125 or 250 volts D.C., usually obtained from direct-connected exciters.

Low-speed Direct-connected Synchronous A.C. Generators for direct connection to steam and internal combustion engines range in speed up to 450 r.p.m., 60 cycles, and in capacity from 25 to 8750 kva. The standard generator in this classification is supplied with rheostat, foundation caps and brush holder support, but without base, shaft, bearings, foundation bolts, or shaft keys.

Power Factor.—Standard generators are designed for an 80% power factor (lagging) load, but can be built for unity or any other power factor required.

Standard Ratings of low-speed engine type generators, in kva. available at generator terminals at 0.8 power factor, are: 31, 44, 63, 94, 125, 156, 187, 219, 250, 312, 375, 438, 500, 625, 750, 875, 1000, 1125, 1250, 1563, 1875, 2188, 2500, 2812, 3125, 3750, 4380, 5000, 5625, 6250, 7500, 8750, 10,000. The ratings are based on the load that the generators are capable of carrying continuously without exceeding temperature guarantee. The ratings are on a continuous basis for Diesel or gas engine drive and with a 2-hr. overload capacity of 25% for steam engine drive.

Voltage Ratings are standardized at 240, 480, 600 and 2400 volts.

Frequencies of 25, 50 and 60 cycles are standard, with the trend away from 25 and 50 cycles.

Speed Ratings in r.p.m. are:

60 cycle: 450, 400, 360, 327, 300, 277, 257, 240, 225, 200, 180, 164, 150, 138, 128, 120, 109, 100, 90, 80.
50 cycle: 429, 375, 333, 300, 273, 250, 231, 214, 200, 188, 167, 150, 136, 125, 115, 107, 100, 91, 83.
25 cycle: 375, 300, 250, 214, 188, 168, 150, 136, 125, 115, 107, 100, 94, 83.

Rated Load Current in amperes is: Single-phase = kva. × 1000/E; two-phase = kva. × 1000/2E; three-phase = kva. × 1000/$\sqrt{3}E$, where E = rated voltage.

Overload.—Standard generators can carry 150% of rated-load current for one minute, the rheostat being set for rated-load excitation.

Overspeed.—Operation at 25% overspeed is possible without causing mechanical injury. Greater overspeed requires special design.

Temperature Rise for normal maximum-rated generators, *i.e.*, as applied for internal combustion engine drive, operated at rated load until temperature is constant is: Armature core and coils, by thermometer, 50° C.; armature coils, by temperature detector, 60° C.; field coils, by resistance, 60° C.

For 25%, 2-hr. overload-rated generators, the temperature rise allowed is:

	Rated Load Until Constant	125% Load, 2 hr.
Armature core and coils, by thermometer..	40° C.	55° C.
Armature coils, by temperature detector...	50° C.	65° C.
Field coils, by resistance................	50° C.	65° C.

Regulation.—Voltage regulation is the percent rise in voltage from rated load to no load on the generator, with the excitation at rated-load value. Regulation for standard generators is:

Power factor..............................	0.8	0.9	1.0
Full-load regulation, 50° C. generator..........	40%	35%	25%
Full-load regulation, 40° C. generator..........	34%	30%	20%

Direction of Rotation (standard) is clockwise when viewed from the exciter end or end opposite the driven end.

Generator Field Rheostats are recommended for all A.C. generators, but may be omitted when: *a*, the generator is excited from its own individual exciter, which is used for no other purpose; *b*, exciter never will be paralleled with other exciters.

PARALLEL OPERATION OF ENGINE-TYPE GENERATORS is the responsibility of the engine builder, as many factors affecting parallel operation are contained in the engine and in the characteristics of the equipment connected to the system with which the generator must parallel. (See N.E.M.A. Motor and Generator Standards, Publication No. 34–22). Two generators driven by reciprocating engines, and connected in parallel, supplying power to a steady load, may transfer power back and forth due to pulsations in engine torque. The magnitude of the interchange depends on engine and generator characteristics and the total WR^2 of engine flywheels and generator rotors. It may be sufficient to increase mechanical stresses, produce excessive heating in the generators, or even cause them to pull out of synchronism. A power pulsation of 66%

is the maximum that safely may be allowed if injurious heating or other undesirable conditions are to be avoided.

In order to determine paralleling conditions, the following information on each engine and generator is necessary: *For the engine.*—1. Horsepower rating. 2. Number of cylinders. 3. Number of stroke cycles. 4. Single or double acting. 5. Amount of continuous unbalance of any one cylinder. 6. Maximum periodic displacement of the rotor in either direction from the position of uniform rotation. 7. WR^2 of flywheel, lb.-ft.^{2} *For the generator.*—1. Kva. rating. 2. Power factor. 3. Frequency. 4. Speed, r.p.m. 5. WR^2 of rotor, lb.-ft.^{2} 6. P_R, synchronizing power, or rate of change of power with respect to displacement angle, expressed in kw. per radian. With this information available, the commonly accepted method for preliminary determination for successful parallel operation is as follows:

Total flywheel effect of each of the units operating in parallel shall be such that: *a*, maximum periodic displacement of rotor in either direction from its position of uniform rotation will not exceed $3\,1/_2$ electrical deg.; *b*, natural frequency of oscillation will differ at least 20% from frequency of any forced impulse of any of the engines operating in parallel; *c*, engine governors shall not create or sustain an oscillation; *d*, the curves (percent speed *vs.* percent load) of the several engines in parallel shall be alike; *e*, engines shall be so adjusted that each cylinder will contribute its share of turning effort.

Critical Frequencies to be avoided are: *a*, *For a 4-cycle engine*, particularly one half of the revolutions of the engine crank, but also the revolutions of the crank; *b*, *For a 2-cycle engine*, particularly the revolutions of the engine crank, but also twice the revolutions of the crank.

To avoid dangerous values of flywheel effect, in any given unit, the natural frequency at which the rotor tends to oscillate can be changed by changing the flywheel effect as indicated in the equation $F = 35{,}200/n\sqrt{(P_R \times f)/WR^2}$, where F = natural frequency in periods or beats per min.; n = rev. per min.; P_R = kw. input to generator at synchronous speed, corresponding to torque exerted on rotor per radian displacement; f = frequency of generator, cycles per sec.; WR^2 = total flywheel effect, lb.-ft.^{2}. WR^2 and P_R are given in manufacturers' specifications for engine type generators.

Example.—For a 60-cycle, 150-r.p.m. direct-connected generator with P_R = 1420, and driven by a 4-cycle engine, the natural frequency must not be between 60 and 90 nor 120 and 180 periods per min. That is, total WR^2 (flywheel and generator) must not lie between 1,305,000 and 480,000 lb.-ft^2, nor between 526,000 and 145,000 lb.-ft^2.

The combined natural frequency of two units operating in parallel can be determined from

where F_{1+2} = natural frequency of two units in parallel; $(P_R)_1$, $(P_R)_2$ = synchronizing power of units operating in parallel as defined above; P_1, P_2 = number of poles on each unit; $WR_1{}^2$, $WR_2{}^2$ = total flywheel effect of each unit. The above rules are approximate, but will cover most applications.

For discussion of parallel operation of generators driven by reciprocating engines, see R. E. Doherty and R. F. Franklin, Design of Flywheels for Reciprocating Machinery, *Trans.* A.S.M.E., xlii, p. 523, 1920, and H. V. Putnam, Oscillation and Resonance in Systems of Parallel Connected Synchronous Machines, *Jour.* Franklin Inst., May, June 1924.

TORSIONAL VIBRATION.—N.E.M.A. Standards Publication No. 34–22, Item MG 15–84, states that since factors which affect torsional vibration are contained principally in the design of the engine . . ., the responsibility for avoiding torsional vibration shall rest with the engine builder. Since design of the generator rotor is an important factor which must be considered, generator builder will give complete information in so far as generator design affects torsional vibration. He will furnish the engine builder with flywheel effect, weight of generator rotor, and any other information such as stiffness of spider, as engine builder may need to successfully design the combined unit. Shaft diameter will be specified by the engine builder. . . . Before generator spider and such part of the shaft as may be supplied by generator builder are manufactured, final drawings of the same are to be submitted to the engine builder for approval in so far as their design affects torsional vibration.

LIGHT FLICKER in lamps connected to the circuit may be produced by internal combustion engine-generator units. Flicker is due to pulsations in driving torque, which originate in the engine and produce periodic variation in speed, with resultant variation in generator terminal voltage. The frequency of the variation will be the same as the frequency of torque pulsations in the engine. Whether or not flicker is objectionable depends on the frequency and magnitude of voltage fluctuation.

Fig. 2 shows relation between flicker and voltage variation. Accurate measurement of the degree of light flicker is difficult. Voltage variations producing flicker are too small to be indicated on the ordinary voltmeter, and the only device that appears to be satisfactory for measurement of power pulsations is the oscillograph. Frequency and

magnitude of power pulsations should be considered in engine design. The power pulsation produced by any engine-generator unit can be reduced by using the proper amount of inertia or flywheel effect.

NORMAL EFFICIENCIES of standard low-speed synchronous generators, engine-driven, have been standardized by N.E.M.A. See Publication No. 34-24. Efficiencies are determined by including I^2R losses of stator and rotor coils at 75° C., core losses and stray load losses, but excluding losses of field rheostat, exciter, windage and bearing friction. Efficiencies are for 80% power factor generators; approximate full load values range from 82% for a 31 kva. generator to 97% for a 10,000 kva. generator. To include exciter losses, deductions are made from standard values, ranging from 0.2% for generator efficiencies of 96.2 and above, to 1.6% for generator efficiencies of 82.2. Similar deductions can be made for rheostat losses, but only if generator is excited from a D.C. bus where voltage cannot be varied. A deduction from standard full-load efficiency of 0.5% is made for windage and bearing friction losses for machines with one, two or three bearings. Fig. 3 shows typical approximate efficiencies of engine type generators without base, shaft or bearings.

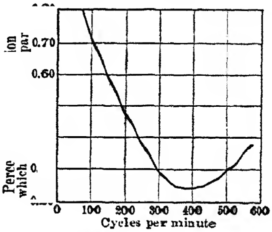

Fig. 2. Voltage Flicker at Various Frequenci... Average for 115-volt, 60-watt M...

Approximate Prices of standard 60-cycle engine-type A.C generators including direct-connected exciters are given in Fig. 4. These prices are based on 1935 figures.

Weights and Dimensions of engine-type A.C. generators are given in Table 2 for representative standard ratings, also WR^2 and required D.C. excitation.

Construction.—Frames are fabricated. Sides are cut from heavy steel plate, and a wrapper plate is formed around outside periphery and welded to the end plates. Stacking studs hold armature or stator punchings between the side plates. Both cast-iron and fabricated rotor spiders are used.

Amortisseur windings consist of hard drawn copper bars built into the field pole faces and silver-soldered into copper end segments at each end of every field pole, to form a short circuited path for induced currents. These windings are recommended for generators direct connected to internal combustion engines to help dampen oscillations set up by the pulsating torque of the engine.

HIGH-SPEED SYNCHRONOUS A.C. GENERATORS are generators of 500 r.p.m. and over, and built either for belt drive or direct connection, with or without direct-connected exciters.

Standard Ratings in kva. available at generator terminals at 0.8 power factor are: 1.25, 2.5, 3.75, 6.3, 9.4, 12.5, 18.7, 25, 31, 44, 63, 94, 125, 156, 187, 219, 250, 312, 375, 438, 500, 625, 750, 875, 1000, 1125, 1250, 1563, 1875, 2188, 2500, 2812, 3125, 3750, 4380, 5000.

Fig. 3. Approximate Normal Full-load Efficiencies of Low-speed, Engine-driven Synchronous Generators

Fig. 4. Approximate 1935 Prices of A.C. Low-speed, Engine-type Synchronous Generators, Including Direct-connected Exciters

Speed Ratings are: 60-cycle, 1800, 1200, 900, 720, 600, 514; 50-cycle, 1500, 1000, 750, 600, 500; 25-cycle, 750, 500.

Standard Voltages are: Up to and including 25 kva., 1800 r.p.m., 120 and 240 volts only; up to 25 kva., 1200 r.p.m. and less, 240, 480 and 600 volts; 25 kva. and above, 240, 480, 600 and 2400 volts.

Temperature Rise, Overload, Overspeed, Direction of Rotation, and Regulation for standard high-speed generators are the same as for low-speed, engine type generators. See p. 15-23.

Construction.—Revolving armatures are usual for 1800 r.p.m. generators up to and including 25 kva., 3-phase, 60-cycle, with power taken from slip rings. Field poles are stationary. All other ratings are of the conventional revolving field, salient pole type.

Bearings of standard generators are not designed to support any weight except that of the rotor. Endshield type bearings are standard for generators up to approximately 1000 kva. at speeds of 514 to 1800 r.p.m. inclusive. Pedestal type bearings are usual on generators larger than 1000 kva. at speeds of 514 to 1800 r.p.m.

EFFECT OF ALTITUDE ON GENERATOR RATINGS.—Rating and temperature rise are based on cooling air of not over 40° C., and altitude not over 1000 meters or 3300 ft. When altitude exceeds 3300 ft. an allowance is made of 1% temperature rise for each 330 ft.

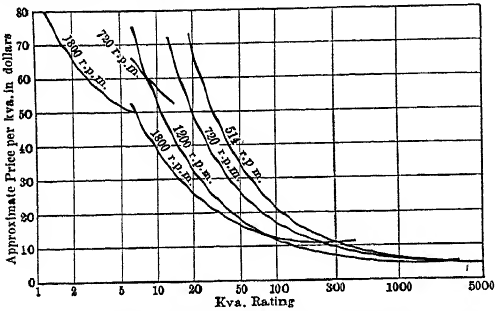

Fig. 5. Approximate 1935 Prices of A.C. High-speed Generators, including Direct-connected Exciters

Example.—Required the operating temperature at 3300 ft. of a generator to operate at 40° C. rise at 7425 ft. *Solution.* $7425 - 3300 = 4125$; $4125/330 = 12.5$; $12.5 \times 0.01 = 0.125$; $1.00 - 0.125 = 0.875$. Temperature rise at 3300 ft. $= 40 \times 0.875 = 35°$ C.

Prices of High-speed A.C. Generators.—Fig. 5 shows approximate 1935 prices of standard generators.

Approximate Weights and Dimensions of standard high-speed A.C. generators are given in Table 3.

Efficiencies.—Fig. 6 shows full load efficiencies of representative high-speed A.C. generators, including I^2R losses of stator and rotor coils at 75° C., but excluding losses of rheostat, exciter, core, stray load, windage and bearing friction. Efficiencies are determined and all tests made in accordance with 1927 A.I.E.E. standards.

Belt Drive.—The limits of bearing speed and shaft deflection of two-bearing generators for belt drive are shown in Fig. 7.

3. TURBINE-DRIVEN GENERATORS

Standard turbine-driven A.C. generators usually are considered in connection with a steam turbine as a combined generating unit. They are so handled as regards price, weight, dimensions and efficiency.

TURBO-GENERATOR DESIGN AND CONSTRUCTION.—Standard generators are designed with enclosed revolving fields, 2-pole, 3-phase, 60-cycles between 500 and 7500 kw. They operate at 3600 r.p.m., direct-connected to the steam turbine, with direct-connected exciters of 125 or 250 volts. The frame of the generator is supported by feet at the sides. Within the frame, sheet steel laminations are built in sections and separated by spacers to form ventilating ducts. Laminations are slotted to receive armature coils. The generator is ventilated by fans at both ends of the rotor. Rotors are round, with field coils of copper ribbon wound edgewise and placed in slots in the periphery, and fastened by metal wedges. Collector rings are of steel. 25-cycle generators are driven through reduction gears.

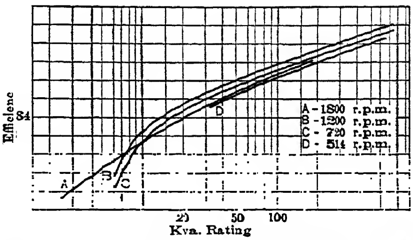

Fig. 6. Approximate Efficiencies of Standard High-speed A.C. Generators, 3-phase, 60-cycle

Standard Ratings in kw. at 0.8 power factor, and the corresponding weights are:

Rating, kw.:	500	625	750	1000	1250	1500	2000
Weight lb.:	7000	8020	9320	10,750	12,500	14,550	17,400
Rating, kw.:	2500	3000	3500	4000	5000	6000	7500
Weight, lb.:	22,100	24,900	28,600	31,550	37,700	45,570	53,900

Usual practice includes dimensions of direct-connected turbine-driven generators in the complete dimensions of the combined unit, because base and foundation construction is laid out for the combined unit.

Temperature Rise of generators for ambient temperatures of 40° C. and altitude of 3300 ft. or less is: armature, 60° C., measured by embedded detectors; field, 85° C., measured by resistance. Temperature rise of exciter is: core and windings, 40° C., measured by thermometer; commutator 55° C., measured by thermometer.

REVOLVING-ARMATURE TYPE A.C. TURBINE GENERATORS.—Units of from 12.5 to 75 kva. are available for operation at 3600 r.p.m., 60-cycle, 3-phase. The armature is wound on the rotor, and power is taken off at collecter rings on the shaft. Field poles are stationary. Voltages are limited to 240 and 480 volts.

Standard Ratings at 0.8 power factor are: 10, 15, 20, 25, 35, 50, and 60 kw. Direct-current units also are available in these ratings to operate at 3600 r.p.m., direct-connected, 250 volts.

GEARED TURBINE GENERATOR SETS from 75 to 400 kw. inclusive are available in standard units, consisting of high-speed turbines and speed reducing gears direct-connected to either an A.C. or D.C. generator. These sets are used to obtain minimum steam consumption by operating the turbine at its most efficient speed, which is different from that of the standard high-speed generator at either 50 or 60 cycles. D.C. geared units operate at 1800 r.p.m. for ratings of 75 and 100 kw. All ratings from 125 to 400 kw. inclusive operate at 1200 r.p.m. See standard high-speed D.C. generators, p. 15-31.

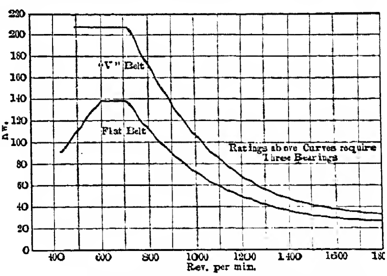

Fig. 7. Maximum Rating of 2-bearing A.C. Generators for Belt Drive

Standard Ratings in kw. of A.C. (0.8 power factor) and D.C. generators are: 75, 100, 125, 150, 200, 250, 300 and 400 kw.

Standard Voltage Ratings are: A.C., 240, 480, 600, 2400 volts. D.C., 125 and 250 volts, for 2-wire, or 125/250 volts for 3-wire.

Approximate Prices of A.C. and D.C. turbine-driven generator units, including turbines, in standard industrial sizes, are shown in Fig. 8. All D.C. generators are 250 volts and all A.C. generators are 0.8 power factor, 3-phase, 60 cycles. Prices for 50-cycle turbine-generator sets are approximately 12% higher; 25-cycle sets are approximately 20 to 25% higher.

Weights and Dimensions of turbine generator sets corresponding to curve A, Fig. 8, are given in Table 4. Table 5 applies to curves B and C, Table 6 to curve D and Table 7 to curve E.

EXCITERS for A.C. generators are supplied direct-connected or for belt drive. The standard exciter is shunt-wound, rated at 125 volts, 40° C. temperature rise, with 1.15 service factor.

* A = with exciter; B = without exciter. † C = before erection; D = after erection.

Standard Exciter Ratings are: 1, 1 1/2, 2, 3, 5, 7 1/2, 10, 15, 20, 25, 30, 40, 50, 60 and 75 kw. Overhung direct-connected exciters are available for all generators of bracket-type bearing construction, as high-speed A.C. generators. With pedestal-type bearing construction, for example, low-speed engine-driven A.C. generators, exciter armatures are overhung from the generator shaft extension and the stator or field structure is supported by a sub-base built up from the main generator base.

Exciter Prices are similar to those of small standard high-speed D.C. generators. See Fig. 11.

MOTOR-GENERATOR EXCITER SETS often can be used to advantage where a separate source of power is available, especially to excite generators of very low speed. A direct-connected exciter here would be comparatively large.

4. DIRECT-CURRENT GENERATORS

A direct-current generator produces voltage, which when applied to an external circuit causes a current, constant in direction, to flow. The magnetic flux produced in the generator develops alternating current in the armature conductor, which, by means of a commutator, is caused to flow in but one direction.

ENGINE-DRIVEN D.C. GENERATORS usually are supplied without shaft, base or bearing, and are mounted by the engine builder. They are available for either 2- or 3-wire service.

Voltage Rating.—Standard voltages are 125 and 250 for 1000 kw. and less, and 250 volts above 1000 kw. For 115- and 230-volt motor circuits, generator voltages of 125 and 250 are recommended. See N.E.M.A. standards for D.C. generators. All generators will deliver rated current output at all voltages between 80% and 100% of rated voltage.

Compound-wound Generators are supplied flat compounded, *i.e.*, with windings which will give the same voltage at no load and full load, when operated at constant speed at a temperature equivalent to that which would be attained after a continuous run at rated load, and with field rheostats set to obtain rated voltage at rated load, and left unchanged. Brushes are set approximately on neutral. The curve of voltage *vs.* load current then will not vary more than 3% from a straight line between no load and full load.

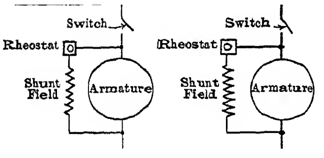

Fig. 9. Connections for Parallel Operation of Shunt-wound D.C. Generators

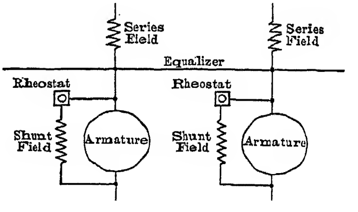

Fig. 10. Connections for Parallel Operation of Compound-wound D.C. Generators

To compensate for line drop, D.C. generators can be over-compounded to give higher voltage at full load than at no load, *i.e.* 120 volts at no load to 125 volts at full load, or 240 volts at no load to 250 volts at full load. The compounding curve may vary from 3 to 4% from a straight line connecting these two voltages.

Commutation.—D.C. generators are designed to commute successfully all loads up to 200% of rated current without burning or injuring brushes or commutator. Full load can be thrown on and off without appreciable sparking and without shifting brushes.

Speed Range.—Rated speed corresponds to A.C. 60-cycle speed. Permissible variation is a range of ±3% from rated speed without change in capacity, temperature guarantees or price. Permissible overspeed is 25%.

Rotation of standard generators is clockwise facing commutator end.

Overloads.—Generators will commutate successfully, for 1 min., loads of 200% of continuous rated amperes, with rheostats set for rated load excitation. No temperature guarantee is made. Temperature rise, by thermometer, of standard D.C. engine-driven generators, operating continuously under rated conditions, should not exceed:

	Time Rating	Core and Windings	Commutator	Bare Copper Winding
100% of rated current	Continuous	40° C.	55° C.	50° C.
125% of rated current	2 hr.	55° C.	65° C.	65° C.

Field Rheostats.—Generators rated at 250 kw., 125 volts, and 500 kw., 250 volts and smaller, are supplied with hand-operated back-of-board or chain-operated field rheostats. Generators rated at 300 kw., 125 volts, 600 kw., 250 volts and 1750 kw., 600 volts and larger, are supplied with motor-operated rheostats.

Service Factor of engine-driven generators is 1.15, *i.e.* when operated at rated speed and voltage they will carry continuously 1.15 × rated load.

Efficiencies as determined include the following losses: I^2R of armatures and fields at 75° C., brush contact, open circuit core, brush friction, stray load, field rheostat, and bearing and windage. Stray load losses are included as 1% of the output, and D.C. brush contact losses are based on a brush drop of 2 volts.

Parallel Operation.—Compound-wound D.C. generators will operate in parallel with other compound-wound generators where: *a*, load voltage characteristics are similar; *b*, equalizing connections are provided and are of the same polarity; *c*, at their respective rated loads, voltage drop from equalizers through the series fields to the bus bars is the same for all generators; it may be necessary to install resistance to get this condition; *d*, speed regulation of prime movers from no load to full load is the same. Figs. 9 and 10 show parallel connections for shunt- and compound-wound generators.

Standard Ratings of engine-driven generators are: 25, 30, 35, 40, 50, 60, 75, 100, 125, 150, 200, 250, 300, 350, 400, 500, 600, 700, 800, 900, 1000, 1250 and 1500 kw. Larger standard sizes are, for low-speed generators, 1750, 2000, 2250, 2500, 3000, 3500, 4000, 4500 and 5000 kw.

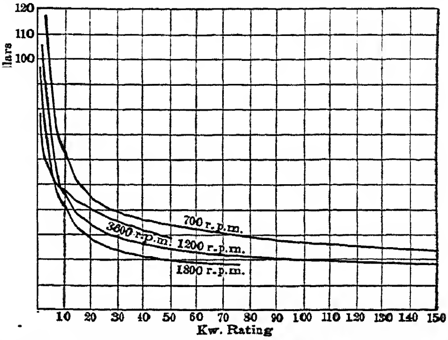

FIG. 11. Approximate 1935 Prices of Standard High-speed General-purpose D.C. Generators

STANDARD HIGH-SPEED D.C. GENERATORS for general purposes, belt driven or direct connected, are supplied with shaft and two endshield-type bearings. When supplied for belt drive, pulley and sliding base are included. The belt drive limitations of Fig. 7 apply for D.C. generators.

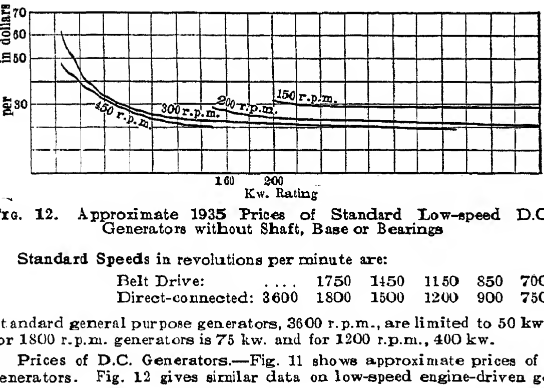

FIG. 12. Approximate 1935 Prices of Standard Low-speed D.C. Generators without Shaft, Base or Bearings

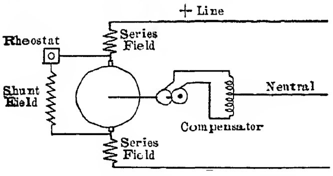
Standard Ratings are: 1, $1\frac{1}{2}$, 2, 3, 5, $7\frac{1}{2}$, 10, 15, 20, 25, 30, 40, 50, 60, 75, 100, 125, 150, 200, 250, 300, 400, 500, 600, 750, 1000, and 1250 kw.

Standard Speeds in revolutions per minute are:

Belt Drive:	....	1750	1450	1150	850	700	575	500
Direct-connected:	3600	1800	1500	1200	900	750	600	514

Standard general purpose generators, 3600 r.p.m., are limited to 50 kw. and less. The limit of size for 1800 r.p.m. generators is 75 kw. and for 1200 r.p.m., 400 kw.

Prices of D.C. Generators.—Fig. 11 shows approximate prices of high-speed general purpose generators. Fig. 12 gives similar data on low-speed engine-driven generators.



G. 13. Connections of 3-Wire D.C. Generators

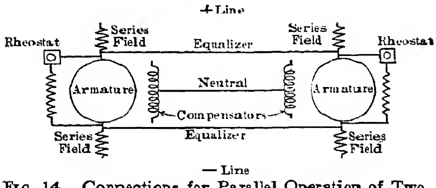


FIG. 14. Connections for Parallel Operation of Two Compound-wound 3-wire D.C. Generators

THREE-WIRE GENERATORS designed for operation on D.C. 3-wire systems are standard above $7\frac{1}{2}$ kw. The armature winding is tapped at diametrically opposite points and leads are brought out to two collector rings on the generator shaft. An auto-transformer is connected across these two rings, its mid-tap forming the neutral. Standard equipment provides for 10% unbalanced current in the neutral. Fig. 13 shows 3-wire connections, and Fig. 14 shows parallel connection of two 3-wire generators. The neutral

provides for load at half the generator voltage, and both motor and lighting loads can be supplied from one generator.

Approximate Weights, Dimensions and Efficiencies of representative high-speed D.C. belt-driven generators are given in Table 8. Table 9 gives similar information for representative direct-›nnected generators. Table 10 gives data for engine-driven D.C. generators.

SHUNT-WOUND GENERATORS are excited from a single winding, of comparatively igh resistance, connected across the brushes of the generator, in parallel with the arma-ure and the load. With a given field rheostat setting, voltage drops as load is applied. uch generators are used where load remains unchanged over long periods as in electro-ytic plants, furnaces, electro-chemical and exciter services. Shunt generators also may e separately excited by connecting the shunt field to a source independent of the arma-ure circuit. Such generators are stable from zero to rated voltage and should be used where stable operation is required over a wide voltage range. Typical applications are oosting, Ward Leonard systems, where the voltage is carried through zero from maximum ositive to maximum negative for reversing purposes and speed control of motors by rmature or voltage control.

COMPOUND-WOUND GENERATORS are the most commonly used D.C. gen-rators for all kinds of service. They have a shunt winding connected across the generator erminals, and a series winding of fewer turns of heavy wire through which the entire urrent output flows. The shunt winding supplies most of the excitation; the series

winding increases excitation with increase of load. Compound-wound generators are used to supply constant voltage with continuous change in load. Compounding generally is flat, but in mining and railway service generators often are over-compounded to give higher voltage at full load than at no load, thus compensating for increased line drop as load is applied. The voltage of a flat-compounded D.C. generator averages 3 to 4% higher near half load than at either no load or full load.

5. VOLTAGE REGULATION

To avoid drop in terminal voltages of generators when load is applied, they must be so compounded as to increase total excitation, or field excitation must be adjusted either manually or automatically. Field current required to maintain full rated voltage of standard A.C. generators, 0.8 power factor, at no load is 50% of that required at full load.

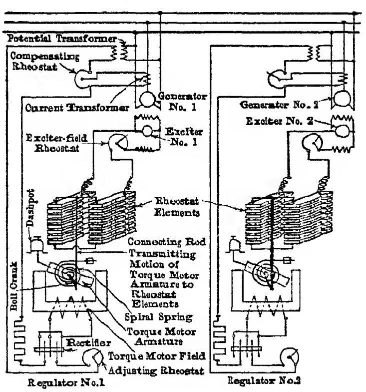

FIG. 15. Connection Diagram of Two Direct-acting Field Rheostat Type Generator Voltage Regulators Controlling Two Paralleled A.C. Generators

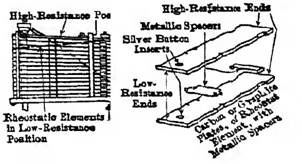

FIG. 16. Elements of Direct-acting Generator Voltage Regulator

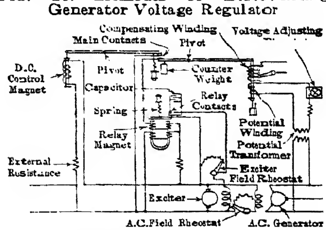

FIG. 17. Connection Diagram of Vibrating-contact Type Generator Voltage Regulator

AUTOMATIC GENERATOR VOLTAGE REGULATORS, in general, fall into three classes as follows:

Direct-acting Field Rheostat Type, which operates in shunt field of self-excited exciters, will control A.C. generators, synchronous condensers and small and medium size synchronous motors. Fig. 15 is a diagram of this type controlling two paralleled A.C. generators. The regulator operates only when a change in excitation is required. The torque motor operates against a spiral spring and moves the rheostat element, Fig. 16, to vary the field strength of the exciter. While designed to control but one exciter, it can control several generators in parallel served by the same exciter.

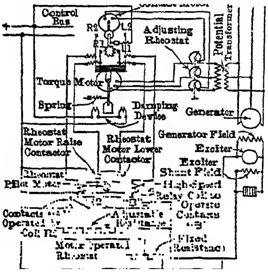

Fig. 18. Connection Diagram of Exciter Field Rheostat Type Generator Voltage Regulator

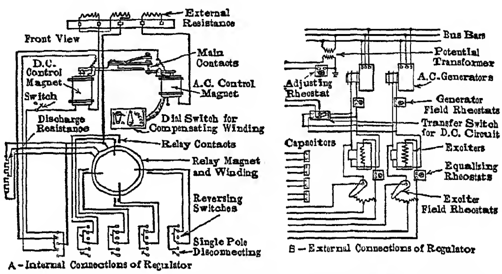

Fig. 19. Connection Diagram of Single Vibrating-contact Type Voltage Regulator Controlling Two Generators with Individual Non-paralleled Exciters

Vibrating Contact Type Regulators, Fig. 17, for small and medium capacity A.C. machines, operate in the shunt field of self-excited exciters. These regulators are rated 100/125 volts A.C., 125 or 250 volts D.C., and operate on any frequency between 25 and 125 cycles, over an exciter voltage range of 50 to 125 volts for 125-volt exciters, and 100 to 250 volts for 250-volt exciters. The two main parts are a D.C. control and an A.C. control. The former is a D.C. regulator with a main control magnet and relay magnet connected across the exciter lines. The relay contacts shunt the exciter field rheostat. The operation maintains voltage which varies with the demands of the A.C. control magnet connected to the A.C. bus.

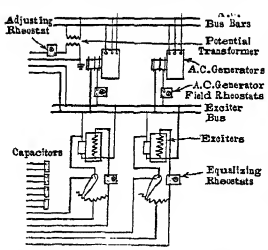

Fig. 20. External Connecti ns ingle Voltage Regulator Controlling Two Generators with Individual Paralleled Exciter

Exciter Field Rheostat Type with High-speed Features is suitable for any size or type of A.C. synchronous machine. It has no continuously-vibrating contacts. It operates only on A.C. voltage changes. Excitation is controlled by automatic adjustment of the exciter field rheostat, and by high-speed relays which cut in or out the entire regulating resistance in the exciter field with large changes in A.C. voltage. It is used widely in central stations to maintain system stability. In industrial use, it usually is limited to special cases of relatively large transient loads where rapid generator voltage recovery is required. Fig. 18 shows typical connections.

AUTOMATIC VOLTAGE CONTROL OF PARALLELED A.C. MACHINES.—Machine ratings and type of excitation system determine the type of regulator and method of control to be used. The three methods commonly used are:

Unit Exciters with Individual Regulators.—See Fig. 15. The exciters are operated non-parallel. The voltage of each A.C. machine is automatically and independently controlled by its own regulator. Division of reactive kva. among machines is controlled by A.C. compensation of the individual regulators, and there is no problem of load division among exciters. All three types of regulators may be applied. Voltage regulation is completely automatic, and no manual adjustment of field rheostats is required. Exciter or regulator trouble affects only one machine.

Unit Exciters with Common Regulator.—Each A.C. machine has an individual exciter operated non-parallel, but a common regulator controls all A.C. machines and exciters. See Fig. 19. The vibrating-contact regulator is the only standard type designed for such operation. A.C. potential for the regulator is taken from the station bus, and the D.C. supply is taken from any one exciter at a time, with transfer arrangement for connection

to any exciter. Proper division of reactive kva. among A.C. machines, and division of load among exciters, require manual adjustment of exciter equalizing rheostats, or of main generator field rheostats, or of both.

Common Exciter Bus and a Common Regulator.—A.C. machine fields are excited in parallel from a variable-voltage exciter bus, supplied by one or more exciters. All exciters

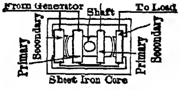

FIG. 21. Diagram of Induction Type Feeder Voltage Regulator

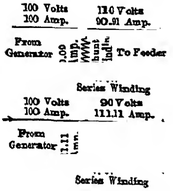

FIG. 22. Voltage and Current Relations in Single-phase Induction Feeder Voltage Regulator

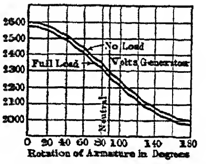

FIG. 23. Boosting and Lowering of Feeder Voltage by Induction Regulator

and A.C. generators are controlled by one regulator. If two or more exciters operate in parallel, only the vibrating contact type regulator can be used. With only one exciter, the regulator may be of any type, depending on machine ratings. This method is not entirely automatic. A.C. bus voltage is controlled automatically, but division of reactive kva. and exciter load must be manually adjusted. Fig. 20 with Fig. 19A show the regulator connections. Difficulties which may be encountered are: Exciters, operating in parallel, with different rates of response (voltage build-up) to regulator action, will cause unequal loading of exciters during load changes; exciters may not share light loads properly; paralleling an incoming exciter with the fluctuating voltage of the exciter bus may be difficult; continual manual adjustment of rheostats may be required to maintain proper division of exciter load and reactive kva.

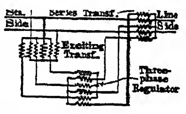

FIG. 24. Regulation of 3-phase High-voltage Circuit

VOLTAGE REGULATION OF D.C. GENERATORS.—Voltage of small and medium capacity D.C. generators may be controlled by the direct-acting regulator, Fig. 15. The rectifier is omitted and the torque motor is operated directly from the generator bus. The rheostatic type regulator, with or without high speed features, is suitable for any size of machine, and for any range of voltage, speed or current control. It also is suitable for control of separately-excited D.C. machines.

INDUCTION FEEDER VOLTAGE REGULATOR is a variable-ratio auto-transformer with primary and secondary windings. The primary is connected across the feeder to be controlled; the secondary is in series with the feeder. Fig. 21 is an elementary diagram. The primary winding is placed on a core which can be rotated to produce a voltage, variable in value and direction, in the secondary winding. Fig. 22 shows current and voltage relations in a single-phase regulator, for a 10% boost and lower. In maximum boost position, about 9% of the generator current flows through the primary winding and back to the generator. This amount is deducted from the current in the feeder, but the voltage on the feeder is boosted 10%. In the maximum lowering position, current in the regulator primary winding is reversed, increasing feeder current 11% and lowering voltage 10%. Fig. 23 shows the boosting and lowering of feeder voltage caused by rotation of an induction feeder regulator armature.

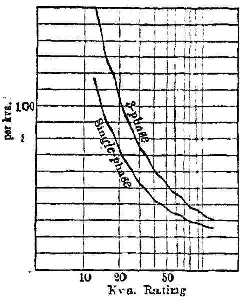

FIG. 25. Approximate 1935 Prices of Automatic Indoor Type Induction Feeder Voltage Regulator

Regulators can be built for any voltage and current for which it is practicable to build motors or generators of corresponding sizes. However, regulators are used on feeders where their kva. capacity is only about 10% of feeder capacity, and they must be wound for voltages and currents corresponding to much larger machines. Exciting and series transformers may be required. To control a circuit of high current but small kva. capacity, a series transformer is used in the regulator secondary only. To control a circuit of high voltage but of small kva. capacity both exciting and series transformers are required. Fig. 24 shows connections for these auxiliary devices for a 3-phase circuit.

Automatic Operation of Induction Feeder Regulators.—A modern distributing station may deliver power over a large number of individual feeders. Since the amount of voltage adjustment required depends on the load and voltage drop on any one feeder, automatic regulation of individual feeders is essential to good regulation on the entire system. Regulators for automatic service are motor operated.

Approximate Prices (1935) of standard 2400-volt automatic indoor type induction regulators which will vary feeder voltage ± 10%, are shown in Fig. 25. Outdoor equipments run about 15% higher.

Weights and Dimensions are given, approximately, in Table 11.

CONVERSION EQUIPMENT

Power generated as alternating current frequently must be changed to some other form before it can be utilized for industrial application. It may be changed in voltage, phase, frequency, from alternating to direct, or from direct to alternating current.

VOLTAGE CONVERSION on A.C. circuits is by means of transformers; on D.C. circuits, motor-generators are used.

PHASE CONVERSION.—Single-phase loads of sufficient magnitude to cause objectionable unbalance on a 3-phase system are best converted by use of a motor-generator. Phase conversion between polyphase systems, as 3-phase to 2- or 6-phase may be accomplished by transformers with special windings and taps (see p. 15–18).

FREQUENCY CONVERSION, necessary for interchange of power between two systems of different frequency, is most simply done by a motor-generator set. Another application is machinery operated by high-speed motors, requiring a frequency higher than the power supply; for example wood-working machinery.

1. MOTOR-GENERATOR SETS

CLASSIFICATION AND USES.—1. D.C. to D.C., used as balancer sets on 3-wire systems supplied by 2-wire generators, battery-charging sets, and booster sets for boosting voltage. 2. A.C. to A.C., used for frequency and phase conversion. 3. A.C. to D.C., used for all types of service, battery charging from A.C. supply, generator and motor excitation, railways, electrolytic work, material handling equipment, speed control, machine tool circuits and testing. Standard sets have a wide range of rating, with either induction or synchronous motor drive. 4. D.C. to A.C., used to a limited extent for special applications.

INDUCTION MOTOR-GENERATOR SETS for general purpose use are standardized for 25-, 50- and 60-cycle systems. They have a 2-bearing, squirrel-cage induction motor with a short shaft extension, connected through a solid coupling to the single-bearing generator. Foundations to prevent deflection of bases are necessary. Sets larger than 125 kw. have speed limit devices. Generators for 3-wire service have two collector rings for deriving the neutral.

Voltage Ratings are the same as for standard motors and generators used separately.

Temperature Rise Rating is 40° C. for continuous operation, based on 40° C. ambient temperature.

Overloads of 150% of rated generator current, in amperes, are permissible with successful commutation as defined by the A.I.E.E.

Service Factor is 1.15 for all except 50-cycle sets.

Used as Exciters for A.C. generators, rating should be not less than 110% of excitation required for all generators to be excited.

Standard kw. Ratings of 25-, 50- and 60-cycle sets are: 1, 1.5, 2, 3, 5, 7.5, 10, 15, 20, 25, 30, 40, 50, 60, 75, 100, 125 and 150 kw.

Standard Speeds are: 60-cycle, 1 to 50 kw., inclusive, 1800 r.p.m.; 60 to 150 kw., inclusive, 1200 r.p.m.

50-cycle, 1 to 50 kw., inclusive, 1500 r.p.m.; 60 to 150 kw., inclusive, 1000 r.p.m.

25-cycle, 1 to 50 kw., inclusive, 1500 r.p.m.; 60 to 150 kw., inclusive, 750 r.p.m.

Approximate List Prices (1935) of induction motor-generator sets for general purposes are given in Fig. 1.

Efficiencies, Dimensions, Weights and Power Factors are given in Table 1.

SYNCHRONOUS MOTOR-GENERATOR SETS are built in small sizes as follows: 50 to 150 kw., 1200 r.p.m., 60 cycles; 1000 r.p.m., 50 cycles; 750 r.p.m., 25 cycles. Motors can be wound for either 2-phase or 3-phase operation. Standard power factor is 0.8 leading. Motor voltages are 220, 440, 550, and 2200 volts. Standard large sizes range from 200 to 1000 kw. at 125 volts; to 4000 kw. at 250 volts; from 300 to 6000 kw. at 600 volts. Three-unit, 4-bearing sets, with two generators each of half the set rating, are used for sizes of 300 kw. and over at 125 volts. Three-unit sets are used at 250 and 600 volts for 2000 kw. and over.

Temperature Rise.—Usual ratings are: 150 kw. and less, continuous operation, 40° C.; 200 kw. and over, 2-hr. rating at 125% of load, 55° C.

Standard kw. Ratings are: Small size, 25-, 50- and 60-cycle, 50, 60, 75, 100, 125 and 150 kw.; large size, 125 volts, 60-cycle, 200, 250, 300, 400, 500, 600, 800, and 1000 kw.; 250 volts, 60-cycle, 200, 250, 300, 400, 500, 600, 750, 1000, 1250, 1500, 2000, 2500, 3000 and 4000 kw.; 600 volts, 60-cycle, 300, 500, 750, 1000, 1250, 1500, 1750, 2000, 2500, 3000, 3500, 4000, 5000 and 6000 kw. Standard 25-cycle ratings are similar.

Approximate Prices (1935) of small synchronous motor-generator sets are given in Fig. 2. In the large sizes, prices average between $20 and $25 per kw. at 60 cycles with 2300- or 4000-volt motors. 25-cycle sets average about 20% higher.

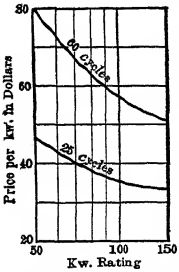

Fig. 2. Approximate 1935 Prices of Synchronous Motor-generator Sets, 125 Volts

Approximate Efficiencies, Weights and Dimensions of representative A.C. to D.C. motor-generator sets for continuous, constant-voltage service are given in Tables 2 and 3. Efficiencies are determined by including I^2R losses in armature and field windings, and in field rheostats for both motor and generator, bearing windage and friction, core, stray load, brush friction and brush contact losses. Segregated losses are measured in accordance with A.I.E.E. Standards.

REVERSED OPERATION OF SYNCHRONOUS MOTOR-GENERATOR SETS.—With the A.C. motor acting as a generator, at 0.8 power factor, the A.C. output will be 80% of the rated D.C. output, for the same temperature rise as specified for A.C. to D.C. operation.

PARALLEL OPERATION OF MOTOR-GENERATOR SETS usually is practicable. For satisfactory operation, special adjustments may be necessary after installation. See Parallel Operation of D.C. Generators, p. 15–31.

PARALLEL OPERATION OF MOTOR-GENERATORS WITH SYNCHRONOUS CONVERTERS in the same station is possible only when the machines are connected by several thousand feet of feeders, and the converters are not subject to serious A.C. voltage fluctuations. There must be sufficient minimum resistance to maintain some feeder drop from the interconnected substation to the loads. The machines inherently are unsuited for parallel operation, and careful study of A.C. supply voltage and D.C. load is necessary.

MOTOR-GENERATOR SETS FOR ELECTROLYTIC SERVICE usually are rated for continuous operation. Load is at constant current, and generator output varies with voltage. The kw. rating is determined by maximum voltage and current required continuously. A voltage range of 20% below normal usually can be obtained by field control on a shunt-wound generator; separate excitation is required for wider ranges.

D.C. TO A.C. MOTOR-GENERATOR SETS.—An important application is provision of variable-frequency A.C. supply. Within a specified range an infinite number of speeds is possible, because of the speed characteristics of the D.C. motor. A typical use of a variable frequency is in the manufacture of machine tools or business machines, where motors of various frequencies must be tested. The equipment will include a variable-speed D.C. to A.C. motor-generator set, auto-transformers with suitable taps for obtaining the required voltages at the required frequencies, a generator control and tap changing panel, and a

speed controller for the D.C. motor. Fig. 3 shows a connection diagram for a test set. The generator can be wound for 2- or 3-phase output, and change in connections made with a triple-pole, double-throw switch, which also connects two single-phase auto-transformers for either 2-phase, 4-wire, or 3-phase, open delta, 3-wire, output. Single-phase power also is available at the same frequencies and voltages. Single-phase capacity of the generator at any given frequency is 66% of the 3-phase capacity. Generator excitation remains constant, and voltage and kw. capacity vary directly with speed.

2. SYNCHRONOUS CONVERTERS

SYNCHRONOUS CONVERTERS comprise a synchronous motor and a D.C. generator combined in one machine, with an armature winding common to both A.-C. and D.C. circuits. The effective A.C. voltage, V_{ac}, between collector rings, for a given D.C. voltage, V_{dc}, is $V_{ac} = 0.707 V_{dc} \sin (\pi/n)$, where n = number of collector rings. For a single-phase converter, $n = 2$; for a polyphase converter n = number of phases. Fig. 4 shows arrangement of windings, and Fig. 5 connections to control apparatus.

Converters are widely used where the D.C. load remains constant, as in electrolytic work. Converters, with transformers, occupy about the same floor space as motor-generator sets of the same rating, but the efficiency of the former is higher. The transformers can be located away from the converter, which often is an advantage. Since the A.C. and D.C. circuits are electrically connected through the converter, fluctuations in the A.C. supply circuit are immediately reflected in the D.C. load circuit. With wide A.C. voltage fluctuations, flashovers may occur, and the motor-generator then is preferable to the converter.

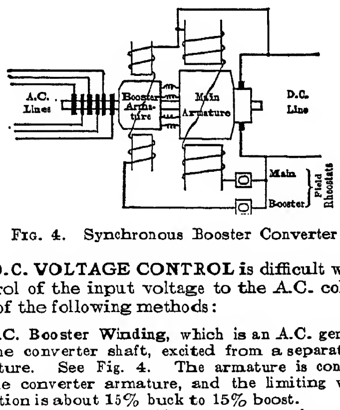

FIG. 4. Synchronous Booster Converter

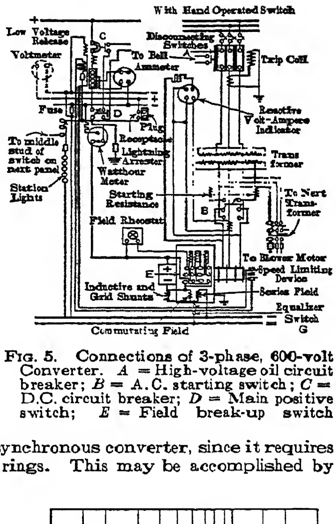

FIG. 5. Connections of 3-phase, 600-volt Converter. A = High-voltage oil circuit breaker; B = A.C. starting switch; C = D.C. circuit breaker; D = Main positive switch; E = Field break-up switch

D.C. VOLTAGE CONTROL is difficult with a synchronous converter, since it requires control of the input voltage to the A.C. collector rings. This may be accomplished by one of the following methods:

A.C. Booster Winding, which is an A.C. generator on the converter shaft, excited from a separate field structure. See Fig. 4. The armature is connected to the converter armature, and the limiting voltage variation is about 15% buck to 15% boost.

Transformer Taps.—Since power must be removed to change taps, this method is useful only to compensate for line drop. Load ratio control permits changing taps under load, and can be applied to synchronous converters. Rapid changes in voltage are not possible, as two steps are required to change from one tap to another.

Induction Regulators permit a continuous variation in D.C. voltage, but seldom are used because of high cost. If continuous variation is important, the cost of induction regulators may be warranted. Although apparatus for voltage variation reduces the efficiency of synchronous converters, it still is higher than that of any other type of conversion equipment.

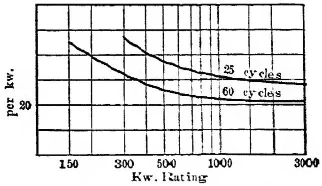

FIG. 6. Approximate 1935 Prices of Standard Synchronous Converters and Transformer Banks for Industrial Application. 2300, 4000 volts A.C.

STARTING SYNCHRONOUS CONVERTERS.—Methods are: 1. Star-delta connection of transformer primary winding, giving about 58% voltage for starting. 2. Low-

voltage secondary tap; common for manual control; a 50% tap is used to give a starting kva. of about 25% of full voltage value. 3. Separate starting transformer or auto-transformer. 4. Starting motor; a direct-connected motor, specially designed for high starting torque per ampere; is expensive, and not used unless system limitations demand it. 5. D.C. starting; the converter is started as a D.C. motor from an available D.C. supply.

Approximate Prices (1935) of 250-volt compound-wound synchronous converters with banks of three single-phase transformers, are given in Fig 6.

Efficiencies, Weights and Dimensions of synchronous converters of standard ratings for industrial service are given in Table 4.

3. POWER RECTIFIERS

A rectifier is a device which converts alternating to direct current, by permitting flow of current in but one direction. The essential parts are the electrodes (anode and cathode) and a medium for conducting current between them. Current flows from the anode into the arc and from it into the cathode. A starting anode is used to start the initial arc. Its grids are placed in the arc stream, to which a voltage control can be applied. Excitation anodes maintain an auxiliary arc in the vacuum tank.

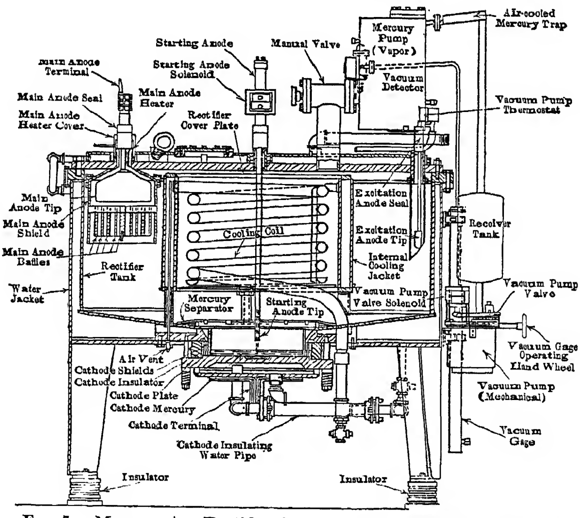

Fig. 7. Mercury Arc Rectifier, Metallic Tank, 3000 kw., 625 Volts

MERCURY ARC RECTIFIERS depend on ionized mercury vapor to conduct the current between electrodes. Fig. 7 shows the arrangement of a metallic tank mercury arc rectifier. Fig. 8 shows typical connections of a rectifier and its associated apparatus as used for railway service.

Railway Applications.—The advantages of the mercury arc rectifier for electric railway service are its high efficiency at light loads and at D.C. voltages above 550, its lack of rotating parts, and its low maintenance. Standard rectifiers for railway service are 6- and 12-phase, and range in capacity from 500 to 6000 kw. at 600, 750, 1500 and 3000 volts. A complete installation usually will comprise power transformer, interphase transformer, auxiliary and insulating transformers, rectifier, ignition and excitation equipment, switchboard and cooling system. A low-voltage, high-current transformer and loading resistor also are required to bake out the rectifier and remove foreign gases from it before placing it in service. Transformers with 6- or 12-phase secondaries are used to cut down the A.C. ripple in the D.C. output and to get the most efficient use of the transformer.

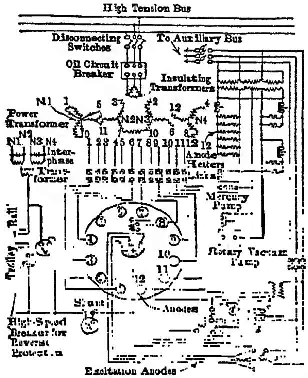

Fig. 8. Connection Diagram of 12-phase Rectifier Using Quadruple-delta Zigzag Main Transformer

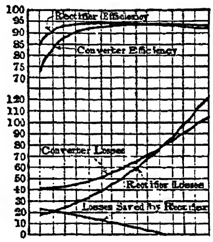

Fig. 9. Relative Efficiencies, 1000-kw. Rectifier and 1000-kw. Synchronous Converter at 600 Volts

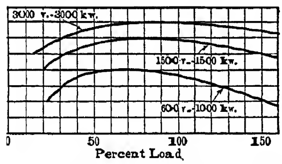

Fig. 10. Overall Station Efficiencies of Rectifiers at Various Voltages

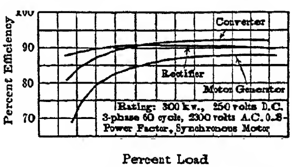

Fig. 11. Efficiency Characteristics of Motor-generator Sets, Synchronous Converters and Mercury Arc Rectifiers, with Transformer Losses

Industrial Applications usually require direct current at 250 volts, where the mercury arc rectifier is at a disadvantage. The principal loss in a rectifier is the loss in the arc. Arc drop varies with load, ranging from 20 to 35 volts, and is independent of rated D.C. output voltage. Hence, for high D.C. voltages, efficiency is high, but is relatively low for low voltages. Higher efficiencies at part loads are an advantage, and for low load factor applications, 250-volt rectifiers may be warranted. The relative advantages of a rectifier, a motor-generator set or a converter in industrial service depend on the type of load and the D.C. voltage required. Three-wire operation is not so readily obtained with a rectifier as with a motor-generator or converter. A balancer set is necessary, which increases cost and lowers efficiency. Switch-gear control equipment can be manual or automatic.

Efficiencies of mercury arc rectifiers in comparison with other types of conversion apparatus are shown in Figs. 9, 10, and 11.

Power Factor of a mercury arc rectifier is shown in Fig. 12, which is representative. Since power factor is due almost entirely to wave distortion, it does not result in appreciable increase in reactive current in the system, and is less important than in rotating apparatus.

Voltage Regulation of a mercury arc rectifier is about 5%, from 5% to 100% load. For most installations this is satisfactory.

Approximate Prices (1935) of 250-volt mercury arc rectifiers are shown in Fig. 13.

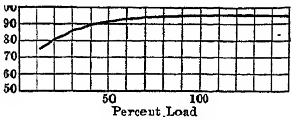

FIG. 12. Power Factor of 600-volt, 1000-kw., 12-phase Rectifier at Various Loads

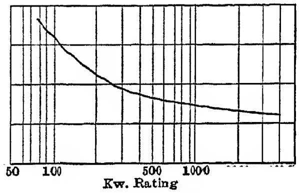

FIG. 13. Approximate 1935 Prices of Mercury Arc Rectifiers, 3-phase, 60-cycle, 2300 Volts A.C., 250 Volts D.C.

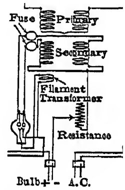

FIG. 14. Internal Wiring for Full-wave Tungar Rectifier, 30 Volts, 0.3–0.5 Amperes

TUNGAR RECTIFIERS are used for small battery-charging installations. They use a tube rectifier with transformer and means of regulating the D.C. output. Current capacities are small. A few standard equipments are: 6–90 volts, 6 and 12 amperes; 120–175 volts, 0.5–2 amperes and 2–6 amperes; 24–30 volts, 0.5–2.5 amperes; 40–60 volts, 0.5–2.5 amperes. Fig. 14 shows typical connections for a full wave tungar charger.

SWITCHBOARD EQUIPMENT

1. PANEL CONSTRUCTION AND EQUIPMENT

TYPES OF PANELS.—Two general classifications are vertical type and bench type. The vertical type is applicable to most conditions. Protective equipment may be mounted directly on panels or mounted remotely and electrically controlled, with only the control on panels. Bench boards are used largely in high-capacity A.C. stations, where switching conditions are complicated, and electrically-operated switchboard apparatus is employed.

SWITCHBOARD PANEL MATERIALS ordinarily used are steel, ebony-asbestos, and slate. Characteristics and advantages of these materials are:

Steel Panels are almost universally used for all types of switchboards, except where live equipment is mounted on the front of panels. They are formed in one piece of 1/8-in. panel steel, with angle sections integral with the panel at top, bottom and sides. The bottom angle is bolted to the channel-iron sill. See Fig. 1. Standard panel widths are 16, 20, 24, 28 and 32 in. for panel heights of 64, 76 and 90 in.

Ebony-asbestos consists of asbestos fiber and other insulating and waterproofing materials. It will withstand high heat without disintegration, is impervious to moisture and oil, is hard and of permanent form, but easily machined and worked, has dull-black finish, weighs less than slate, and can be used for any kind of switchboard service.

Slate is suitable for insulating up to and including 1200 volts A.C. or D.C. Its present use is limited to matching existing installations.

Marble, as a panel material, has almost disappeared, except where demanded by the user.

STANDARD SWITCHBOARD PANEL SIZES for ebony-asbestos and slate boards are shown in Fig. 2. For ebony-asbestos panels, the one-section panel is recommended as it provides a larger unbroken mounting surface.

Channel Iron Sills are recommended for all panels with sub-bases.

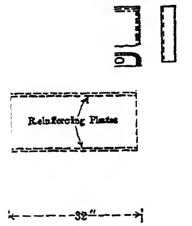
Grounding.—All switchboard panel supports should be grounded.

ALTERNATING-CURRENT SMALL-PLANT AND INDUSTRIAL SWITCHBOARDS.—Manufacturers list standardized panels, using knife switches with fuses for 60-cycle service. These control generators and feeders for general power and lighting

service in small plants. The maximum capacity of a single generator or feeder panel is 600 amperes for 240- or 480-volt, 3-phase, 3-wire non-grounded service. Construction includes a one-section ebony-asbestos panel 48 in. high, mounted on 76-in. angle-irons.

GENERATOR PANELS are of two classes: 1. Isolated Installation, to control one generator, one exciter and one or two feeder circuits. 2. Switchboard Assembly to control one or more generators and one or more feeders.

Feeder Panels have knife switches and fuses for one or more circuits, and are arranged to line up and connect to a common generator bus for switchboard assembly. Panels for isolated installation are shown in Fig. 3*a*. Each panel controls one generator, one exciter and one or two feeder circuits. Maximum capacity available in standard equipments is 250 kva. at 240 volts, or 500 kva. at 480 volts.



[F]IG. 1. Panel

Panel Devices consist of: 1 ammeter; 1 voltmeter; 3 ground detector lamp receptacles; 1 push button switch for ground detector lamps (480-volt panels); 1 double-pole, single-throw discharge switch, mounted on back of panel with operating lever in front; 1 nameplate and card holder; 1 three-pole, single-throw 250-volt or 500-volt knife switch, with fuse cutouts on front of panel, including 1 set of N.E.C.S. fuses; 1 current transformer; 1 potential transformer 440/110 volt, with fusible cutouts (for 480-volt panels), and all main connections, small wiring and cable terminals. The framework is angle-iron with floor braces. For switchboard assembly, panel devices are essentially the same except that a main bus is required, in back of the panels, to which each generator and feeder circuit is connected. A synchroscope receptacle is added to each generator panel.

NECESSARY ACCESSORIES include:

Main 3-phase bus for each panel in an assembly of two or more panels, to carry current continuously with a temperature rise not over 30° C., based on 40° C. ambient, size to be as follows:

Ampere capacity, 25-60 Cycles	Up to 750	751-1200	1201-1675	Up to 1300	1301-2050	2051-2500
Bus bars, 1/4 in. thick for each leg of bus...	1 2-in.	2 2-in.	3 2-in.	1 4-in.	2 4-in.	3 4-in.

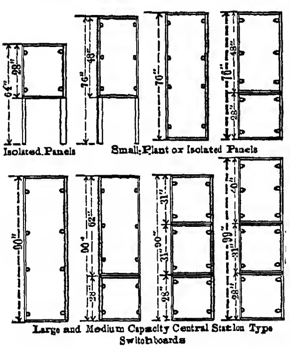


FIG. 2. Standard Sizes of Ebony-asbestos and Slate Switchboard Panels

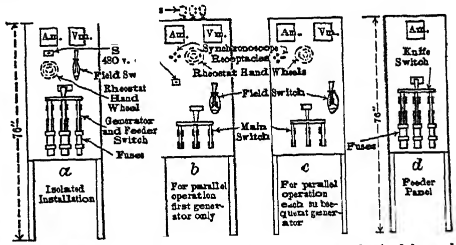

FIG. 3. A.C. Small Plant and Industrial Switchboard

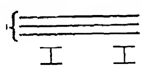

FIG. 4. Usual Order of Panel Assembly

Current that a bus must carry back of a specific switchboard panel is determined as follows: Assume the usual order of panel assembly recommended, as shown in Fig. 4. For the most economical distribution of copper, if the bus has more than one bar per leg the smaller-capacity panels of the same kind should be placed nearest the right-hand end of the board. Let I_g, I_f = respectively, current in bus back of the panels under consideration, and I_{rg} and I_{rf} = their rated ampere

Table 1.—Net Weights of Panel Materials.

Material	Lb. per sq. ft.			
	1/8 in.	1 in.	1 1/2 in.	2 in.
Steel	5.1	....	....	....
Ebony-asbestos	....	10.6	15.9	21.2
Slate	....	....	21.8	29.1
Marble	....	...	21.6	28.8

capacity; I_{g1}, I_{g2}, I_{f1}, I_{f2} = respectively, rated capacity of each generator and feeder panel to the left of the ones under consideration. Then

$$I_g = I_{rg} + I_{g1} + I_{g2} + \ldots, \text{ etc.}; \quad I_f = I_{rf} + I_{f1} + I_{f2} + \ldots, \text{ etc.}$$

If this gives a result exceeding the current which the bus is required to carry back of the extreme right-hand generator panel, use the latter value as the current the bus is required to carry back of the feeder panel. Incoming lines should be regarded as generators. If the panels are arranged in the reverse order from that shown in Fig. 4, interchange the values for right and left in the formulas.

Synchronizing Equipment is necessary if the switchboard controls two or more generators operating in parallel. This includes a swinging bracket, synchroscope and synchronizing plug.

A Governor Motor Control Switch is required for turbine- or engine-driven generators, and the prime mover speed is adjusted from the switchboard.

Field Rheostats and operating mechanisms are considered as generator and not switchboard equipment. The combined generator and exciter panels are designed for the exciter rheostat to be supported back of the panel and the generator rheostat mounted separately, operated from the front of the panel by concentric hand wheels.

Heating of switchboard equipment should not exceed limits prescribed by the A.I.E.E. Standardization Rules.

APPROXIMATE PRICES AND WEIGHTS applying to a 240-volt panel (Fig. 3*a*) are given in Table 2. Table 3 gives similar information for a 480-volt panel (Fig. 3*b*).

Table 2.—Approximate Prices and Weights of 240-volt Panels.

* Based on a factor of safety of 3 1/2 between live parts of opposite polarity, and of 3 between live parts and grounds. † Good practice for larger plants.

2. ALTERNATING-CURRENT SWITCHBOARDS

MANUALLY-OPERATED A.C. SWITCHBOARDS WITH OIL CIRCUIT BREAKERS control generators, transformers and feeders for general power and lighting service in public service, municipal, and industrial plants. Panels are primarily for switchboard assembly, connected to a single set of buses. Standard equipments are listed for 240, 480 and 2400 volts, 60-cycle, 3-phase, non-grounded, 3-wire circuits. Maximum capacities provided for are: Generators, 3100 kva. at 2400 volts; exciters, 125 kw. (250 kw. at

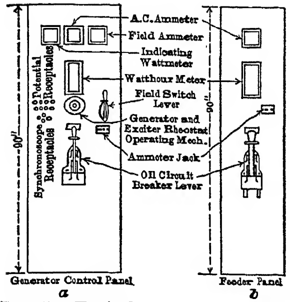

FIG. 5. Typical 90-in. A.C. Panels, Manually Operated

250 volts); feeders, 800 amperes. Standard panel material is steel, but ebony-asbestos or slate can be used.

Fig. 5a shows a typical 90-in. panel, including devices for average operating conditions, to control one generator, parallel or non-parallel operated, with individual belted or direct-connected exciter.

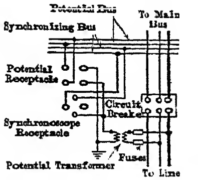

FIG. 6. Connections Showing Potential and Synchronizing Receptacles Added to Fig. 5b to Serve as Incoming Line Panel

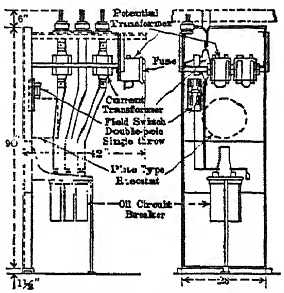
Generator Panels may include A.C. ammeter, indicating wattmeter and field ammeter, a 3-pole ammeter transfer jack and plug for reading in each phase on one meter and an 8-point potential receptacle for reading voltage across all phases.

Feeder Panels may have one ammeter and 3-pole ammeter jack and plug. A typical 90-in. feeder panel is shown in Fig. 5b; it also is suitable for an incoming line panel. In stations where generators are installed, synchronizing equipment must be added to the feeder panel to make it serve as an incoming line panel as shown in Fig. 6.

Watthour Meters, when desired, usually are included with the generator panel rather than the feeder panel, where they are most likely to operate continuously at full load for highest efficiency.

Swinging Brackets are necessary for mounting the synchroscope used in paralleling two or more generators, or where it is necessary to parallel a generator with an incoming line. It is usual to mount voltmeter plugs and receptacles on each generator and incoming panel. In synchronizing, it then is possible for the operator to see the voltage of station bus and incoming generator at the same time.

PROTECTION OF GENERATORS AND FEEDERS is provided by automatic disconnection of feeder circuits when load current exceeds a predetermined value. Improved operation often is obtained by adding time delay to such protection, so that service on a feeder is not interrupted for momentary overloads. Automatic protection is not applied to generator field or exciter circuits, as continuity of service usually is more important, and possibility of trouble in these circuits is remote.



FI . 7. Construction and Assembly of A.C. Generator and Feeder Panels

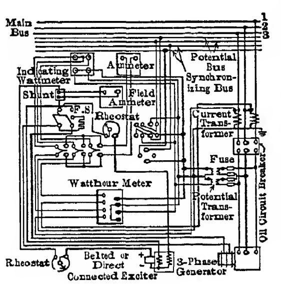


FIG. 8. Connection Diagram of A.C. Generator Panel

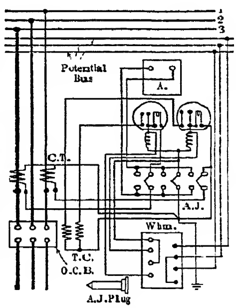

FIG. 9. Connection Diagram of A.C. Feeder Panel

A = A.C. Ammeter; A.J. = Ammeter jack; C.T. = Current transformers; D.R. = discharge resistors; F = Fuses; F.A. = Field ammeter; F.S. = Field discharge switch; I.W. = Polyphase indicating wattmeter; O.C.B. = Oil circuit breaker; P.T. = Potential transformers; Pe.Re. = Potential receptacle; Re = Relays; Rh = Field Rheostat; S.Re = Synchronizing receptacle; Sh = Ammeter shunt; T.C. = Trip coils; Whm = Polyphase integrating watt-hour meter

Disconnecting Switches provide for convenient isolation of oil circuit breakers from the bus for inspection, changing oil, and adjustments. They are recommended particularly for switchboards under 24-hr. loads that cannot be shut down at intervals.

Selection of Oil Circuit Breakers for switchboard assembly should not be made until proper ratings are determined from investigation of short circuit conditions. (See p. 15-63.)

Construction and Assembly of typical 90-in. generator and feeder switchboard is shown in Fig. 7. Figs. 8 and 9 show typical connection diagrams.

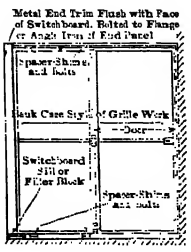

FIG. 10. Typical End Screen for Switchboards

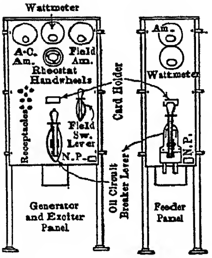

FIG. 11. Typical A.C. Panels for Small Plants

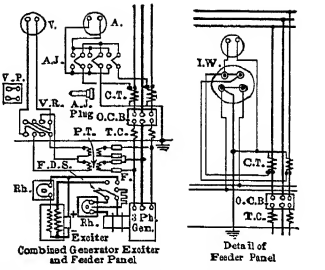

FIG. 12. Standard Connections for Small Plant A.C. Panels. See Key under Fig. 8

Grille-work End Screens provide complete enclosure for switchboards installed parallel to, and within a few feet, of a station wall. Accidental contact with live parts is prevented. Fig. 10 shows typical construction.

Ground Detector Equipments are required by the National Electrical Safety Code.

SMALL-PLANT INDUSTRIAL-TYPE A.C. SWITCHBOARDS are standardized for 240, 480, 600 and 2400 volts, 3-phase, 3-wire circuits. They use oil circuit breakers instead of fused knife switches. Manufacturers list them for 60-cycle service, but they are available for all standard frequencies. Listed panels are limited generally to generators, not exceeding 332 kva. at 240 volts, 665 kva. at 480 volts, and 750 kva. at 600 volts.

Typical panels are shown in Fig. 11, and typical connections in Fig. 12. Construction is shown in Fig. 13, *a* and *b*.

3. DIRECT-CURRENT SWITCHBOARDS

D.C. SMALL-PLANT AND INDUSTRIAL MANUALLY-OPERATED SWITCHBOARDS, limited to generators of 150 kw. at 125 volts, or 300 kw. at 250 volts and 1200 amperes maximum feeder capacity, are shown in Fig. 14. Feeder circuits may be included on the generator panel or on separate panels. The panels provide for isolated or parallel operation, and when furnished with proper bus connections can be assembled for control of two or more generators and feeders. Knife switches generally are used for lighting, and circuit breakers for power service. Circuit breakers are required where feeder circuits may be subjected to abnormal conditions of dangerous character, and it may be necessary to open the feeder circuits to relieve the connected apparatus.

Usual panel dimensions are: Length 36 and 48 in.;

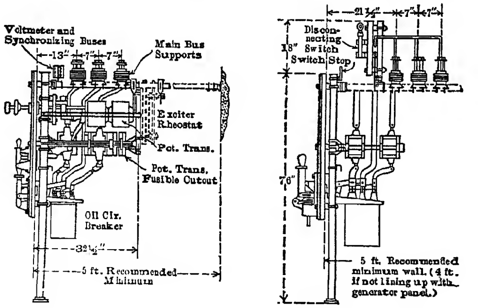

FIG. 13. Construction of Small Plant Generator and Feeder Panels

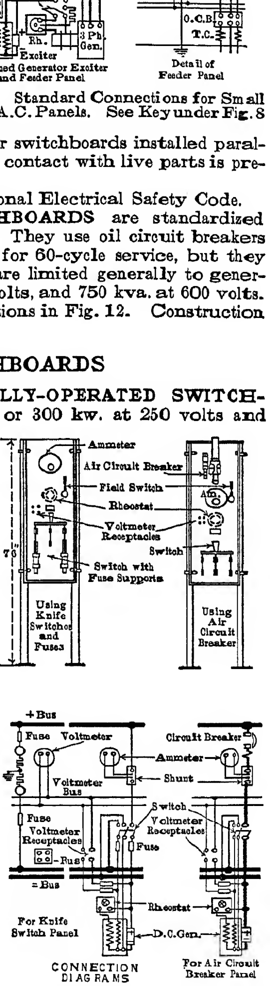

FIG. 14. Typical Small Plant D.C. Generator Panel and Connection Diagrams

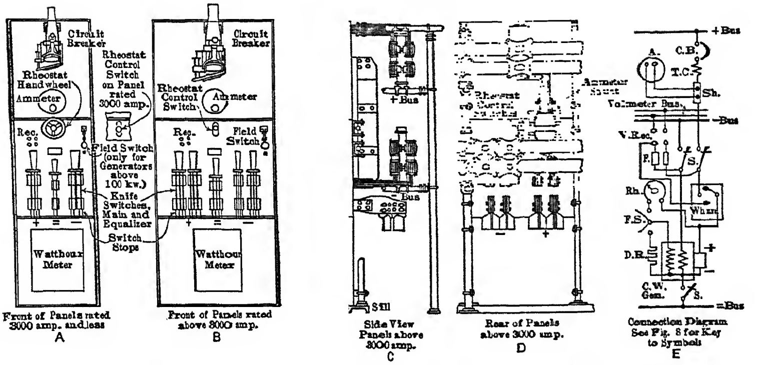

FIG. 15. D.C. Generator Switchboard for 2-wire Service and Parallel Operation

width 20, 24, 28, 32 in. These panels are mounted on 64- and 76-in. angle-iron supports as required. For small isolated generators, panels can be wall mounted.

D.C. SWITCHBOARDS FOR GENERAL POWER AND LIGHTING SERVICE.—Standard individual panels designed for switchboard assembly, provide control for generators and circuits as follows: 2-wire generators, 25 to 1500 kw. (on both 3-wire and 2-wire systems); 2-wire, shunt- or compound-wound synchronous converters; 3-wire generators 50 to 1500 kw.; 3-wire balancer sets, 14 to 1000 amperes neutral current; 2- and 3-wire feeder circuits, 30 to 6000 amperes, and for 125- and 250-volt, 2-wire non-grounded, or 125/250-volt, 3-wire systems.

Typical D.C. Panel Construction for 2-wire Generators for assembly in 2-wire non-grounded switchboards is shown in Fig. 15. Each panel controls one compound-wound D.C. generator operating in parallel with others. Three-wire generator panels are shown in Fig. 16.

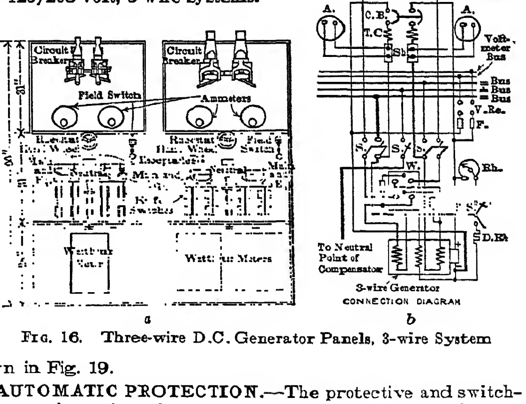

FIG. 16. Three-wire D.C. Generator Panels, 3-wire System

Complete D.C. Switchboard Connections.—Fig. 17 is typical for a 2-wire system. A 3-wire system for 3-wire generators is shown in Fig. 18. Typical connections for a 3-wire system using balancer sets are shown in Fig. 19.

D.C. SWITCHING AND AUTOMATIC PROTECTION.—The protective and switching schemes upon which the control panels and connections are based, in general, are:

Two-wire Systems.—Over-current protection for 2-wire generators and converters is obtained by single-pole, single-coil circuit breakers connected in the positive lead. The series fields of 2-wire,

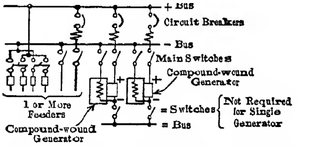

FIG. 17. Connections for D.C. Switchboard with One or More Compound-wound Generators, 2-wire System

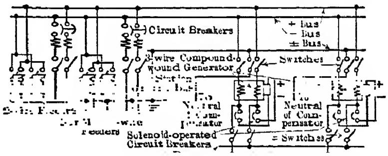

FIG. 18. Connections for D.C. 3-wire System with 3-wire Generators

compound-wound, generators and converters are equalized on the negative sides and the breaker trip coil is actuated by full armature current for both compound-wound and shunt-wound machines. This is important when compound-wound generators operate in parallel, because otherwise unnecessary disconnection from the bus, or injurious overloading may occur, depending on the direction of equalizing currents. In synchronous converters, additional protection is afforded in the control of the A.C. end.

Speed limit devices on converters or motor-generator sets also actuate circuit breakers through under-voltage devices, to prevent parallel-operated machines from motoring from the D.C. bus at dangerous speeds, when the converter or motor supply is accidentally disconnected. Speed limit devices usually are set at about 15% over-

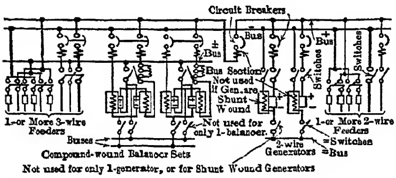

Fig. 19. Connections for D.C. 3-wire System with 2-wire Generators and Balancer Sets, Non-grounded System

When paralleling compound-wound generators or converters, less voltage disturbance occurs if series fields are established before connecting the machines to the bus. The connection diagrams show knife switches arranged to permit this procedure.

Three-wire Generators on 3-wire Systems usually are compound-wound, and operated in parallel. Switchboard panels are standardized on this basis. Generators have divided series fields, connected on opposite ends of the armature. This is necessary for equalization. Circuit breakers are so connected between generator brushes and equalizer switches that they are actuated only by armature current. Knife switches are so arranged that series fields may be established in the proper direction and the generators brought to full voltage before final connection to main bus. Incidentally, this affords a means of correcting the polarity of a generator. With other switching arrangements voltage disturbances may occur at paralleling, with possibility of heavy armature short circuits. Automatic circuit breaker elements are mechanically or electrically interlocked, so that when one side opens the other also must open.

Two-wire Generators with Balancer Sets and Bus Sectionalizing on 3-wire Systems.—On 3-wire systems, when the neutral is derived from a balancer set, unbalancing may exceed the capacity of the balancer set and shift the neutral enough to burn out lamps on the lightly loaded side. A balanced voltage differential relay, which functions when unbalanced voltage exceeds a predetermined limit affords protection against this contingency.

Control is provided on panels whereby the relay trips the breakers on all 2-wire generators, shutting the system down completely, or a bus section breaker can be used on a separate panel (see Fig. 19) which disconnects the balancers and 3-wire load, leaving the generators and 2-wire load in operation. Switches on 2-wire generator panels on 3-wire systems provide the same operating sequence as on 2-wire systems.

Balancer panels have double-pole, double-coil breakers, a starting and positive switch, a neutral switch, and for parallel-operated balancers, a rheostat switch and two equalizer switches. To start a balancer set which operates singly, the neutral switch must be open; if parallel-operated, the rheostat switch also must be open when starting.

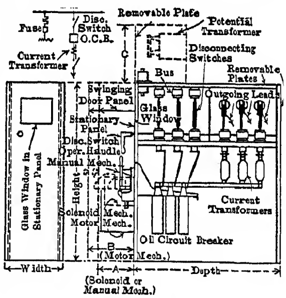

Fig. 20. Single-bus Cubicle with Group-operated Switches for Isolating Oil Circuit Breaker. See Table 4

Feeder Circuits on 3-wire Systems.—For 2-wire and 3-wire feeders on grounded neutral systems, double-pole, double-coil circuit breakers are used with single-pole knife switch in series with each breaker pole. If the neutral is not grounded, the equipment for 3-wire feeders is the same as if the neutral is grounded except, to comply further with the Code, a triple-pole switch is used, to make sure that outside legs are open when the neutral is opened.

D.C. Circuit Breakers are equipped to operate instantaneously on over-current. Immediate interruption of abnormal current is necessary.

4. CUBICLE SWITCHGEAR

INDOOR A.C. CUBICLE SWITCHGEAR consists of steel-enclosed switchboard units, in which all apparatus for one panel, including potential transformers, current transformers, oil circuit breaker, disconnecting switches, meters and instruments, and mounting structures are compactly assembled in one cubicle. Typical construction is shown in Fig. 20 with various devices assembled. The hinged door in the front forms the meter panel. All switching operations can be made without opening the cubicle.

Indoor cubicles are used in central station, substations, industrial plants and office buildings. They control generators, motors, incoming lines, feeders, bus-sectionalizing and bus-tie circuits. Either manually- or electrically-operated circuit breakers can be used.

Advantages of Cubicle Construction are: They are completely assembled when shipped; are designed for switchboard assembly; to put them in operation it is necessary only to set each unit in place, and connect the leads; breakers can be isolated by disconnecting switches; all live parts are enclosed; high-voltage compartment is completely isolated from low-voltage compartment; they economize space; installation cost is low.

Standard Ratings are available with breakers having current ratings from 200 to 2000 amperes and voltage ratings up to 15,000 volts. The interrupting ratings range from 20,000 to 500,000 kva. All ampere ratings are based on the maximum current which

the cubicles will carry continuously without overheating. Equipment should be selected which has a rating at least equal to the maximum rating of the circuit.

Weights and Dimensions applying to the type of cubicle shown in Fig. 20 are given in Table 5.

OUTDOOR SWITCH HOUSES are self-contained switching and metering equipments, enclosed in weather-proof housings. They are used as temporary or permanent feeder or line protective installations for manual or automatic operation. Any type of standard metering, relay or control equipment can be used.

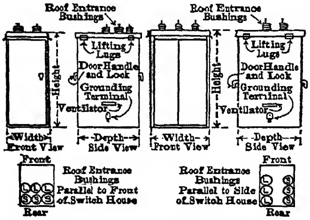

FIG. 21. Outdoor Switch Houses. See Table 5

To install an outdoor switch house it is only necessary to anchor the house, connect the ground terminal and the incoming and outgoing leads to the entrance bushings. A concrete pad, or corner pieces, are sufficient for mounting. If system changes require relocation of the switch house, it is easily disconnected and moved as a unit.

Typical construction is shown in Fig. 21. Dimensions of standard units are given in Table 6.

BATTERIES

A battery comprises two or more cells which convert chemical energy to electrical energy. In each cell two unlike electrodes are immersed in an electrolyte. The electrolyte is a solution of water and acid, alkalies or salts.

Primary Cells generate current by consuming one element, usually zinc. The electrodes may be copper or carbon and zinc. Such cells become exhausted in use and have to be replaced, because the chemical reactions are not reversible.

Secondary or Storage Cells convert chemical energy to electrical energy by chemical reactions which are reversible. Such cells can be recharged by passing direct current through in the opposite direction.

1. TYPES OF STORAGE BATTERIES

Storage Batteries comprise one or more storage cells, of which there are two major types:

THE LEAD-ACID CELL.—The positive plate contains peroxide of lead; the negative plate contains finely-divided pure lead. The electrolyte is sulphuric acid and pure water, with a specific gravity ranging from 1.200 to 1.280 according to type of cell. In the lead battery, specific gravity falls during discharge and rises during charge, thus indicating the condition of discharge of the cell.

THE NICKEL-ALKALI CELL (Edison cell) uses a positive plate containing an oxide of nickel and a negative plate containing metallic iron. The alkaline electrolyte does not change in specific gravity during charge or discharge. The container is a nickel-plated steel can, and individual cells must be insulated

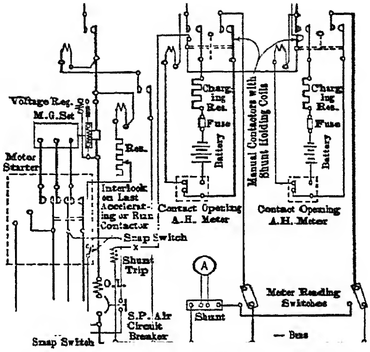
2. METHODS OF CHARGING

To fully charge a storage battery, current must be passed through the cells in a direction opposite to that of discharge. The ampere-hours of current required for charge must equal the discharge plus an excess of 5 to 20% to make up losses. In general, any charging rate is permissible which does not produce excessive gassing or a cell temperature exceeding 110° F.

THE VARIABLE-RESISTANCE METHOD (series-resistance or constant-current method) uses an adjustable, charging rheostat in series with each battery to give manual control of the charging rate. For a lead battery the starting rate is maintained until battery voltage rises to about 2.5 volts per cell. The rate then is reduced to a finishing rate, of about 40% of the starting rate, until battery voltage rises to 2.5 volts per cell. With an Edison battery, this method results in a constant current instead of a starting and finishing rate; the battery volts per cell will, however, be different. This method of

charging is applicable to, and almost necessary for charging different batteries of a different number of cells from the same D.C. supply.

THE MODIFIED-CONSTANT-POTENTIAL METHOD maintains a constant bus voltage of about 2.6 volts per cell for lead batteries, and between 1.85 and 2.0 volts per cell for Edison batteries, with a fixed resistance in series with each battery to be charged. For lead batteries, each battery must have the same number of cells but with Edison batteries it is possible to adjust each fixed resistor to a proper value for the particular battery to be charged, irrespective of the number of cells. The fixed resistance usually is provided with several taps for seasonal adjustment. More resistance will be required when batteries are warm, because required charging voltage is lower, than when they are cold.



. 1. Connections for Modified Constant-potential Charging of Two Batteries

The modified-constant-potential method of charging, if conditions warrant it, is considered the best method. It automatically regulates current to battery requirements, and makes it unnecessary for the operator to determine current setting for each circuit. This method is used when fully automatic equipment is required for two or more charging circuits. Fig. 1 shows typical connections.

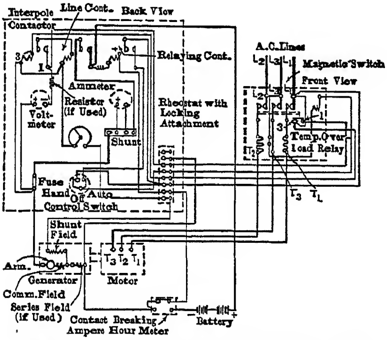


Fig. 2. Connections of Automatic Taper Charging Equipment for Vehicle Batteries, Showing Starting Switch

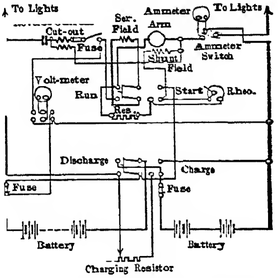
TAPER CHARGING EQUIPMENT for single batteries usually is automatic, using a motor-generator set designed to give the modified-constant potential characteristics, but without fixed resistance in the circuit between battery and generator. Fig. 2 shows connections for such equipment. A typical equipment includes a motor-generator set and a control panel: a single pole contactor, closing on battery voltage; shunt-trip relay, hand-reset, operated by ampere-hour meter preferably located at the battery; ammeter; voltmeter; generator field rheostat; fuse for over-current protection; snap switch for motor starting.

A battery often is used as an emergency source of power. Under normal operating conditions it floats on the line and is kept charged by the generator. After long periods of discharge it is necessary to recharge the battery in a short time. This can be accomplished manually with connections as shown in Fig. 3, where the battery is split into two sections. When floating, or on discharge, the sections are connected in series. When on charge they are connected in parallel and charged through a series resistance.



IG. 3. Arrangement for Manually Charging Emergency Battery from Engine-driven Generator, also Used as Starting Motor for Engine

BATTERY VOLTAGES.—A Lead Battery starts discharging at about 2.05 volts per cell and finishes at about 1.75 volts. It starts charging at about 2.1 volts per cell and finishes at 2.5 volts per cell. Normal charging time is 8 hr.

Edison Batteries on a 5-hr. complete discharge start discharging at about 1.45 volts per cell, and finish at 1.1 volts. On charge, the starting voltage is about 1.55 volts per cell, finishing at 1.80 volts per cell.

Average Current Requirements for charging typical batteries of both types are given in Table 1. These charging current rates apply to batteries for industrial trucks and tractors, street trucks, and electric locomotives.

Table 1.—Charging Rates per Cell

Lead (Ironclad)					Edison			
Type	Variable Resistance Method		Modified Constant Potential Method		Type	Variable Resistance Method	Modified Constant Potential Method	
	Start, amp.	Finish, amp.	Start, amp.	Finish, amp.		Normal Rate, amp.	Start, amp.	Finish, amp.
7 MV	19	8	22	8	A–4, G–4	30.0	38	25
9 MV	24	10	29	10	A–5	37.5	47	31
11 MV	30	12	36	12	A–6, G–6	45.0	57	37

25 MV	66	26	86	26				

3. CHARGING SETS

BATTERY CHARGING MOTOR-GENERATOR SETS (Variable resistance method). —Standard equipment is available, designed particularly for multiple charging of two or more electric industrial trucks, street trucks and electric locomotives. To select the proper set the following information is necessary: Voltage, frequency and phases of power supply, number and sizes of batteries, lead or Edison, number of cells in each. number of plates per cell and maker of lead batteries, number of batteries to be charged at one time.

Generator Voltage must be higher than that of the highest-voltage battery. The highest charging voltage of lead cells is 2.60 volts; of Edison cells, 1.85 volts. With long lines from control board to batteries, allow for line drop. To determine voltage of generator, multiply number of cells by volts per cell. For example, a 44-cell lead battery requires $44 \times 2.60 = 114.4$ volts; a 60-cell Edison battery, $60 \times 1.85 = 111.0$ volts. A 115-volt generator would be used in either case.

Current Rating of Generator.—Add starting rates of all batteries to be charged at one time. See Table 1 for charging rates for 8-hr. charging of lead, 7-hr. charging of Type A and 4 3/4-hr. charging of Type G Edison batteries.

Kilowatt Capacity.—After determining voltage and current rating of generator, amperes $\times$ volts/1000 = kw. capacity of motor-generator set.

MODIFIED CONSTANT-POTENTIAL CHARGING requires the same voltages per battery cell, but generator must have close voltage regulation under all operating conditions of load and temperature. Regulation must not exceed $\pm 30\%$. A compound-wound generator with voltage regulator is recommended.

Current Rating of Generator.—Add starting rates of all batteries to be charged (see Table 2), and multiply sum by 0.8.

Kilowatt Capacity.—Amperes $\times$ volts/1000 = kw. generator capacity required.

Automatic Battery-charging Motor-generator Sets and Control Panels provide the following automatic features: Independent cut-off for each battery when fully charged; shut-down of motor generator set when last battery has cut off; shut down of motor-generator set in case of line interruption; restart of the set upon return of power supply after interruption; control of charging rate by modified-constant-potential method.

Standard kw. Ratings of Charging Motor-generator Sets are as follows:

32 and 40 volts—3, 5, 7.5, 10, 15, 20, 25, 30.

48 and 63 volts—3, 5, 7.5, 10, 15, 20, 25, 30, 40, 50.

84 volts—3, 5, 7.5, 10, 15, 20, 25, 30, 40, 50, 60.

115 volts—3, 5, 7.5, 10, 15, 20, 25, 30, 40, 50, 60, 75.

Standard Motor Voltages are 110, 220, 440, 550, and 2200 volts

Generator Voltages for Lead Batteries should not be higher than the following:

Hour charge	5	6	7	8	9	10	11	12
Volts per cell, Type MV or MVA	2.53	2.56	2.59	2.63	2.69	2.745	2.835	2.97
Volts per cell, Type TL	....	2.494	2.512	2.55	2.552	2.574	2.607	2.643

Edison batteries normally are charged in 8 hours with generator voltage based on 2 volts per cell.

Motor-generator Prices and Efficiencies will be approximately the same as for standard sets under Conversion Equipment. See p. 15-37.

General.—In fixing the time required for complete battery charge all the time available should be used, since it will result in lower charging rates, smaller capacity of charging apparatus and circuits, and lower battery temperatures. For vehicle or other cyclically-charged batteries, automatic charging is recommended.

Trickle Charging Rates are those sufficient to keep an idle battery in condition.

A Floating Charge is sufficient to bring a battery back to full charge after a partial discharge. Rates are determined as required by operating conditions. Typical installations of floating batteries are emergency lighting, and control power for circuit breaker operation. These applications consist of a steady load with occasional peaks, or occasional periods when the battery is the only source of supply. Generator capacity is determined by the normal steady load plus that necessary to restore the battery to full charge in a specified time after a period of discharge. During normal operation, the battery floats on the line at line voltage. To charge the battery, generator voltage is raised to give the required charging current.

Portable Charging Equipments are available for charging batteries used with air conditioning apparatus on railway cars. Automatic or manual equipment can be provided.

POWER FACTOR

1. POWER FACTOR EFFECTS

CURRENT AND E.M.F. RELATIONS IN A.C. CIRCUITS.—In an alternating-current circuit, maximum values of current and voltage will occur simultaneously if the circuit contains only ohmic resistance. Current and voltage then are *in phase*. If the circuit contains inductive reactance, as will be produced by induction motors, electric welders, etc., voltage will attain its maximum value in advance of the maximum value of the current; that is, the current *lags* the voltage. If the circuit contains capacitive reactance, as produced by a condenser, the maximum value of the voltage will occur after the maximum value of the current; that is, the current *leads* the voltage. These relations are shown in Fig. 1*a*.

The current flowing in the circuit will be the resultant of the power component, in phase with the voltage, and of the reactive component, lagging or leading the voltage 90 deg. The power in the circuit at any instant is the product of the simultaneous values of current and electromotive force at that instant. It is the product (volts × amperes) only when the circuit contains ohmic resistance alone, or when inductive and capacitive reactance exactly balance each other. For all other cases the power in the circuit equals the product (volts × amperes × power factor).

POWER FACTOR is the proportion of the energy in an A.C. circuit, represented by the product (volts × amperes) that can be applied to useful work. Power factor can be represented graphically by a vector diagram. See Fig. 1. Diagram *b* shows a circuit containing a resistance R, an inductive reactance X_l, and with an electromotive force E_0 impressed on it. A capacitive reactance X_c may be added to the circuit. If the inductance of reactance X_l be L henrys and the frequency of the circuit be f, then $X_l = 2\pi fL$. The reactive component of the current will be $I_{xl} = E/X_l$, lagging the voltage 90 deg. The power component, in phase with the voltage, will be $I_r = E/R$. E and R are taken in volts and ohms respectively. In vector diagram *c*, let vector OE represent electromotive force E_0, and OI_r the power component of the current I_r. Let vector OI_{xl} at 90 deg. from OE represent the reactive component of the current. Then, completing the parallelogram, OI_0 is the resultant of I_r and I_{xl}, and represents the actual current I_0 in the circuit as shown by an ammeter. Current I_0 lags voltage E_0 by angle θ. Power factor, $\cos\theta = I_r/I_0$. The power component of the current I_0 is kw $= I_0 \cos\theta$,

and the reactive component is $I_0 \sin\theta$. Heating in the circuit is produced by current I_0, but useful energy is produced only by the power component I_r.

If the inductive reactance X_l, diagram *b*, be replaced by an equivalent dielectric resistance consisting of a condenser X_c, the reactive component of the current will be $I_{xc} = 1/(2\pi fC)$, and will lead the voltage. C is the capacity in farads. In the vector diagram I_r is laid out as before, and OI_{xc} represents the reactive component. The total current is I_{01}, represented by the vector OI_{01}, leading the voltage by angle θ_1. Power factor is $\cos\theta_1 = I_r/I_{01}$.

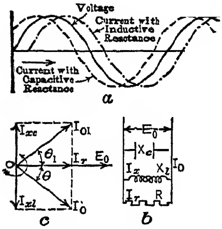

FIG. 1. Power Factor Diagrams

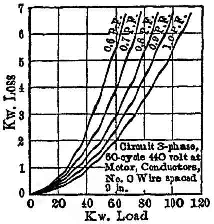

FIG. 2. Line Loss per 1000 Ft. at Various Power Factors

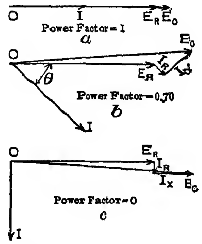

FIG. 3. Voltage Drop with Varying Power Factor

If X_c and X_l are equal and are both connected in the circuit, they will neutralize each other, and $I_{xl} + I_{xc} = 0$. I_r, I_o, and I_{01} will coincide in the vector diagram *c*, I_r will be the power in the circuit, and kva. = kw.

With a given power factor, the amount of copper required in a circuit is the same whether power factor lags or leads. A capacitive load will cause voltage to rise; inductive load will cause it to drop. No gain results in changing reactive kva. from lagging to leading at the same power factor. At unity power factor, kw. = kva.; at other power factors, the current for a given kilowatt load varies inversely as the power factor.

EFFECT OF LOW POWER FACTOR.—The kva. rating specifies the current that safely can be carried by motors, transformers, and other apparatus connected to the circuit, regardless of power factor. A 1000-kva. load at 0.5 power factor will deliver 500 kw., but will produce the same heating effect in generator, transformers and line as 1000 kva. at 0.8 power factor, delivering 800 kw. For the same kilowatt load, the investment in electrical apparatus varies inversely as power factor.

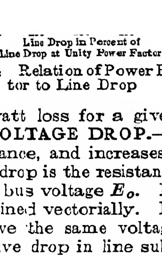

FIG. 4 Relation of Power Factor to Line Drop

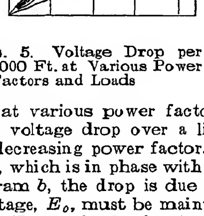

FIG. 5. Voltage Drop per 1000 Ft. at Various Power Factors and Loads

LINE LOSS.—Power is lost as heat in a conductor carrying current, and equals I^2R, where I is current in amperes, and R is resistance in ohms. For constant kilowatt load, power loss in any circuit varies inversely as (power factor)^2. Fig. 2 shows actual kilowatt loss for a given line at various power factors.

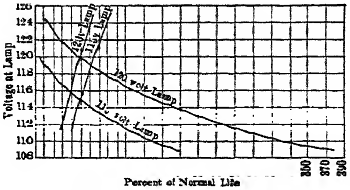
VOLTAGE DROP.—Actual voltage drop over a line depends on its resistance and reactance, and increases with decreasing power factor. See Fig. 3. In diagram *a*, the only drop is the resistance drop, which is in phase with voltage and current and subtracts from bus voltage E_o. In diagram *b*, the drop is due to resistance and reactance drops combined vectorially. Bus voltage, E_o, must be maintained at a value higher than in *a* to give the same voltage drop E_R at the load. At zero power factor, in diagram *c*, reactive drop in line subtracts almost directly from bus voltage. Fig. 4 shows relation between power factor and line drop in percent of line drop at unity power factor for constant kilowatt load. Fig. 5 shows effect of reduced power factor.

EFFECT OF POOR VOLTAGE REGULATION ON LOAD APPARATUS.—**Induction Motors.**—Voltage drop below normal increases motor slip. Maximum torque varies as (voltage)^2, *i.e.* motor loses torque rapidly with dropping voltage. A drop much below 10% may cause a motor to fail to develop the torque required by its load. If a

motor develops 200% maximum torque on full rated voltage, it will develop barely 100% torque at 70% voltage, speed being reduced to approximately 85% of normal. Loaded motors take increased current at reduced voltage. This causes increased heating, thereby limiting capacity to carry peak loads because of excessive heating and reduced torque.

Synchronous Motors do not drop in speed on reduced voltage, but pull-out torque varies directly with voltage.

Lamps vary in life and efficiency with voltage. See Fig. 6. Over-voltage produces greater light intensity, but reduces life. Under-voltage prolongs life at a sacrifice in efficiency, and less light is available for a given investment in equipment and distribution circuits.



Effect of Voltage Variation on Lamps

Heating Devices.—Proper temperature control of electrical heating equipment is not possible with variable voltage. Improving plant power factor will improve voltage regulation on plant distribution circuits. Maintenance of voltage on circuits of low power factor means greater investment.

2. POWER FACTOR IMPROVEMENT

ADVISABILITY OF IMPROVING POWER FACTOR.—Supply of reactive current, incident to low power factor loads, is considered by public utilities an additional service which justifies an additional charge. If power is generated by the industrial plant, additional investment in equipment would be necessary for the same quality of service.

High power factor has corresponding advantages. The benefits of high power factor must be balanced against the cost of corrective equipment for low power factor. A power factor survey of an individual plant will determine the advisability of power factor correction, and will balance the cost of corrective equipment against lower public utility charges, smaller investment in the plant, and improved operating conditions. In a new industrial plant, initial economies can be obtained by planning for high power factor.

In existing plants operating conditions may become critical if the load grows to the limit of generator and distribution system capacity. For instance, the installation of a 300-kva. and a 500-kva. synchronous condenser at different locations in the same plant may make possible an additional load of 500 Hp. without changes in existing equipment. Otherwise, a new generator, a new line and two additional transformer banks may be necessary.

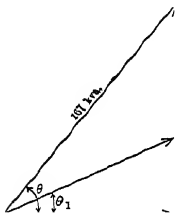


Fig. 7. Correction of a 100-kw., 0.6 Power Factor Load to 0.9 Power Factor

SOLUTION OF POWER FACTOR PROBLEM.—To improve power factor, it is necessary to reduce the ratio of reactive kva. to kw. In the vector diagram, Fig. 7, *OA* represents a load of 100 kw. at 0.6 power factor. The kva. load = (100/0.6) = 167, or $(\sqrt{3} \times E \times I)/1000$ if 3-phase, where E = line-to-line voltage and I = current, amperes, in each line. Since $\cos\theta$ = (100/167) = 0.6, represents power factor, reactive kva. =

$$167 \times \sin\theta = 167 \times \sqrt{(1 - \cos^2\theta)} = 167 \times \sqrt{1 - (0.6)^2} = 133 = AB, \text{ Fig. 7.}$$

For a power factor of 0.9 with the load at 100 kw., kva. = (100/0.9) = 111 kva. In the vector diagram, the reactive kva., *OC*, will be drawn at the angle θ_1, cosine of which is 0.9. The reactive kva. will be *AC* which scales to 48.4, and which is mathematically equal to $111 \times \sqrt{1 - (0.9)^2}$ = 48.4. Capacity of corrective equipment required will be (133 − 48.4) = 84.6 kva. leading. That is, 84.6 kva. must be neutralized by connecting to the line apparatus which will draw leading current. Lagging kva. in Fig. 7 is plotted from *A* to *B*, and leading kva. from *B* to *A*.

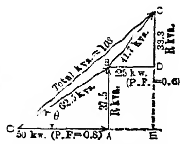

Fig. 8. Correction of Power Factor of Combined Loads

Fig. 8 shows a combined vector diagram for obtaining overall power factor and total kva. A 50-kw. load at 0.8 power factor on one feeder circuit, and a 25-kw. load at 0.6 power factor lagging on another feeder are assumed. The line *OA* drawn to scale represents 50 kw. At 0.8 power factor, kva. = (50/0.8) = 62.5. *OB* is drawn equal to 62.5 at the angle $\cos^{-1}\theta = 0.8$. Then AB = 37.5 = the reactive kva. for the 50-kw. load. From point *B*, *BD* is drawn to scale to represent 25 kw., and following the same procedure, the reactive kva. *DC* is found to be 33.3 kva. The total kva. is found to be 103 at a power factor of 0.73 and the combined

reactive kva. is 70.8 with a total load of 75 kw. The capacity of corrective apparatus to improve power factor to any other value is determined by the same procedure as outlined for Fig. 7.

POWER FACTOR IMPROVEMENT TABLE.—In Table 1, the tabulated figures multiplied by the kw. input will give the leading kva. necessary to correct from the original to the desired power factor.

Table 1.—Power Factor Corrections

Original Power Factor, percent	Desired Power Factor, percent					Original Power Factor, percent	Desired Power Factor, percent				
	100	95	90	85	80		100	95	90	85	80

1.—Wattmeter indicates a plant load of 100 kw. at 0.7 power factor. Required the leading reactive kva. necessary to correct power factor to 0.95. In Table 1, line 70, column 95, find factor 0.691. Reactive kva. = 100 × 0.691 = 69.1 kva. If capacitors are used, the nearest standard unit will be selected.

Example 2.—Assume the power factor correction required in Example 1 to be made by substituting synchronous motors of 0.8 power factor for induction motors. For each kw. of induction motors operating at 0.7 power factor, Table 1 shows a 1.020 lagging reactive kva. For each kw. input to 0.8 power factor synchronous motors, the table shows leading kva. of 0.75. If the induction motors are replaced by synchronous motors, each kilowatt in synchronous motors reduces lagging reactive kva. by (1.020 + 0.75) = 1.77 kva. Total reduction to correct power factor to 0.95 is 6.91 kva. (Example 1). Required capacity of synchronous motors is 69.1/1.77 = 39 kw. Nearest standard synchronous motor would be 50 Hp.

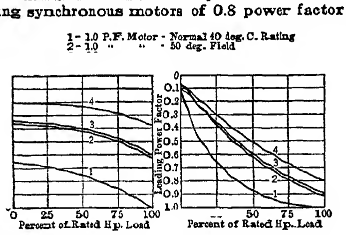

Fig. 9. Corrective Kva. and Power Factor of General-purpose Synchronous Motor with Normal Full-load Excitation

CORRECTIVE KVA. AVAILABLE FROM SYNCHRONOUS MOTORS.—The approximate amount of kva. available from, and the power factor of, general purpose synchronous motors at any load, with full load excitation, is shown in Fig. 9.

METHODS OF POWER FACTOR IMPROVEMENT.—1. A power factor survey often will show several induction motors to be operating below rated output, at least part of the time. Kva. input to an induction motor has a lower power factor when the motor is operating below rated load than it has at full load. Interchanging motors to give each more nearly its rated load will improve conditions. Often it will pay to substitute new motors with better operating characteristics. 2. Replace induction motors with synchronous motors of unity or 0.8 power factor. 3. Install capacitors at points where loads are at low power factor. Maximum improvement in loading on generators, transformers, and distribution lines is obtained by installing corrective equipment near the terminals

of low power factor loads. If correction is made solely for rate reduction, corrective equipment can be installed at the terminus of the public utility line supplying the plant. 4. Install synchronous condensers.

TYPICAL PLANT POWER FACTOR SURVEYS.—**Example 1.**—Plant is supplied with power at 11,000 volts, 3-phase, transformed to 460 volts and distributed to the power circuits. A second transformer bank reduces voltage to 220 volts, 3-phase, for power, with a 3-wire single-phase arrangement from one transformer for 110/220 volts for lighting. Fig. 10 shows arrangement of circuits. The rate schedule allows a bonus for high power factor, power bill being reduced 0.5% for each percent average power factor is held above 80%. Test showed the average load to be 62 kw. and the reactive load to be 89 kva., corresponding to a power factor of 0.67. Existing equipment includes an air compressor, driven by an induction motor rated at 40 Hp., 1160 r.p.m., 220 volts. Compressor is driven at 115 r.p.m. through a speed reducer and belt, although suitable for operation at 200 r.p.m.

Two methods of improving power factor are available. 1. Installation of capacitors, the approximate savings being determined by test and from power bills by means of Table 2. 2. If the additional air can be used, it can be obtained together with plant power factor correction by replacing the induction motor driving the air compressor with a 75-Hp. 0.8 power factor, 440-volt synchronous motor. This will remove the inductive load and provide an equivalent correction of 65 kva. The substitution of the synchronous motor will cost, including reduced voltage starter, base and V-belt drive, $1850.00. The results are compressed air supply increased about 80%, and reduced transformer and drive losses. The cost of a 65-kva., 440-volt capacitor is approximately $650.00. The advisability of purchasing a new synchronous motor and changing the drive depends on the need for the additional compressed air capacity that would be available.

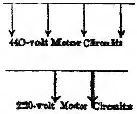

FIG. 10. Typical Industrial Plant Distribution System

Conclusion.—Table 2 shows a greater saving from the use of 130-kva. 440-volt capacitor equipment with incidental benefits of improved voltage regulation, increased transformer and feeder capacity, improved motor operation at peak loads and more uniform motor speed. Capacitors, either floor, ceiling, or wall mounted, installed at the point of origin of load will give a flexible arrangement and result in greatest benefit from power factor correction.

Table 2.—Capacitor Savings

* Based on average monthly power factor using ratcheted reactive meters. † Savings after deducting cost of capacitors with depreciation at 10% per year. ‡ Negligible. ¶ Small.

Example 2.—A flour mill driven entirely by electric motors may obtain a discount of 0.5% of its power bill for every 1% increase in power factor over 85%. The motors in the mill are loaded as follows, the total load being 74.0 kw.:

Motor Hp......................	200	40	20	15
Kw. input......................	103.8	9.0	6.4	3.2
Hp. output....................	126	9.0	7.3	3.5
Power factor..................	0.77	0.635	0.675	0.58

Recommendations.—To reduce energy consumption, the 15-Hp. motor should be changed to drive the grain elevator where it would approximately carry 10 Hp. maximum. A new 10-Hp. motor is recommended to drive the corn mill and feed plant and a new 5-Hp. motor for the wheat elevator. The motors would operate at near full load and effect the following savings in energy and improvements in power factor:

Load	Motor Rating	Load	Power Factor	Energy Saving per Month
Grain Elevator..............................	15 Hp.	9.0 Hp.	0.84	134 kw.-hr.
Corn Mill and Feed Plant..................	10 Hp.	7.3 Hp.	.83	36 kw.-hr.
Elevator in Mill..............................	5 Hp.	3.5 Hp.	.81	38 kw.-hr.
Total Load..................................	......	......	.775	208 kw.-hr.

In determining energy saving, 200 hr. of operation per month were used for the 5- and 10-Hp. motors and 100 hr. per month for the 15-Hp. motor.

No energy would be saved by using a smaller main motor. Even at less than full load, its efficiency is a little better than a smaller motor at full load. Of three possible methods of power factor correction, only synchronous motors or capacitors are considered, because for small amount of correction a synchronous condenser is the most expensive. In this case, a capacitor was lowest in first cost. A synchronous motor would require special design to get torque required for mill service and its efficiency would be no better than that of a slip ring motor. Starting characteristics of the slip ring motor are better for the present type of load.

Demand meter charts show loads of 120 kw. for grinding soft wheat and 136 kw. for grinding

hard wheat. For power factor correction a 60 kva. and a 90 kva. capacitor were considered with the following results:

	60-kva. Capacitor			90-kva. Capacitor		
Conditions	Present Power Factor	Expected Power Factor	Discount Earned	Present Power Factor	Expected Power Factor	Discount Earned
No Motor Changes						
Soft wheat............	0.74%	0.92	3 1/2%	0.74%	0.98	6 1/2%
Hard wheat...........	77%	.93	4%	77%	.985	6 3/4%
With Motor Changes						
Soft wheat............	74%	.95	5%	74%	Unity	7 1/2%
Hard wheat...........	77%	.96	5 1/2%	77%	Unity	7 1/2%

3. EQUIPMENT FOR POWER FACTOR CORRECTION

SYNCHRONOUS MOTORS often can be used instead of induction motors, and the cost of corrective kva. then is chargeable to the difference in price between a synchronous motor with controls and an induction motor with controls. The cost of leading kva. obtained from synchronous motors increases rapidly for sizes below 75 Hp. See Fig. 11. Above 100 Hp., synchronous motors provide power factor correction at very low cost.

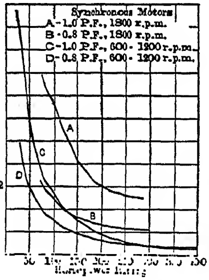

Fig. 11. Average 1935 Unit Prices of Leading Kva. Obtained by Synchronous Motor

CAPACITORS or static condensers are manufactured in small units; size depends on use. A capacitor unit comprises one or more flattened rolls of paper and aluminum foil pressed together and enclosed in a steel case with a fluid of good dielectric properties. Capacitors are applicable for power factor correction to four general types of service conditions: 1. To improve power factor of individual or groups of motors rated at 230, 460, or 575 volts. These units are for indoor installation and are enclosed. 2. To improve power factor at 230, 460, 575, 2300, 4000, or 4600 volts in small blocks at one or more points in a plant. These units are for indoor installation and are assembled in stacks. 3. Similar to (2) but for outdoor installation and pole mounting, for power factor correction at 2300, 4000, and 4600 volts. 4. To improve power factor of a large block of power at one point on circuits from 230 to 6900 volts. Suitable for either indoor or outdoor installation.

A capacitor equipment will include: 1. A group or stack of individual units, number depending on bank rating required. 2. Fuses for each individual unit to protect against a fault within the unit. 3. A circuit breaker that can serve as a main switch and provide over-current protection. The breaker must be capable of clearing successfully a short circuit between itself and the capacitor bank. 4. A discharge device which will allow charge on capacitor to leak off when bank is disconnected from the power circuit. Fig. 12 shows typical connections.

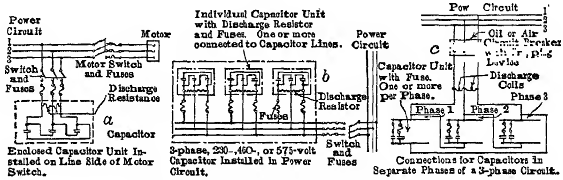

Fig. 12. Typical Capacitor Connections

Losses of capacitors, in kilowatts, will not exceed 1/3 of 1% of the kva. rating, including losses in individual units and all accessories.

Ambient Temperature.—Standard capacitors are designed for a maximum allowable temperature of 40° C.

Voltage Range.—Permissible working voltages for standard capacitors are:

Voltage Rating	230	460	575	2300	4000	4600	6900
Maximum Permissible Voltage	264	528	660	2640	4565	5280	7920

Installation and Maintenance.—The only foundation necessary for a capacitor bank is that necessary to support its own weight. Capacitors can be set on existing floors and natural ventilation is sufficient. They can be installed in isolated locations and inspected monthly. No adjustment or frequent attention is necessary. Low maintenance is an important factor in the economics of capacitor installations.

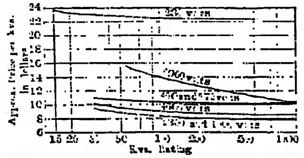

FIG. 13. Approximate 1935 Prices of Standard Capacitors, Including Racks, Indoor Type

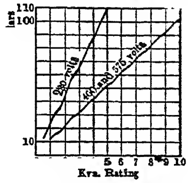

FIG. 14. Approximate 1935 Prices of Standard Individual Capacitor Units for Small Loads

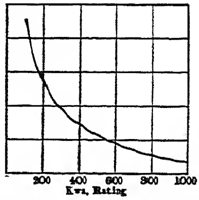

FIG. 15. Approximate 1935 Prices of Standard Synchronous Converters

Sizes of Capacitor Units Available.—Enclosed units for application to individual motors, or other small loads, are made in sizes of 0.5 to 5 kva. at 230 volts, 1-, 2-, or 3-phase, 60-cycle, and 1 to 10 kva. at 460 and 575 volts. For higher voltages and when power factor correction is applied to the distribution bus, or primary feeder, individual 5-, 10-, or 15-kva. units are assembled in racks and a sufficient number connected in parallel to give the required bank capacity. Figs. 13 and 14 show approximate 1935 prices of capacitors.

SYNCHRONOUS CONDENSERS are similar in construction to A.C. generators. They are designed to float on the line, fully excited, without load, and to supply leading kva. The rotor has a squirrel cage winding to assist in starting and to prevent hunting while in operation.

Standard Sizes range from 100 kva. up, with direct-connected exciters. Ratings below 100 kva. can be obtained, but for power factor correction below 100 kva., a capacitor usually is used. Control can be manual or automatic. A manual equipment will include one each of the following: Starting auto-transformer, condenser field rheostat chain operated, exciter field rheostat, indicating lamp for pilot light, ammeter, voltmeter, field ammeter, reactive-volt-ampere meter with auto-transformer, field switch, concentric operating mechanism for condenser and exciter field rheostats, main and starting oil circuit breaker. Separate main and starting breakers may be necessary.

Cost.—Fig. 15 shows the approximate 1935 price of synchronous condensers between 100 and 1000 kva. including simple manual control.

Synchronous Condenser Losses in kilowatts loss percent of kva. rating from 100 to 1000 kva. are shown in Fig. 16.

CHOICE OF SYNCHRONOUS CONDENSERS OR CAPACITORS FOR POWER FACTOR CORRECTION.—Power factor clauses in rate schedules usually are classified as: 1. Where power factor is determined during period of maximum demand. 2. Where power factor is determined as monthly average. If the power factor clause is in Group 1, corrective equipment, which will supply a large amount of leading kva. when the demand is maximum, is necessary. During periods of light loads, power factor is not important, which favors the use of synchronous motors or synchronous condensers. The cost of leading kva. is low and losses and maintenance are not important, as corrective equipment may operate only a few hours per day.

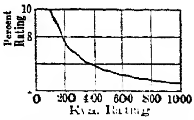

FIG. 16. Synchronous Condenser Losses

When the power factor clause is in Group 2, capacitors are preferred. Power factor will be lower during periods of light loads, because ratio of magnetizing current to load current then is higher than at full load. To improve average power factor, corrective equipment always must be connected to the line. While the cost per leading kva., is higher for a capacitor, its low loss and negligible maintenance often are the deciding factors.

The amount of leading kva. that economically can be provided in a given plant is limited. Reactive kva. meters cannot run backwards, and there is no economy in providing equipment for power factor improvement from lagging to leading.

4. METHODS OF POWER FACTOR MEASUREMENT

INDICATING POWER FACTOR METER.—Fig. 17 shows the connections for this type of meter. Its principle is based on the two-wattmeter method of measuring power in a 3-phase circuit, where the power factor or

where W_1, W_2 are the two wattmeter readings. The only variable in this equation is the ratio W_2/W_1. The indicating meter is designed to indicate this ratio and is calibrated to read directly in power factor.

THE RECORDING METER works on the same principle as the indicating meter, but includes a chart and a stylus for making a permanent, continuous record of power factor.

INTEGRATING METERS are preferred for billing purposes because a more accurate record may be obtained which is simpler to analyze. These meters do not require the attention necessary for recording instruments.

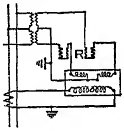

FIG. 17. Connections for a 3-phase Indicating Power Factor Meter

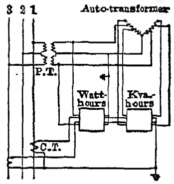

FIG. 18. Meter Connections for Measuring Reactive Volt-amperes or Reactive Volt-ampere-hours

REACTIVE VOLT-AMPERE-HOUR METERS.—Power factor can be obtained readily from integrating meters by the combined use of a watt-hour meter and a reactive-volt-ampere-hour meter. Fig. 18 shows connections for leading reactive-volt-amperes, or reactive-volt-ampere-hours.

CALCULATIONS OF POWER FACTOR FROM WATT-METER AND REACTIVE-VOLT-AMPERE-METERS.—The readings of reactive volt-amperes, or reactive-volt-ampere-hours cannot be used to determine power factor unless wattmeter or watt-hour readings also are taken. If V = volts, A = amperes, VA_r = reactive volt-amperes, W = watts, $W/VA = \cos\theta$, or power factor, which is the quantity desired; $W/VA_r = \tan\theta$, or power factor $= \cos\tan^{-1}(VA_r/W)$.

Apparent power, or volt-amperes, $VA = \sqrt{W + (VA_r)^2}$.

POWER DISTRIBUTION

1. PRINCIPLES OF DESIGN

Design of a distribution system must take into account the physical layout of the plant, future growth, kind of power required, type of loads in various departments, economy, continuity of service, voltages, protection and code requirements. For any given system several arrangements are possible, ranging between maximum economy and maximum continuity of service. Comparative data should be tabulated, and the final design then can be made incorporating desired features at minimum cost.

PRIMARY DISTRIBUTION.—The extent of primary distribution depends on plant layout. Where distribution is confined to one building and small loads, the most economical distribution will be at utilization voltage. If power must be distributed over a large area, and in relatively large blocks, it is economical to run primary feeders from the main substation or generating station to load centers and there step down voltage for secondary distribution.

Primary Voltage will depend on load carried by primary feeders, total number of feeders, and distance of transmission from power source to load centers. Generally, higher voltage decreases power loss, but increases cost of line construction. A common primary distribution voltage for power is 2300 volts, but for any given installation the most economical voltage must be determined by comparing the cost of cable and wire. Whether primary distribution or distribution at utilization voltage is best can be decided by a cost comparison of several plans, which consider: 1. Character of loads. 2. Cost of low-voltage feeders plus capitalization of higher line losses as compared with lower line losses plus line costs for primary distribution at a higher voltage, plus cost of additional switching apparatus and transformers to step down to utilization voltage at load centers. 3. Size of motors. 4. Physical layout, which determines area over which power must be distributed, and to some extent, voltage of the power source. In small industrial plants, secondary distribution only is possible, as power is supplied from public utility lines through transformers at 230 or 450 volts.

Secondary Voltages are determined by the apparatus being supplied. It is difficult to build satisfactory small motors for high voltage. Small and medium size motors are

standardized at 220, 440 and 550 volts. Also in many applications of small motors, high voltages are undesirable because of hazards to operators. As motor size increases, low voltage becomes less desirable because of the large currents to be handled. Larger size motors are standardized at 2200 volts, and often can be operated directly from primary feeders. Large quantities of power at low voltage cannot be transmitted over any great distance without a voltage drop below the minimum allowable at the receiving end of the circuit. See Tables 10 and 12. Hence, it is economical in larger plants to use primary distribution to supply a secondary system through transformers or conversion equipment at load centers. Too many different voltages will complicate distribution and increase cost. Usual practice is to operate all small equipments at 220 or 440 volts, and sometimes at 550 volts. Common practice is 440 volts for motors of 50 Hp. and less, and 2200 volts for larger motors.

ARRANGEMENT AND DESIGN OF FEEDER CIRCUITS.—Under normal operating conditions, voltage at the load should not vary more than $\pm$ 10% from normal, which is the maximum allowable deviation recognized by the A.I.E.E. and maximum for which motor manufacturers' guarantees will apply. Feeder circuits, therefore, must be designed on the basis of load requirements.

Individual feeder circuits in industrial plants may be subject to considerable load fluctuation, especially if load consists of a few large units. A load of 10 or more units of uniform size usually can be considered as constant, even with wide fluctuations on individual units, unless peak loads on several units occur simultaneously.

Laying Out a Feeder Circuit requires determination of the overall load cycle. The feeder must be designed with ample capacity to carry the root-mean-square value of current represented by the fluctuating load without overheating, and to deliver sufficient voltage under peak load conditions. The various departments of an industrial plant should have an estimated daily load curve (see p. 15–22) for each season of the year. This will give the average yearly load curve, which, with proper consideration of future growth, will determine the capacities of departmental feeders.

Heating often is the limiting factor in short feeders. Thermal protection usually is not provided for feeder circuits. Occasional temperature measurements usually are sufficient to indicate circuit conditions.

Voltage Drop more often is the limiting factor in longer circuits. It is first necessary to determine what voltage drop can be tolerated. Peak loads may be due either to a combination of loaded units, no one of which operates above normal rating, or to overloads on one or more units. A greater voltage drop can be tolerated in the first case than in the second. It is difficult to establish definite voltage limits, since much depends on peak loads to be carried by motors and the importance of feeder circuits.

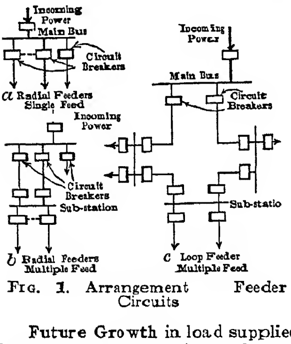

FIG. 1. Arrangement Feeder Circuits

Motor Starting Loads must be considered in design of feeder circuits. Many motors, including medium sizes, are started on full voltage if power system conditions permit. Circuits supplying such motors must be more liberally designed to limit voltage drop. Starting kva. required by motors may be from approximately five to nine times normal at full voltage, and starting power factor may vary between 20% and 60% depending on type of motor; under such conditions voltage drop in the feeder circuits may be excessive. Voltage must not drop so low that the motor being started is unable to develop sufficient torque, nor so low that under-voltage devices operate to shut down other motors connected to the feeders.

Future Growth in load supplied by the feeder circuit can be provided for initially by a feeder of larger capacity, or by providing for addition of duplicate feeders.

Continuity of Service required depends on character and importance of load. In continuous processes, continuity of service is highly important and more than one feeder will be required. With two feeders, either must be able to carry the total load. With three feeders, any two must carry the total load. Feeders can be taken over separate routes to eliminate possibility of trouble involving more than one feeder. Selection of high quality cable and equipment, careful observance of codes, and approved type of construction will give greater continuity of service.

CIRCUIT ARRANGEMENTS for distribution generally are: 1. Stub or radial feeders, single or double, Fig. 1 *a*. 2. Parallel feeders, Fig. 1 *b*. 3. Loop feeders, Fig. 1 *c*. 4. Network, or combination of radial and loop; power is supplied to the loop at several

points and radial feeders are taken off for individual loads. Radial and loop feeder systems cover most industrial plant requirements.

A stub or radial feeder circuit is separated from all others and prevents feed back; load can be supplied at any point on the line. Continuity of service is limited unless duplicate feeders are provided as in the parallel system of Fig. 1 *b* where the degree of continuity is high. The loop feeder circuit leaves the power source, loops through several distribution points and returns to the source. Continuity of service is about the same as for the parallel feeder. Its use depends on the physical layout of the plant and may prove economical in supplying power over wide areas. The fundamental circuit arrangement can be modified to meet conditions in any particular plant. Some flexibility is desired and often necessary to insure uninterrupted power, which is obtained in the switching arrangement and number of circuits. On some feeder circuits power can be shut off long enough for inspection of apparatus, but on others power always must be available. Switching arrangements must provide for isolation of apparatus without interrupting power.

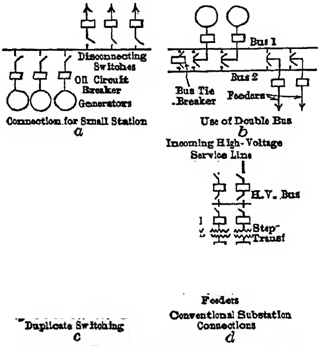

FIG. 2. Typical Distribution System Connections

DEPARTMENTAL SUBSTATIONS are required: 1. Where utilization voltage differs from distribution voltage. 2. Where direct current must be provided. The substation should be located at the load center, and the switching apparatus used will depend on flexibility, degree of reliability and inspection required. Transformers should be located at load centers. Usual connections for power are 3-phase, delta-delta, and for lighting single-phase or 3-phase, 4-wire.

Transformer Capacity Required depends on load characteristics and future growth. All-day efficiency should be considered in selecting transformers. If core loss is low and copper loss high, efficiency will be highest at part load. If the reverse is true, efficiency will be higher at full load. If average demand is low, select a transformer with highest efficiency at low loads.

All-day Efficiency of a distribution transformer is $E = (100P_2h)/(P_2h + Ah_1 + hI_2^2R_2)$, where E = all-day efficiency, percent; h = hours per day of secondary load; h_1 = hours per day transformer is on line; A = core loss, watts; P_2 = secondary output, watts; I_2 = secondary current, amperes.

Total resistance = $R_2 = (r_1^2/a^2) + r_2$, where a = ratio of transformation; r_1, r_2 = primary and secondary resistance.

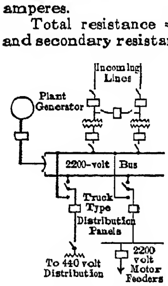

FIG. 3. Flexible Connections for Purchased and Generated Power

CONTROL EQUIPMENT required depends on protection of feeders, tie lines, transformers and rotating apparatus, and short circuit conditions. When the distribution circuits have been laid out, it is necessary to connect them in a distribution system. If solidly connected, trouble on any one circuit would cause complete loss of power. System connections, therefore, are made through control devices. Beginning at the main generating station, or main substation, generators or transformer banks should be provided with control equipment which will permit isolation of any one unit. Feeder circuits leaving the main station should have similar control. Main distribution centers will require, in general, a bus structure, feeder switches and switchboard and metering equipment for each circuit. If power is purchased, the typical incoming panel will include disconnecting switches, circuit breaker, a watthour meter, a curve-drawing demand meter and, if the power contract includes a power-factor clause, a kva. meter.

TYPICAL SYSTEM CONNECTIONS of Fig. 2 represent common practice and are flexible enough to meet most service conditions. Fig. 2 *a* is the simplest, each generator being connected through a circuit breaker, and disconnecting switch to a common bus serving various feeders. Fig. 2 *b* uses a double generator bus with disconnecting switches to permit connection of any generator or feeder to either bus. The bus tie breaker facilitates transfer of apparatus from one bus to the other. Fig. 2 *c* shows a more elaborate scheme using duplicate switching throughout. Fig. 2 *d* shows connections for a conventional substation. This arrangement can be modified to increase flexibility. Fig. 3 shows an arrangement used in a distribution system where part of the power is

generated and the balance purchased. The various loads can be supplied from either the plant generator or the public utility. The feeder switchboard consists of truck type panels which can be disconnected from the switchboard assembly and rolled out for inspection of circuit breaker and associated devices.

2. SHORT CIRCUITS

No power system should be laid out without consideration of possible short circuit currents. The magnitude of short circuit currents should be determined at all strategic points on the system, and arrangments made to remove automatically from service any circuit or piece of apparatus in which a short circuit occurs. It also is essential that the faulty circuit or apparatus be disconnected from the power source without interrupting service on other circuits. This is done with differential and other selective relaying schemes with circuit breakers.

EFFECT OF FUTURE GROWTH ON SHORT CIRCUIT CURRENTS.—Short circuit currents increase simultaneously with system capacity. Present circuit interrupting devices and bus structures may be inadequate within a few years. The increase in short circuit duty with plant growth is greater at the main power station. The number of circuits increases with increased power demand, with a proportionate increase in the number of breakers. At the same time the short circuit duty on all breakers in the plant increases. Two remedies are possible when power requirements reach the point where circuit breakers are inadequate: 1. New circuit breakers to meet requirements. 2. Current limiting devices to keep short circuit currents at about the original value. In small systems, it usually is less expensive to meet increased short circuit duty with new breakers. As the system further increases in size, the cost of current limiting equipment becomes less than the cost of new breakers. The size to which a system must increase to reach this critical point increases with system voltage and depends largely on the type and number of circuits, which should be considered when selecting the original system voltage.

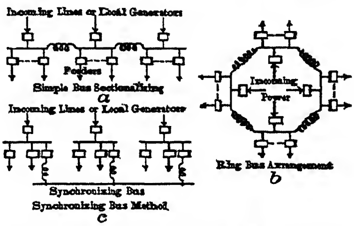

FIG. 4. Methods of Reducing Short Circuits

LIMITATION OF SHORT CIRCUIT CURRENTS.—Short circuit currents are limited by increasing the circuit impedance between power source and point of short circuit. Series reactance added to the circuit would produce the desired result, but at the expense of increased voltage regulation under normal operation. Since full feeder kva. would be transmitted through the reactance, feeder loss would be increased. A more efficient method is to split the power system into independent generator and load sections, tied together through current limiting reactors so located as to give a maximum of short circuit protection with a minimum of interference with normal system operation. Fig. 4 *a* shows such an arrangement. If power fails on one bus section, essential load can be supplied from adjacent sections through the reactors without serious voltage drop. With load properly proportioned on each bus section, little or no current flows through the interconnecting reactors and the system operates as if solidly tied together. If a short circuit occurs on any bus section or its feeders, the reactors are effective in limiting short circuit current fed from adjacent sections. Three general arrangements for applying current limiting reactors are: Bus sectionalizing, Fig. 4 *a*; the ring bus arrangement, Fig. 4 *b*; the synchronizing bus, Fig. 4 *c*. Heavy short circuit currents largely are limited to systems of 2200 volts and above. On circuits of 230 or 450 volts, the reactance of distribution network, circuit breakers, bus structures and the short circuit arc itself is effective in limiting maximum short circuit current, which experience indicates will not exceed 20,000 amperes.

MAGNITUDE OF SHORT CIRCUIT CURRENT.—Considering only A.C. circuits and apparatus, the current flowing into a short circuit is limited by the impedance between generator and point of short circuit. Impedance $= Z = \sqrt{r^2 + X^2}$, where r = resistance, and X = reactance to point of short circuit. For usual circuits and apparatus for power generation and distribution, resistance can be neglected. Results still will be within the required accuracy. The short circuit current then is $I = E/X$, where E = generator voltage; X = instantaneous value of reactance to point of short circuit.

SHORT CIRCUIT OF A.C. GENERATORS.—At the instant of short circuit of an A.C. generator, current flow will be considerably higher than at a fraction of a second later. Initial current will decrease exponentially with time until sustained at a lower value. The reactance exhibited at the instant of short circuit, called the sub-transient reactance, is used in short circuit calculations. It ranges from approximately 8 to 15% for high-speed turbine generators, from 15 to 25% for salient-pole, medium-speed gen-

erators, and 25 to 35% for slow-speed, engine-type generators. The effective short circuit current may be a maximum of 1.73 times that determined by the sub-transient reactance, depending on the point of the voltage wave at which short circuit occurs. As time elapses, current decreases so that when circuit breakers are able to operate, 1/4 to 1/3 second later, the current will have decreased to approximately 30 to 60% of maximum value, depending on amount of reactance external to the generator, and between generator and point of short circuit.

CALCULATION OF SHORT CIRCUIT CURRENT IN A.C. CIRCUITS.—It is customary to express reactances of generators and transformers in percent of rated capacity; *i.e.*, a generator with 10% sub-transient reactance would deliver 100/10 = 10 times rated current if short circuited at its armature terminals with full load excitation. It is more convenient to use percent reactance in short circuit calculations, and assume a common base kva. to which all individual reactances are converted. Line reactances usually are given in ohms, and when two parts of a distribution system are connected through transformers, these reactances must be put on a common voltage basis as follows: Let X_1 = actual ohms reactance; X_2 = ohms at assumed common voltage; E_1 = actual circuit voltage; E_2 = common voltage chosen. Then $X_2 = X_1\ (E_2/E_1)^2$.

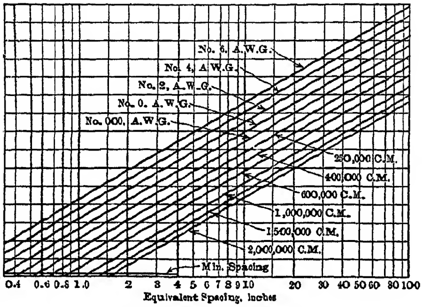

Fig. 5. Reactance Chart

To convert ohms reactance to percent reactance: $X\% = (X_2 \times \text{kva. base})/(\text{kv.}^2 \times 10)$, where X_2 = ohms reactance and kv. = (line voltage/1000).

Fig. 5 is a chart for determining the reactance at 60 cycles of conductors of various sizes, spaced at various distances. The chart is entered at the bottom on the ordinate of equivalent spacing. Opposite the intersection of this ordinate with the curve of conductor size, read reactance on the scale at the left. The equivalent spacing of 3-phase conductors in the same plane at a distance a apart is 1.26 a. The equivalent spacing of 3-phase conductors not in the same plane is $\sqrt[3]{a \times b \times c}$, where a, b and c are the distances between pairs of conductors.

To obtain reactance at other than 60 cycles, multiply the reactance at 60 cycles by the following factors: 25 cycles, 0.4167; 50 cycles, 0.8333; 120 cycles, 2.0; 180 cycles, 3.0; 240 cycles, 4.0; 300 cycles, 5.0.

Example.—Fig. 6 represents a 3-phase, 60-cycle system, power being generated at 6600 volts on one 2000-kva. and one 5000-kva. generator, with 12% and 8% sub-transient reactance, respectively, and transmitted over two parallel feeders to a substation where voltage is stepped down to 2200 volts. Required value of short circuit current at points A and B.

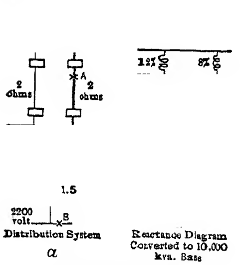

Fig. 6. Data for Short Circuit Calculation

Assume transformer to have 6% reactance on its rating of 500 kva. Reactance of each transmission line will be 2 ohms per conductor, and of 2200-volt feeder, 1.5 ohms per conductor. Assume 10,000 kva. as a convenient base, and a common voltage of 6600 volts. Equivalent reactance of 2200-volt feeder = $1.5(6600/2200)^2 = 4.5$ ohms. Fig. 5 b shows all reactances converted to percent on the common base of 10,000 kva.

Reactance of generator No. 1	$= 12(10{,}000/2000)$	= 60%
Reactance of generator No. 2	$= 8(10{,}000/5000)$	= 16%
Reactance of transmission line	$= (2 \times 10{,}000)/(6.6^2 \times 10)$	= 46%
Reactance of transformer	$= 6\,(10{,}000/500)$	= 120%
Reactance of 2200-volt feeder	$= (4.5 \times 10{,}000)/(6.6^2 \times 10)$	= 103%

t at A is fed by two generators in parallel having equivalent reactance of + 16) = 12.6%. Since a generator with 100% reactance will deliver normal current on short circuit, a generator of 12.6% reactance will deliver 100/12.6 = 7.9 times normal current on short circuit. With base kva. of 10,000,

$$\text{Initial current} = \{(7.9 \times \text{kva. base})/1.73E_2\} \times 1000$$
$$= (7.9 \times 10{,}000 \times 1000)/(1.73 \times 6600) = 6940 \text{ amperes minimum.}$$

Maximum value = 1.73 × 6940 = 12,000 amperes. Since current is limited by only reactance

of generators, interrupting duty on the circuit breakers will be about 33%, assuming an operating time of 1/4 sec. Circuit breaker must interrupt 0.33 × 12,000 = 3960 amperes, but must have mechanical strength to withstand an initial current of 12,000 amperes.

Total reactance to point B is: Two generators in parallel, 12.6%; two lines in parallel, 23.0%; reactance of transformers, 120%; reactance of 2200-volt feeder, 103.0%; total, 258.6%. Short circuit current = 100/258.6 = 0.386 × normal current = 0.386 × 10,000 × 1000/2200 = 1756 amperes maximum. Interrupting duty = 0.57 × 1756 = 1000 amperes.

Calculations are laborious on complex distribution systems. The larger manufacturers of electrical apparatus have available calculating tables for making short circuit studies of complicated systems.

SHORT CIRCUIT PRECAUTIONS.—1. Construction should be such as to confine any fire resulting from a short circuit to a small part of the installation. 2. All apparatus should have sufficient mechanical strength to resist stresses resulting from current flow during short circuit. 3. Short circuit current should not be allowed to flow any longer than necessary. A great amount of heat is generated by abnormal currents which quickly damages insulation. 4. All circuit breakers that are required to open on short circuit should have ample capacity to interrupt safely the maximum current flowing at the instant they operate.

3. CIRCUIT CONSTANTS

Every circuit or transmission line has definite electrical characteristics or constants depending on the material of conductors, their cross-sectional areas, outside diameters and spacing. Electrically, each line consists of resistance and inductance in series, through which current must flow, and a capacitance between conductors into which, in A.C. circuits, charging current flows.

Resistance of a unit length of line is a function of the material of the conductors and cross-sectional areas.

Inductance of a unit length of line is a function of the outside diameter of conductors and the distance between them. The inductance of one conductor of a single- or 3-phase circuit may be determined from:

$$L = \{1.41 \log_{10}(s/r) + 0.1524\} \times 10^{-4}, \quad [1]$$

where (s/r) is large as in overhead lines, or

$$L = [1.41 \log_{10}\{(s - r)/r\} + 0.1524 + 0.304(d/s)] \times 10^{-4}, \quad [2]$$

where (s/r) is small as in multi-conductor cables. L = inductance of one conductor, henrys per 1000 ft.; s = spacing between center lines of conductors, in.; r = radius of conductor, in.; d = diameter of conductor, in. If conductors of a 3-phase circuit are horizontally spaced, $s = \sqrt[3]{a \times b \times c}$, where a, b, c = respectively distance between phases 1 and 2, 2 and 3, and 1 and 3.

Capacitance of a line is the function of the outside diameter of the conductors and their spacing. Where (s/r) is large

$$C = \{7.354/\log_{10}(s/r)\} \times 10^{-9}, \quad [3]$$

where C = capacitance, farads per 1000 ft., of one conductor to neutral. In industrial distribution systems, circuits are too short to cause appreciable error if capacitance is neglected.

Kva. Power, Voltage and Current Relations in various types of circuits are given in Table 1.

Table 1.—Formulas for Amperes, Horsepower, Kilowatts and Kilovolt-Amperes *

Desired Data	Alternating Current			Direct Current
	Single-phase	2-phase, 4-wire †	3-phase	
Kilowatts	$IEF/1000$	$2\,IEF/1000$	$1.73 \times IEF/1000$	$IE/1000$
Kilovolt-amperes	$IE/1000$	$2\,IE/1000$	$1.73\,IE/1000$	....
Horsepower	$IEeF/746$	$2\,IEeF/746$	$1.73 \times IEeF/746$	$IEe/746$
Amperes	Hp. × $746/EeF$	Hp. × $746/2\,EeF$	Hp. × $746/1.73\,EeF$	Hp. × $746/Ee$
Amperes	Kw. × $1000/EF$	Kw. × $1000/2EF$	Kw. × $1000/1.73EF$	Kw. × $1000/E$
Amperes	Kva. × $1000/E$	Kva. × $1000/2E$	Kva. × $1000/1.73E$	....

* I = amperes; E = volts; e = efficiency; F = power factor; Hp. = horsepower; Kw. = kilowatts; Kva. = kilovolt-amperes.

† In 3-wire, 2-phase circuits, the current in the common conductor is 1.41 times current in either of the other conductors.

VOLTAGE DROP, POWER LOSSES AND POWER FACTOR IN POWER TRANSMISSION easily can be determined if line or cable constants and characteristics of power supplied to or received from the line are known. The most common methods of trans-

mission are: Direct current, and single-phase, 2-phase, 4-wire, and 3-phase alternating current.

Notation.—E = voltage between conductors; e = voltage line to neutral = $E/1.73$; f = frequency, cycles per sec.; I = current, amperes; kva. = kilovolt-amperes; L = inductance of one conductor, henrys; P = power, kilowatts; R, r = resistance of one conductor, ohms; X = reactance of one conductor, ohms = $2\pi fL$; Z = impedance of one conductor, ohms $= \sqrt{r^2 + X^2}$; θ = displacement angle between voltage and current (see p. 15–53); $+\theta$ = lagging current; $-\theta$ = leading current; $\cos\theta$ = power factor. Subscripts g, r, l, respectively, indicate: at generating end, at receiving end, and loss in line.

DIRECT CURRENT.—$P_g = E_gI/1000$; $P_r = E_rI/1000$. $E_l = 2RI = E_g - E_r$.

$$_l = E_l I/$$

$$\text{Percent regulation} = (E_l/E_r) \times 100;$$

$$\text{Percent power loss} = (P_l/P_g) \times 100.$$

ALTERNATING CURRENT.—**Single Phase.**—

$$E_g = \sqrt{(E_r \cos\theta_r + 2rI)^2 + (\pm E_r \sin\theta_r + 2XI)^2};$$

$$\text{Percent voltage regulation} = \{(E_g - E_r)/E_r\} \times 100;$$

$$\cos\theta_g = (E_r \cos\theta_r + 2rI)/E_g;$$

$$\text{Kva}_g = E_g I/1000 = 2e_g I/1000;$$

$$P_g = E_g I \cos\theta_g/1000 = 2e_g I \cos$$

$$P_l = P_g - P_r = 2rI^2/1000;$$

$$\text{Percent power loss} = (P_l/P_g) \times 100.$$

Three Phase.—

$$E_g \quad 1.73\sqrt{(e_r \cos\theta_r + rI)^2 + (\pm e_r \sin\theta_r}$$

$$\text{Percent voltage regulation} \quad \{(E_g - e_r)/E_r\} \times 100;$$

$$\cos\theta_g - (e_r \cos\theta_r + rI)/e_g;$$

$$\text{K}\ _g = 1.73E_g I/1000 = 3e_g I/1000;$$

$$P_g = 1.73E_g I \cos\theta_g/1000 = 3e_g \cos\theta$$

$$P_l = P_g - P_r = 3rI^2/1000;$$

$$\text{Percent power loss} = (P_l/P_g) \times 100.$$

E.—A substation operates at 2200 volts, 60 cycles, 3-phase for a load of 250 kw. at 80% power factor lagging. Power is received from a generating station, 5000 ft. distant over a line of three No. 4 copper cable conductors spaced 24 in. apart in a horizontal plane.

From Table 4, R per conductor = 0.258 × 5 = 1.29 ohms. Equivalent equilateral spacing is $S = \sqrt[3]{a \times b \times c} = \sqrt[3]{24 \times 24 \times 48} = 30.2$ in. From Fig. 5, for an equivalent spacing of 30.2 in., reactance = 0.135 ohms per 1000 ft. per conductor at 60 cycles. For 5000 ft., X = 5 × 0.135 = 0.675 ohms. Reactance also may be calculated from the inductance and frequency by means of equation [1]. From equation [1], inductance per conductor =

$$L = \{1.41 \log_{10}(30.2/0.117) + 0.1524\} \times 5 \times 10^{-4} = 0.00178$$

Reactance = $2\pi f L = 2 \times 3.1416 \times 60 \times 0.00178 = 0.675$ ohms per conductor.

Impedance per conductor = $Z = \sqrt{r^2 + X^2} = \sqrt{1.29^2 + 0.675^2} = 1.454$ ohms.

$I = (250 \times 1000)/(1.73 \times 2200 \times 0.8) = 82$ amperes.

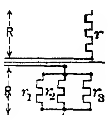
$\cos\theta_r = 0.8$; $\theta_g = 36°\ 52'$; $\sin\theta_r = 0.6$.

Voltage at receiving end = $e_r = 2200/1.73 \quad 1270$ volts.

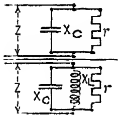
Voltage at generating end = E_g

$$1.73\sqrt{(1270 \times 0.8 + 1.29 \times 82)^2 + (1270 \times 0.6 + 0.675 \times 82)^2} = 2400 \text{ volts}$$

Table 2.—Relation between Resistance and Reactance



$R = 1/(1/r_1 + 1/r_2 + 1/r_3)$



$1/\sqrt{(1/r^2) +}$

Percent voltage regulation = 100 × (2400 − 2200)/2200 = 9.1%.
Power factor at generating end of line is,

$$\cos\theta_g = (1270 \times 0.8 + 1.29 \times 82)/(2400/1.73) = 0.807$$

Kva. at generating end = Kva._g = (1.73 × 2400 × 82)/1000 = 341
Line loss = P_l = $(3 \times 1.29 \times 82^2)/1000$ = 26 kw.
Power supplied to line = P_g = (1.73 × 2400 × 82 × 0.807)/1000 = 276 kw.
Percent power loss = (26/276) × 100 = 9.4%.

Two-phase, Four-wire.—Calculations for transmission of power 2-phase, 4-wire, can be made by considering the 2-phase circuit as two independent single-phase circuits, each carrying half the power, and making use of the single-phase formulas.

Relation between Resistance, Inductive Reactance and Capacitive Reactance in A.C. circuits are shown by the formulas and diagrams of Table 2, in which R, r = resistance; X_L, X_c = inductive and capacitive reactance, respectively; Z = impedance.

4. METHODS OF DISTRIBUTION

OVERHEAD DISTRIBUTION has the advantages of low initial cost, high overload capacity and ease of modification or change in circuit arrangement. Tap-offs easily can be made at any point. Overhead lines may be a hazard to life. They are subject to damage and require lightning arresters for protection. Wood poles, usually spaced 120 to 125 ft. apart, are most common in overhead distribution. Pole height will depend on required clearances. Usual practice is to creosote poles to about two feet above ground to prevent deterioration and damage from insects. Pole hardware is standardized and includes cross arms and braces, insulators and guys where necessary.

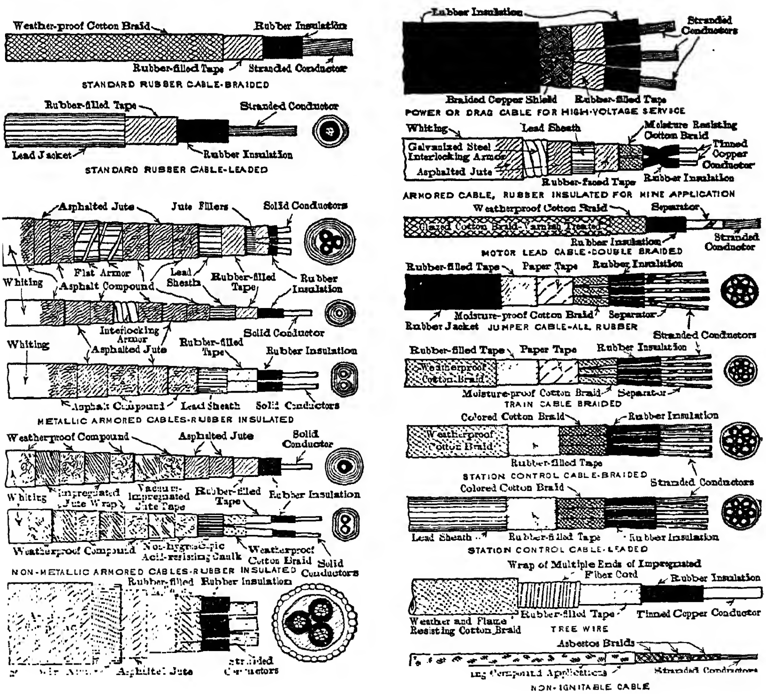


FIG. 7. Types of Cable Construction

UNDERGROUND DISTRIBUTION depends on permanency of installation, flexibility, physical layout of plant and comparative costs. If an industrial plant requires underground tunnels for steam, water and gas, they also can be used for electrical circuits, providing proper physical separation is maintained. Underground distribution requires cable which may be carried in fiber or tile conduit embedded in concrete with concrete separation between ducts. Spare ducts are provided for future requirements. For short cable runs within buildings, such as runs from generating or conversion apparatus to switchboards, common practice is to install cable in pipe conduits in the floor. For distribution to isolated points, or for outdoor lighting circuits, parkway type cable can be used. Table 11 gives data on conduits.

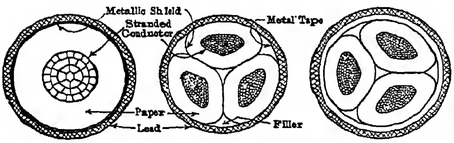

Fig. 8. Shielded and Non-shielded Cable

CABLE consists of solid or stranded conductor, which may be bare for overhead line construction or insulated for underground and conduit wiring. Common insulating materials are: Asbestos, paper, rubber and varnished-cambric. Common finishes are: Asbestos, braid, braided-wire armor, cotton, flat-band armor, compound sheath, interlocked armor, asphalted jute, lead sheath, rubber, tape and wire armor. Fig. 7 shows various cable constructions.

Paper-insulated Cable is generally accepted for transmission of large blocks of power, underground, overhead or underwater, and also for interconnection of apparatus in generating stations, substations and industrial plants. The two types, solid and oil-filled, are insulated with wraps of paper impregnated with oil. They may be shielded or non-shielded. See Fig. 8. A metal shield comprising a thin tape of copper is wound tightly over the paper insulation to protect it from corona or ionization damage. Single-conductor shielded cable is recommended for circuits of from 40 to 69 kv., but it can be obtained for voltages up to 75 kv. The multiple-conductor shielded cable is recommended for circuits of from 10 to 35 kv. and is adaptable to small and medium size conductors. Non-shielded cable has a belt of insulation over the insulated conductors. Single-conductor unshielded cable is recommended for any voltage up to 39 kv. and is adaptable to large conductor sizes. Unshielded multiple-conductor cable is recommended for circuits of any voltage up to 10,000 kv.

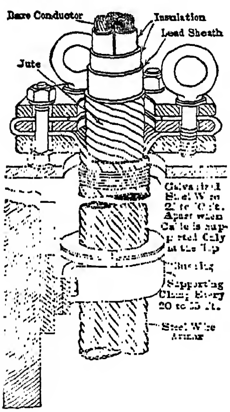

Fig. 9. Methods of Supporting Vertical Cable

Paper-insulated cables are finished with a lead sheath. Armor also is applied to paper-lead cables to prevent corrosion of the lead and prevent mechanical injury. The armor may be flat band steel applied over jute. Cables buried directly in the ground frequently have an overall layer of asphalted jute to protect against corrosion. Steel wire is used for armor if tensile strength and resistance to mechanical injury are required. The lead sheath may be omitted on paper insulated cable for voltages up to 17 kv. and a rubber hose jacket substituted. Such cable is suitable for high voltage overhead construction, where the weight of a lead sheath is undesirable.

Varnished-cambric-insulated Cable is highly moisture resisting but not completely waterproof. It is used for a wide variety of conditions, but it is important that the correct finish be used. In well ventilated exposed positions, braid finish, either weatherproof or flame-resisting as required, can be used. The use of non-metallic finishes without lead or metallic shields (grounded) is not recommended for circuits above 7500 volts except where cable is supported free on insulators.

APPLICATIONS OF VARNISHED-CAMBRIC-INSULATED CABLE.—Central Stations and Substations.—Varnished-cambric cable in all sizes is used for general station wiring and interconnection of apparatus. Single-conductor cable is usual, although multiple-conductor cable often is used for control and auxiliary circuits, handling small blocks of power.

Industrial Plants.—Cambric cable can withstand sharper bends than paper cable without injury to the insulation and it will stand higher temperatures than rubber cable. Varnished-cambric cable is ideal for small systems such as industrial plants in which both single- and multiple-conductor cable are widely used. Any of the standard finishes can be used depending on the service requirements.

Mines.—Varnished-cambric cable with lead sheath is used for horizontal runs in mines and for vertical mine-shaft runs when finished with jute and wire-armor over the lead. It can be suspended from the top of the shaft by means of the wire armor without additional support, but, where possible, good practice requires a support every 25 or 50 ft., depending on length of run. See Fig. 9.

Tall Buildings require high voltage lines run vertically to a substation about half-way up. The height may be 200 to 300 ft. Varnished-cambric cable or a combination rubber and varnished-cambric cable without plastic fillers is recommended.

Parkway Cable Installations, where cable is run in the ground without ducts, is a common use for varnished-cambric cable, when furnished with a lead sheath and with flat-band armor and jute or jute finish over lead.

Transformer Leads.—Varnished-cambric cable is recommended for incoming lines to transformers of all types. It is equally suitable for connections to motors and generators. Single-conductor or multiple-conductor cable of this type is available for circuits of any voltage up to 26 kv., leaded or shielded, or 7.5 kv. non-shielded. Varnished-cambric cable is not injured by oil and therefore it can be run directly into oil switches and oil-filled transformers. Rubber insulation under these conditions would not last.

Rubber-insulated Cables are used widely for all types of exterior and interior wiring. They are available braided and leaded, or armored. Rubber-insulated armored cable can be applied without ducts to general use, power, lighting and control circuits, street-lighting circuits in outlying sections, lighting and power circuits in parks, estates, industrial plants and on bridges, connecting residences to mains, railroad yard and airport lighting, circuits for lighting of baseball and amusement parks, railway signal circuits, crossings under lakes and streams, horizontal runs in mines for power, light and telephone circuits. Rubber-insulated armored cable is resistant to weather conditions, is not affected by frost, and can be buried in the ground from 12 to 18 in. below surface.

Rubber-insulated cable is recommended for portable use with mining machinery, and locomotives, for supplying power to shovels, dredges, welding sets, and for equipment used in quarries, gravel pits, shipyards, and for logging operations. For portable applications, and where a strong, flexible cable is required, cable insulated with tellurium rubber compound is recommended.

Rubber non-metallic cables are used in ducts or aerial applications for low and medium voltage distribution circuits. For overhead line construction in residential districts where lines must be run through tree foliage, and tree cutting minimized, tree wire is used.

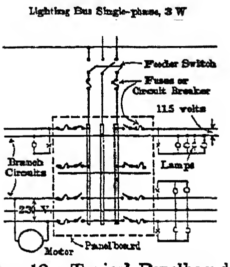

Fig. 10. Typical Panelboard Connections for Lighting and Small Motors

Non-ignitible Cable is designed for use as field rheostat leads and similar low voltage systems where non-combustible covering is desired.

DISTRIBUTION WITHIN BUILDINGS usually will start with one or more main service feeders from the main switchboard, depending on required reliability of service. Depending on the size of load, short circuit duty and voltage, the main feeder may be controlled by: *a*, fused knife switch; *b*, manually-operated air circuit breaker. For lighting and small power loads, fused knife switches are suitable for service switches. Air circuit breakers are more expensive, but are more accurate in operating overloads and short circuits, and do not require re-fusing. Main feeders terminate in motor control devices or in panelboards which serve branch circuits to lights, small motors and heating units. Usually one panelboard controls branch circuits feeding the same type of load. Panelboards usually are metal cabinets with hinged covers, which can be installed flush with the wall in finished buildings. The cabinet contains copper buses to which the main feeder is connected, and outlets and fused knife switches or circuit breakers for each branch circuit. Fig. 10 shows typical panelboard wiring. The remainder of the distribution system consists of conductors for branch circuits and connections between panelboards and feeders. Codes require either armored wire and cable or wires run in metal or fiber conduits. Conduits or armored cable can be run inside walls, in concrete floors, or overhead on beams. Rigid steel conduit is widely used in wiring systems.

Conduit Size for wires depends on number and sizes of wires to be drawn in the conduit without stretching of the conductor or damage to the insulation. Table 11 shows recommended conduit sizes for wires.

Capacity and Sizes of Wire or Cable for feeder or branch circuits depends on current to be carried and type of insulation. Heating of conductor and voltage drop are the limiting factors. Heating largely depends on conditions surrounding the conductor as they affect transfer of heat away from it. The National Board of Fire Underwriters publish tables showing allowable capacities of conductors from which the proper size can be determined. See Table 6.

Selection of Wire Size and Fuses for motor branch circuits can be made from Table 7.
Relation between Load, Distance, Loss and Size of Conductor is given in Table 10.

DISTRIBUTION FOR LIGHTING depends on the required intensity and the type of control, which further depends on the service, office or factory, and whether individual or group switching of the lights is required. Usual lighting distribution systems are: 115-volt, single-phase, 2-wire, A.C. or D.C.; 115/230-volt, single-phase, 3-wire, A.C. or D.C.;

* Values are only for annealed copper of standard resistivity. Hard drawn copper may be taken as about 2.7% higher resistivity than annealed copper.

† The values are 2% greater than for a solid rod of cross section equal to the total cross section of the wires of the cable.

Resistivity of pure copper at 20° C. = 0.15328 ohm per meter.

208/120-volt, 3-phase, 4-wire, A.C.; high-voltage with transformers at lighting centers. With the latter, small air-cooled lighting transformers would be used, supplying branch circuits from 440- or 220-volt primaries to 230/115-volt, single-phase, 3-wire secondaries. Usually this scheme is economical only for large areas.

WIRING SYSTEMS.—Common wiring systems are shown in Fig. 11. Three-wire D.C. or single-phase A.C. branch lighting circuits are taken off from either line and neutral and motors are operated from the two lines. These systems are used mainly for residences, small stores or other small domestic or commercial loads. The 3-phase, 3-wire and the 3-phase, 4-wire systems are used for large stores, offices, public buildings and factories. In 3-phase, 3-wire systems, the single-phase lighting load should be kept very nearly balanced on the three phases. For large lighting loads, 3-phase, 4-wire system is preferable where single-phase loads are taken off from line to neutral. The 2-phase, 4-wire and the 2-phase, 3-wire systems are not widely used. Almost all wiring is now single-phase, 2- or 3-wire, and 3-phase 3- or 4-wire systems. The 2-phase, 3- or 4-wire systems are important only in existing installations. The voltages indicated are those to be maintained at the loads, and, assuming the same load for each system, the current in the feeder lines of the different systems is indicated in terms of the current I of the 2-wire D.C. or single-phase A.C. system.

* To determine wire size for a 2% drop at 220 volts divide the amperes at 220 volts by 2, and find the wire size for the corresponding distance at 110 volts. EXAMPLE.—Required the wire size for 70 amperes at 220 volts for a drop of 2% in a distance of 160 ft. 70/2 = 35. From the table the wire size required is No. 2.

For a given load and a given line loss the size of copper required will vary inversely as the square of the voltage. Distribution at 230-volts will require 1/4 the wire cross-section as for the same system operating at 115-volts. Table 12 gives wire sizes for a given voltage drop for various lengths of line.

5. CIRCUIT PROTECTION

GENERAL CONSIDERATIONS INVOLVED in circuit protection are: Safety to human life, insurance of circuit and connected apparatus against damage, fire hazard, and protection of service. Preventive measures minimize the possibility of circuit failures, and wiring, materials, and construction should be of high grade and approved standards. Danger to life by contact with live parts, and indirectly through fires and explosions, can be minimized by proper precautions. Circuits should be sufficiently protected by enclosures and insulation to prevent accidental contact. Grounding of circuits to limit voltage above ground will minimize hazard to life. Code requirements limit voltages above ground to 150 volts.

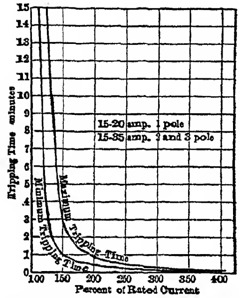

FIG. 12. Time-current Characteristics of Air Circuit Breaker

Over-current and short circuit protection, in the form of fuses and circuit breakers, prevents excessive damage to circuits and equipment under abnormal conditions. They protect the circuit by automatically disconnecting it from the source of power. Over-current protection prevents overheating of the conductors and destruction of insulation. Short circuits must be cleared instantly, to minimize damage to the circuit itself and the possibility of fire at the point of short circuit.

For process where power outages are costly, service protection is important. Duplicate feeders and automatic throwover to a standby power source effect continuity of service. The circuit protective device often sounds an alarm instead of automatically disconnecting the circuit.

Important factors involved in the selection of a circuit interrupting device are: Reliability, over-current and short circuit capacities, normal current and voltage rating, initial cost and maintenance. Fuses afford a high degree of reliability if properly applied. They are low in initial cost and maintenance consists chiefly of replacement. On a circuit subject to frequent overload, fuse replacements may be an expensive item. A manually-operated air circuit breaker of the type designed for use as an alternative to fuses on low voltage circuits may be the proper solution.

FUSES.—A fuse will open a circuit on excess current, with delayed action inversely as the magnitude of the current. Fuses are used for protection of low-capacity circuits of 600 volts and below. The maximum standard rating is 600 amperes, which limits the application of standard fuses to 360 kva. single-phase, 623 kva. 3-phase and 720 kva. 2-phase, 4-wire circuits. Tables 13 and 14 give data on fuses and wiring for various motor circuits.

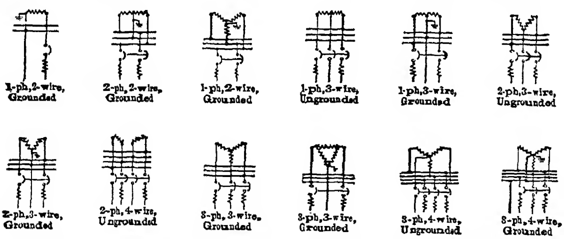

FIG. 13. Typical Circuit Breaker Arrangements for Different A.C. Circuits

AIR CIRCUIT BREAKERS are manually closed and are tripped on overload by a thermal device. They, with fuses, are the chief protective devices for low-voltage distribution circuits. Fig. 12 shows a typical time-current characteristic. Recommended ratings are given in Tables 15 and 16. These circuit breakers are replacing fuses and fused knife switches. Tripping elements are rated in accordance with the ratings of wires as established by the National Electric Code. These breakers are used with panelboards for branch circuits, at load centers, service entrances, and switchboards for the protection

of light and power circuits. They also will protect individual circuits and can be mounted in sheet metal enclosing cases for industrial applications. Their tripping time at all currents is longer than the clearing time of a fuse of the same rating. Arrangement of breakers for over-current protection of common circuits used are shown in Figs. 13 and 14. These will meet Underwriters' rules, except for incoming lines, where provision also must be made for disconnecting the grounded neutral. Table 17 specifies breakers required for direct-current machine circuits.

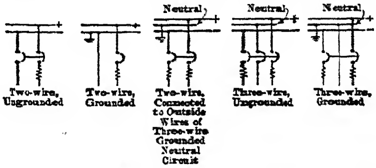

FIG. 14. Typical Circuit Breaker Arrangements for Different D.C. Circuits

Neutral Conductors.—Fuses or protective devices in the neutral conductor are not recommended. Opening the neutral would apply high voltage to the lightly-loaded side of a 3-wire system under unbalanced conditions. On 3-wire, single-phase circuits, each outer wire has over-current protection, and both outer wires must open to prevent overloading the neutral. The breaker should be double-pole with a current coil in each pole.

(*Table continued on following page*)

Grounding.—As shown in Figs. 13 and 14, the neutral wire of secondary distribution circuits are grounded. This limits the voltage to ground to a maximum of 150 volts, and minimizes danger to life. All parts of a grounding circuit must be continuous and of negligible resistance. In addition to limiting the voltage above ground on a secondary circuit, grounding also supplies protection against extraneous voltages which might appear on the circuit, as from a primary circuit accidentally coming in contact with the secondary circuit. Metal conduits and apparatus cases and frames also are grounded.

The actual connection to earth of a grounded system is of great importance. Code requirements suggest grounding to water pipes. Where no such ground connections exist, artificial grounds are

used, consisting of pipes or grounding rods driven in the earth, which often is treated with salt to reduce ground resistance. Ground connections should receive periodic inspection, and where artificial ground conductors are used resistance at the point where the system is actually earthed should be known at all times, and kept at a safe value. If grounding connections are neglected, what was originally installed as a protective measure may become a serious hazard.

CODES.—Numerous codes and standards have been set up, both national and local, covering apparatus for utilizing electricity. In laying out circuits for power distribution,

the National Electrical Code should be consulted. Also local ordinances exist, which may vary in different localities. These should be known and observed. The accepted practice of A.I.E.E., N.E.M.A. and Edison Institute should be used as guides in electrical wiring and construction.

Table 17.—Air Circuit Breakers, 750 Volts and Less Required for Over-current Protection

Direct-current Machine Circuits

Circuit Controlled *	Breaker Required for Over-current Protection †
2-wire D.C. generator (engine-driven, not grounded). 2-wire D.C. generator (motor-driven). 2-wire synchronous converter. 2-wire battery (not grounded).	1 single-pole with 1 over-current coil. With generators, entire armature current flows through over-current coil. Generators used as exciters ordinarily require no protection, but power-directional relays with over-current relays connected in series, may be used. Generators charging large batteries usually require power-directional protection to prevent battery from pumping back into the generator. Usually only over-current protection is provided for small generators charging oil-circuit-breaker control batteries. No general rules can be laid down for battery work. For electrolytic generators below 25 volts and above 2000 amp., use automatic field switches, whose trip coils are actuated by main line current. Generators rated 25 volts and 2000 amp. or under, are not provided with automatic protection.
2-wire D.C. generator (engine-driven, negative grounded). 2-wire battery (negative grounded).	1 single-pole with 1 over-current coil if connected in negative (grounded) side. 2 single-pole with one over-current coil each for railway service. Positive side only is run to the panels. A breaker is connected in both positive and negative leads to take care of grounds. In both cases, entire armature or battery current must flow through over-current coil.
2-wire motor (not grounded).	1 single-pole with 1 over-current coil.‡ 1 double-pole with 1 over-current coil.‡
2-wire motor (negative grounded).	1 single-pole with 1 over-current coil connected in positive (ungrounded) lead.‡ If Underwriters' rules apply, 1 double-pole with 1 over-current coil in positive (ungrounded) lead.
3-wire generator. 3-wire synchronous converter with neutral derived from A.C. end. 3-wire battery.	1 double-pole with an over-current coil connected in each outside wire. In machine circuits, breaker must receive the entire armature current. Rated voltage of breaker must be equal at least to voltage between neutral and outside wires.
Balancer set for producing 3-wire system.	1 double-pole with over-current coil connected in each outside wire and carrying the entire line current. Rated voltage of the breaker must be equal at least to voltage between outside wires.

* Unless specifically stated otherwise, all circuits may be either grounded or ungrounded.

† The proper knife switches are to be used in all circuits, to disconnect them and take care of equalizing compound-wound machines.

‡ Where Underwriters' rules do not apply. See rules for modifications.

SECTION 16

POWER TEST CODES

TABLE OF CONTENTS

INSTRUMENTS AND APPARATUS

TEST CODES

POWER TEST CODES

Tests to determine the performance of power generating apparatus, or of equipment utilizing power, should be conducted under the Power Test Codes of the American Society of Mechanical Engineers. These codes prescribe the methods to be followed, the apparatus to be used, and the measurements and readings to be taken to completely determine the performance of power-generating or power-using apparatus.

Each type of apparatus is the subject of a separate code. In addition, there is published, in connection with the codes, supplementary information dealing with instruments and apparatus, whose use is common to all of the codes. The more important of these codes, and of the instruments and apparatus codes are abstracted below. Complete copies of any code can be obtained from the American Society of Mechanical Engineers, 29 West 39th St., New York.

In the tabulation of data and test results accompanying each of the codes, the following items, which are common to all codes have been omitted, and should be added to any report made in a test conducted under a code: 1. Date of test. 2. Location. 3. Owner. 4. Builder. 5. Test conducted by. 6. Object of test.

INSTRUMENTS AND APPARATUS

1. TEMPERATURE MEASUREMENTS

Approved, 1931

The methods of measuring temperature, the calibration of instruments, and the auxiliary apparatus to be used, together with precautions to be taken, are fully discussed in Section 3. See pp. 3–03 to 3–16. The data therein have been abstracted largely from the chapter on temperature measurement of the Power Test Codes.

2. SPEED MEASUREMENTS

Approved, 1930

Three general methods of obtaining angular speed of rotating machinery are: 1. By means of a revolution counter and time piece. 2. By use of a tachometer. 3. By use of a stroboscope. Linear speed is calculable from angular speed when the two are associated.

COUNTERS are instruments for determining the number of revolutions or strokes of rotating or reciprocating mechanisms. Continuous counters are used where a determination is sought over a considerable period of time. Hand counters are used for determinations over a short period. Continuous counters are of the following types:

A Direct-geared Counter comprises a series of gears arranged to rotate a set of dials or pointers that register the number of revolutions. It is positive, accurate, and is considered the most reliable type of counter.

A Cyclometer-type Counter is considered the next best type of counter. The set-back type counts one for each revolution of the shaft. A set-back device permits returning of all figures to zero. It will add when turned forward but it may not be depended upon to subtract when rotated backward. It is not recommended for determinations exceeding 500 counts per min. The locked-wheel type counts one for each revolution of the shaft and has no set-back device. It is especially recommended for high count determinations, and may be operated at twice the maximum speed of the set-back counter.

Set-back Rotary Ratchet Counters will count 10 for each complete forward rotation of the driving shaft, which is rotated by an oscillating motion of a lever on it. An oscillation of 40 to 60 deg. will count one on the number wheels. Backward rotation of the shaft will not disturb the number wheels. These counters may be operated at 150 counts per min., and for short periods at 200 or 300 counts per min. Without the set-back attachment, it may be run continuously at twice its normal speed if the driving shaft is fitted with ball-bearings.

Flat Ratchet Type Counters involve reciprocating motion and a ratchet drive. Unless

the travel is properly controlled, overtravel may occur especially at high speeds. This type is limited to slow count determinations, and is unsuited to high-accuracy determinations.

Continuous counters usually are fastened rigidly to a part of the machine. The primary drive is operated by gear, chain or flexible shaft in determining revolutions, or a system of continuous or intermittent linkages in determining number of strokes.

Hand Counters may be of either the dial or cyclometer type. If carefully handled and well made they are fairly reliable over a range of 200 to 2000 r.p.m. The possibilities of errors in these instruments are slippage between the shaft and the point of the instrument where contact is made, and also inaccuracy in determining time between making and breaking the contact. The counter should be allowed to operate at shaft speed for a few seconds, and, as the dial passes the zero mark, the stop watch should be started. After running for about two minutes, the stop watch should be stopped as the dial again passes the zero mark. This will give the time for an integral number of revolutions and eliminate errors due to slippage and sudden starting or stopping. The longer the period, the less will be the error. For a $^1/_5$-second stop watch, an error of one scale division on the watch will cause the following percentage of errors in observed r.p.m.

Period of contact.........	15 sec.	30 sec.	1 min.	2 min.	3 min.
Error in r.p.m., %........	±1.33	±0.67	±0.33	±0.17	±0.11

THE TACHOSCOPE is an instrument in which revolution counter and stop watch are mounted in one frame and arranged to operate simultaneously. The range varies from 0 to 5000 r.p.m. Its accuracy depends on the stop watch incorporated in it.

The Speed Indicator is an instrument operating on the same principle as the tachoscope, and averages the speed over a short period of time, indicating directly the speed in r.p.m. It may be used to measure speeds up to 30,000 r.p.m. The errors usually do not exceed 0.3 to 1.0% for readings taken in the upper part of the scale.

TACHOMETERS.—A tachometer indicates speed directly and continuously. Tachometers are made in several different types. They have a substantially constant r.p.m. error over the upper 70 to 80% of the working range, which usually is from 0 to 2500 or 0 to 1200 r.p.m. In most types the readings should be in the upper 75% of the range and preferably in the upper 50%. The driving gear ratio can be changed to meet any actual speed range.

Tachometers may be driven by any one of the following methods, the first three being preferred: 1. Gear or chain. 2. Flexible shaft or cable enclosed in flexible housing. 3. Speed pin threaded into the end of the revolving shaft under observation, with a metal sleeve, slotted in both ends, for a driving link between shaft and tachometer. These three all are positive drives. 4. Adapter on tachometer shaft pressed into contact with a so-called center on the rotating shaft of apparatus under test. 5. Belt and friction drive. This latter method should be avoided as unreliable.

Centrifugal Tachometers of the fly-ball and tilting-ring types operate through the centrifugal force produced by one balance ring or two or more revolving weights acting against springs. The compression of the springs moves the indicator or recorder pen. Good makes of this type of tachometer may have an error of 15 to 30 r.p.m. between the range of 600 and 2500 r.p.m. when new, and an error of 50 to 100 r.p.m., with a 25 to 50 or more r.p.m. difference between up and down readings, after being in service for some time. The temperature effect may be approximately 1 r.p.m. for each 10 deg. F.

Liquid Pump Tachometers comprise a centrifugal pump, a reservoir for liquid and an indicating tube into which the pump forces the liquid. Speed is determined by noting the position of the meniscus on the scale graduated in r.p.m. This instrument should be used only over the upper 40% of its range. The best instruments of this type, in good condition, can indicate speeds within 10 to 15 r.p.m. at 6000 r.p.m.

Air Tachometers are tachometers of the centrifugal type in which air is the working fluid as well as the transmitting medium. With it, indicating or recording mechanism may be located at a distance. An air tachometer should be used only in the upper 75% of its range. With a rotor making a maximum of 1500 r.p.m., it has an accuracy of 10 r.p.m. when provided with a sensitive mechanism for indicating the air pressure produced and when operating under standard atmospheric conditions.

The Autographic Hydraulic Pump Tachometers use an autographic speed recording mechanism which can portray speed changes incidental to changes of load, as in governor testing. It comprises three main elements, *i.e.*, the tachometer pump, the indicating mechanism and the auxiliary or return pump.

Force-drag Tachometers depend on the drag produced by a rotating element which transmits a force from it to another movable part, to which the indicator needle is attached. The motion of the needle is limited by a spring. These tachometers are used largely on

automobiles, but very little in power plant work. They are not recommended for use in connection with the Power Test Codes.

Chronometric Tachometers comprise a repeating type of combination clock and revolution counter. They depend on direct revolution counting during an increment of time. They cannot be depended on closer than 6 to 7 r.p.m. over the entire range of a scale of 2500 r.p.m. maximum reading, and may have errors as great as 20 r.p.m. when new, and an increased error of 5 or more r.p.m. after a reasonable amount of continuous service, with possibility of complete failure.

Electric Tachometers in commercial use are: 1. The electro-magnetic type, consisting of a direct-current generator with indicating volt meter. 2. An ordinary frequency meter calibrated to read speed instead of frequency. The electro-magnetic type should be used with direct drive at not over 2500 r.p.m. Its accuracy is not closer than 20 r.p.m. and it may have a probable error of 0.5% for each 20 deg. F. temperature change.

The frequency meter tachometer may be of the vibrating reed type, the induction type, or the moving coil type. The reed type indicates only certain fixed speeds, corresponding to the individual reed, and these are rarely closer together than 0.5%. The range is from 800 to 12,500 r.p.m. with an accuracy within 50 r.p.m. for individual reeds when new. It may be accurate only within 100 r.p.m. for individual reeds after use.

Vibration Tachometers are similar in construction to vibrating reed frequency meter type tachometers, excepting that they depend only on the mechanical vibration produced by the rotating member. Their range and limitations are the same as those of the electrical instrument.

STROBOSCOPES utilize the persistence of vision when an object is viewed intermittently. The end of the rotating shaft under observation, or a disc attached to it, may be marked with several dots located equidistantly around the circumference of a circle whose center coincides with the center of the shaft. Vision is interrupted by using either a tuning fork arrangement or a rotating perforated disc driven by a separate machine. When sighting through a perforated disc, separately driven, the speed of this disc is varied until the marks or figures on the rotating shaft or disc appear to be stationary. Then the speed of the shaft under observation will be the same as that of the separately-driven shaft, or some multiple of it, and equals (Indicated r.p.m. × number of holes in disc) ÷ (number of images). The number of images is the number of times a single mark on the indicating shaft is seen through all the holes in the disc of the adjusted-to-speed stroboscope. There is practically no limit to the range over which the stroboscope can be used.

3. PRESSURE

Approved, 1929

BAROMETERS are used to measure pressure of the atmosphere. Readings, usually, are in inches of mercury. Barometric pressure plus gage pressure is the *absolute pressure*. Where measured pressure is less than atmospheric pressure, the pressure indicated by the reading of a U-tube or vacuum gage is called the *vacuum*. The absolute pressure then is the difference between atmospheric pressure and the vacuum.

Mercurial barometer and mercury column readings always should be corrected to the value which would obtain if the mercury column were at 32° F. A calibration correction also should be applied. See below for methods of making these corrections.

The Mercurial Barometer is used generally and recommended. The diameter of bore of the glass tube of a barometer used under the test codes shall be not less than 0.25 in. The range usually is 25 to 32 in. of mercury. Special barometers for mountainous regions begin at 15 or 20 in. A vernier attachment permits readings to 0.001 in., although for many engineering purposes readings to 0.01 in. are sufficiently accurate.

The Aneroid Barometer consists of an exhausted chamber whose ends are corrugated diaphragms. Atmospheric pressure on the diaphragms, balanced by a stiff spring, deflects them. The deflection is transmitted to a pointer which gives the reading, equivalent to that which would be given by a mercury barometer in inches or millimeters of mercury. Aneroid barometers are not as reliable as mercurial barometers, the temperature correction being uncertain. Their use is permissible only where accuracy in determination of barometric pressure is not of primary importance. The range of accuracy is from 0.01 to 0.1 in.

The Recording Barometer or Barograph is an aneroid barometer actuating a pen moving over a recording drum rotated by clockwork. It is subject to all of the inaccuracies of the aneroid barometer, plus those due to the pen and its mechanism.

Installation of Barometers.—A barometer must be so installed as to be free from vibration, air currents, and violent temperature changes. It must be in good light, not directly exposed to the sun and not heated by nearby electric lamps. A mercurial barometer

must hang free to insure a vertical position of the column. It must have a small vent to

N.—Barometers should

for

Station (provided it is not over 20 miles distant) as shown on the daily weather maps issued by the bureau. Weather Bureau barometer readings always are taken at 8 A.M., Eastern Standard Time. If the station is at a different elevation than the barometer being calibrated, a correction should be made to compensate for this difference. Calibration also can be made by means of the weather maps. The location of the barometer is indicated by a dot on the map, and the barometric pressure is estimated by interpolation between the values shown on the two adjacent isobars. The isobars are for each 0.1 in., so that interpolation will give pressures to the nearest 0.01 in. The following is an example of the calibration of a mercurial barometer at West Lynn, Mass.

Data	
Uncorrected barometric pressure	29.800 in. Hg
Check reading	29.801 in. Hg
Temperature	75 deg. F.
Height of cistern above floor	3 ft.
Floor elevation above mean sea level	16.82 ft.
Latitude	42.8 deg. N.
Calibration	
Mean uncorrected reading	29.80 in. Hg
Temperature correction, Table 1	− 0.13 in. Hg
Elevation correction, Table 2	0.02 in. Hg
Gravity correction, Table 3	− 0.01 in. Hg
Corrected reading, reduced to sea level	29.68 in. Hg
Weather map reading, reported by Boston station of U. S. Weather Bureau reduced to sea level	29.67 in. Hg
Calibration correction	− 0.01 in. Hg

Observed readings of barometer shall be corrected by the data in Tables 1 to 3, or by Tables in U. S. Weather Bureau Circular F, or by the Smithsonian Tables. The following is an example of a mercurial barometer reading, correction and reduction at West Lynn, Mass.

Uncorrected barometric pressure (actual reading)	29.80 in. Hg
Barometer temperature	75 deg. F.
Temperature correction, Table 1	− 0.13 in. Hg
Gravity correction, Table 3	− 0.01 in. Hg
Calibration correction (*always* must be made)	− 0.01 in. Hg
Barometric pressure (at barometer elevation)	29.65 in. Hg
Level of barometer cistern *below* turbine center line	16 ft.
Elevation correction, Table 2	− 0.02 in. Hg
Barometric pressure at elevation of turbine center line	29.63 in. Hg

Reduced reading, $29.63 \times 0.4912 = 14.55$ lb. per sq. in. = absolute barometric pressure at elevation of turbine center line.

Temperature Corrections.—Table 1 is used to correct, for temperature, the readings of a mercurial barometer, mercury gage or U-tube. The correction reduces the reading to the value that would obtain were the mercury at 32° F. The table also includes a slight correction for temperature expansion of a brass scale which is correct at 62° F.

Elevation Corrections.—For exact work, gage readings must be corrected to account for weight of column of air between the level of the center line of apparatus under test, or any other reference plane, and the level where atmospheric pressure acts on the gage. See Table 2.

The correction is applied as follows: Let C = correction to be applied; c = correction value from Table 2; d = difference in elevation, ft. Then $C = (c \times d)/100$. If the gage reading is below atmosphere and the gage is set below the reference plane, or if the gage reading is above atmospheric pressure, and the gage is above the reference plane, C is *subtracted* from the gage reading. If the gage reading is below atmospheric pressure and the gage is above the reference plane, or if the gage reading is above atmospheric pressure and the gage is set below the reference plane, C is *added* to the gage reading.

Gravity Corrections need not be made for most engineering work, but Weather Bureau barometric readings always include a gravity correction. Hence the corrections in Table 3 are necessary for accurate calibration by comparison with a Weather Bureau reading.

Meniscus Corrections are not necessary with barometers, the correction being allowed for in setting of the scale. For mercury columns comprising a reservoir and a single leg, or for mercury U-tubes with legs of different diameters, the corrections of Table 4 should be added to the reading taken at the top of the meniscus.

Head and Water Column Corrections.—For precise work, the mean of temperatures at inlet and outlet of apparatus under test must be used. Values of density of water at various temperatures together with multipliers for reducing readings in inches of water to lb. per sq. in. or inches of mercury are given in Table 5. For ordinary engineering work variation of density with temperature need not be considered, and density is taken as corresponding to usual room temperatures. Multipliers for conversion of barometer and U-tube readings are given in Table 6.

Table 5.—Density of Water and Multipliers for Water Columns

Hg between levels in the two	Water on top of both columns completely filling both pressure pipes Pressure is given between two points at same level	0.49 − 0.036 = 0.454	1.00 − 0.074	1.048 for water and mercury †
Water U-tube or water gag	In. water at t deg. F.	Requires precision gage and precision computations. See Table 5	$\frac{d}{1728}$	0.001178d	1/12 for same temperature of gage and column
Water U-tube or water gage	In. water	For usual engineering work	0.036	0.074 †	1/12
Bourdon pressure gage	Lb. per sq. in.	Reading to be corrected per gage calibration	1.00	2.036 ‡ 2.04 †	144/d exactly 2.31 for water †

* Readings are to be multiplied by the multipliers indicated. d is density of water, lb. per cu. ft., at actual temperature (see Table 5). † At usual room temperature. ‡ For in. mercury at 32° F.

TEST CODES

4. TEST CODE FOR SOLID FUELS

Approved, 1931

Solid fuels include the lignites, bituminous coals, anthracite and coke.

OBJECTS of testing solid fuels may be any one or more of the following:

Determination of: *a.* Composition of fuel. *b.* Heating value of fuel. *c.* Size of fuel. *d.* Character of combustion by analysis of products of combustion. *e.* Certain ash constituents. *f.* Fusing point of ash. Another object may be classification of fuel. (See p. 4–13.)

COLLECTING SAMPLE.—For a standard test, fuel shall be collected and prepared in accordance with the method described below.* If less accurate results are permissible, a smaller total weight of sample than specified in the code may be collected, with the understanding that the probable error in sampling varies inversely with the weight of the sample.

Every sample must be collected and prepared carefully. If sampling is improperly done, the sample will be in error, and it may be impossible to take another. Gross samples of the quantities designated must be taken, irrespective of the size of the lot to be sampled, because the larger the sample, the smaller will be the effect of accidental errors in sampling. Thus, the accidental inclusion of a 10-lb. piece of slate in a 100-lb. sample would cause an error of 10% in the ash content; in a 1000-lb. sample, the error would be but 1%.

Time of Sampling.—Fuel shall be sampled when it is being loaded into or unloaded from railroad cars, vessels, or wagons, or when discharged from supply bins, industrial railway cars, grab buckets or coal conveying equipment. If fuel is crushed as received, samples usually can be taken after fuel has passed crusher. Samples from the surface of fuel in piles, bins, cars, vessels, etc., usually are unreliable.

Size of Increments may be as small as 5 to 10 lb. for slack or small sizes of anthracite; for lump or run-of-mine coal, increments should be from 10 to 30 lb. All increments shall be of equal size.

Collection of Gross Sample.—Increments shall be regularly and systematically collected, so that the entire quantity sampled will be represented proportionately in the gross sample. Increments shall be collected with such frequency that a gross sample of the required amount will be obtained. Standard gross sample shall be not less than 1000 lb., except that for slack coal and small sizes of anthracite in which impurities are not in abnormal quantities, or in sizes larger than 3/4 in., gross sample may be 500 lb. If impurities are present in abnormal quantities, or are of large size, gross sample should be 1500 lb. or more. Gross sample should contain the same proportions of lump, fines and impurities as the fuel sampled. Preservation of the integrity of the sample is important.

Quantity Represented.—A gross sample shall be taken for each 500 tons or less, or with larger tonnages in agreed quantities.

Crushing.—The gross sample shall be systematically crushed, mixed and reduced in quantity to convenient size, either by hand or by mechanical means, for transmittal to laboratory. Conditions must be such as to prevent loss or accidental admixture of foreign matter. The largest size of fuel and impurities allowable as determined by visual inspection shall be as follows:

Weight of sample before division, lb.	1000	500	250	125	60	30
Largest size of fuel or impurity, in.	1	3/4	1/2	3/8	1/4	3/16*

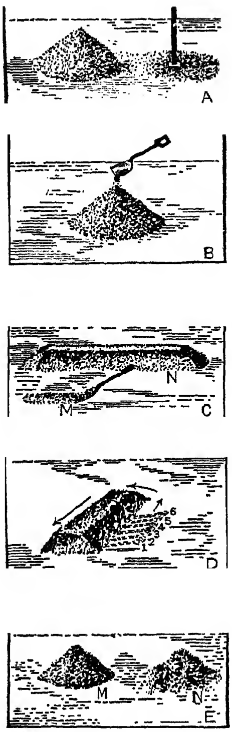
* To pass a No. 16 sieve.

The progressive reduction in size shall be done as follows, the various steps being shown in Figs. 1 to 3.

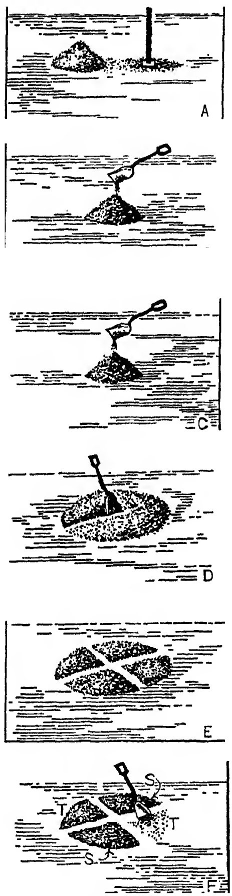
The gross sample shall be formed in a conical pile by depositing each shovelful on top of the preceding one (see Fig. 1B). It then is formed into a long pile by spreading a shovelful in a straight line, 5 to 10 ft. long, and of the width of the shovel (Fig. 1C), followed by a second shovelful, spread on top of the first, but in the opposite direction. The process is repeated, the pile occasionally being flattened, until all the coal has been formed in one long pile as at *N* in Fig. 1C. Half of the pile then is discarded by removing a shovelful from one corner of the pile and setting it aside, advancing along one side of the pile a distance equal to the width of the shovel and removing a second shovelful (Fig. 1D) and discarding it. The process is repeated, travelling around the pile, always in the same direction, until the pile has been divided into two equal parts. The two foregoing steps are repeated until sample has been reduced to 250 lb.

The 250 lb. sample then is reduced by quartering, as shown in Fig. 2, to obtain a 125 lb. sample. Samples of 125 to 250 lb. shall be thoroughly mixed by coning and reconing (Figs. 2B, 2C). Samples less than 125 lb. shall be mixed by rolling on a cloth (Fig. 3B) measuring about 6 × 8 ft., and then formed in a conical pile by gathering together the four corners of the cloth.

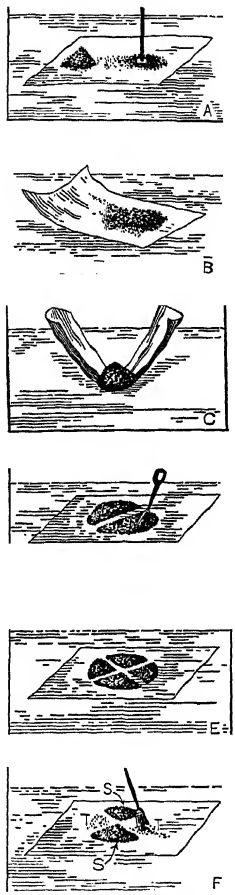
* This method is a modification of that worked out jointly by the Am. Chemical Society and the A.S.T.M. and described in A.S.T.M. specification D21-16.



1st and 2nd Stages



3rd Stage



4th, 5th, 6th Stages

FIG. 1A Crush sample
1B Cone sample
1C Mix in long pile
M—Spreading first shovelful
N—Pile completed
1D Halving by alternate shovelfuls
1E Reserved, M, shovelfuls 1, 3, 5
Rejected, N, shovelfuls 2, 4, 6

FIG. 2A Crush sample
2B Cone sample
2C Mix by forming new cone
2D Quarter after flattening cone
2E Sample quartered
2F Retain quarters SS
Reject quarters TT

FIG. 3A Crush sample
3B Mix by rolling on blanket
3C Form cone
3D Quarter after flattening cone
3E Sample quartered
3F Retain quarters SS
Reject quarters TT

Before each stage, sample is to be crushed to degree of fineness designated under Crushing.

Quartering is accomplished by flattening the cone, by pressing vertically downward with a board or shovel, and then marking it into quarters by two lines at right angles that intersect at a point corresponding to the apex of the original cone (Figs. 2 D, 2E). Diagonally opposite quarters are discarded. The quartering is repeated until a sample of the desired size is obtained. Six stages of obtaining a laboratory sample are shown in Figs. 1 to 3.

The laboratory sample immediately shall be divided into two parts, placed in suitable containers and so sealed as to preclude tampering. One container is sent to laboratory for analysis. The other is retained until the laboratory analysis is complete.

In collecting and reducing coke samples, all instruments for crushing shall be of iron or steel to permit removal by magnetic means of particles abraded from them.

DETERMINATION OF MOISTURE.—See p. 4–14.

PROXIMATE ANALYSIS.—See p. 4–14.

ULTIMATE ANALYSIS should be performed by a recognized laboratory. See A.S.M.E. Test Code for Solid Fuels and A.S.T.M. Specification D271–30 for procedure.

FUEL SIZING.—Gross samples shall be collected as above described, and passed over and through standard screens (see pp. 4–24, 4–35), and percentage by weight remaining

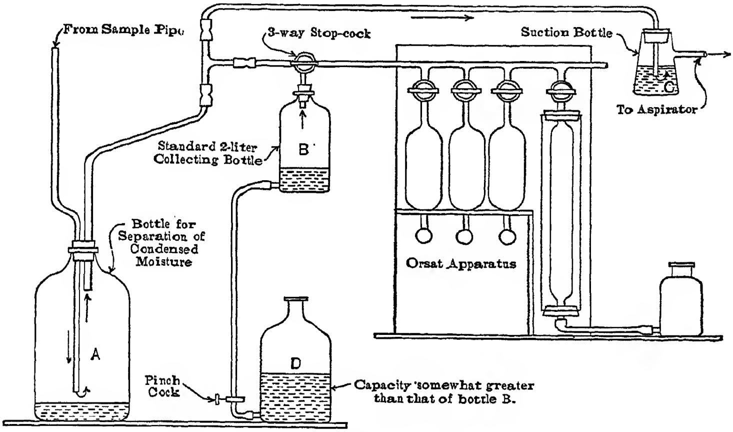


Fig. 4. Continuous Sampling Orsat Apparatus

over each screen determined. First screen in series shall be large enough to retain not over 5% by weight of total sample. Last screen will be of such size that not over 20% by weight of total sample will pass through.

In designating sizes of anthracite used for tests, size of perforations in screens through and over which the coal must pass should be definitely stated. Report should show percentage by weight passing over and retained by each size of screen.

FLUE GAS ANALYSIS shall be made by means of an Orsat apparatus, and shall determine CO_2, CO and O_2. If more than 0.5% CO is present, it shall be removed with two cuprous chloride pipes in the Orsat apparatus. If hydrogen is present, suitable apparatus, as the Orsat or Hempel should be used.

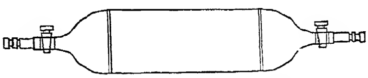

Fig. 5. Gas Sample Collecting Bottle

Sampling.—The standard sampler consists of single open-end iron, copper or glass exploring tubes (1/4 to 3/4 in. diam.). Ends of tubes are so placed that composition of sample is representative of gas being sampled. Fig. 4 shows apparatus, which draws a continuous sample from the main stream of gases. A small portion of this sample is drawn off continuously for 15 to 30 min. and then analyzed in the Orsat. If water is used in bottles *B* and *D*, it should be saturated with gas being analyzed, or concentrated brine may be used. If it is not feasible to draw sample directly into the Orsat, it should be collected at the aspirator in collecting bottles *B*, Fig. 4, or in tin or glass tubes, Fig. 5.

Gas samples may be collected in quantities proportioned to the rate of burning fuel, or in equal quantities at equal intervals. If the latter, average analysis must be determined by weighting the separate determinations proportionally to the weights of the fuel burned during the intervals of collecting samples from which analyses are made.

ASH.—Immediately on removal from ashpit, quench with water to stop further combustion. Method of collecting gross samples depends on whether or not total ash can be crushed.

Collection of Sample.—*Standard Method.* If total ash can be crushed to a maximum size of $^3/_4$ in., gross sample should be collected in increments of about 50 lb. per ton of ash, unless total gross sample is less than 1000 lb. In such event, increments shall be so increased as to give gross sample of 1000 lb. If total ash is less than 1000 lb., total ash is taken as gross sample. Sample shall be collected in galvanized iron cans with tight-fitting covers.

Alternate Method.—If crushing of ash in one operation is not feasible, separate clinker and fines by passing through a 2-in. mesh wire screen. Unburned combustible is to be separated by hand picking and added to fine ash. Weigh both clinker and fines, designating them as *weight of wet clinker from ashpit* and *weight of wet ash plus combustible from ashpit.* Crush and thoroughly mix separated clinker. Thoroughly mix wet ash. Mix crushed clinker and ash plus combustible in proportion, by weight, to the ratio of weight of wet clinker from ashpit and weight of wet ash plus combustible from ashpit. Weight increments in mixing process for gross sample shall be the same as in the standard method.

Moisture.—Sample to be taken from collected gross sample before crushing. A grab sample of 10 to 20 lb. will serve as moisture sample. Before taking it, mix gross sample by turning over several times with shovel.

To determine moisture, crush sample in jaw crusher to pass through a 4-mesh sieve, and reduce to a 5 lb. sample. Spread over galvanized iron pans (A.S.T.M. Specification D271–33) and place in an oven. Air is passed over samples at a maximum temperature of 200° F. until weight loss is not over 0.1% per hr.

Combustible in refuse shall be computed by means of difference in weight of total coal, computed weight of total dry ash from ultimate analysis, and weight of boiler refuse. Heating value of combustible is to be that of pure carbon.

To determine combustible in fuel sifting through grate, treat sifting sample according to method described in A.S.T.M. specification D271–33 for determination of ash in coal. Heating value of siftings shall be determined by the calorimetric method.

POWDERED COAL.—Ash. Gross samples from furnace shall be collected and weighed at convenient intervals, care being taken that none of the fine ash deposit is lost. Large slag formations should be broken down and weighed separately.

Gross ash samples from slack are best collected from a cinder catcher. No standard method is in use where a cinder catcher is not available. Methods that have been used successfully are those reported by the U. S. Bureau of Mines (Bull. 223), and that of the Chicago Dept. of Smoke Inspection (see 1915 Report of Chicago Assoc. of Commerce Committee on Smoke Abatement).

Laboratory samples of from 2 to 5 lb. from both gross ash slack and furnace samples shall be prepared by standard process of reducing, quartering and mixing. Slag to be analyzed shall be crushed to pass through a $^3/_{16}$-in. screen. Analysis of laboratory samples for combustible shall be by the standard method.

5. TEST CODE FOR LIQUID FUELS

Approved, 1930

The Test Code for Liquid Fuels is intended primarily to specify standard methods of determining those ascertainable chemical and physical properties which are extensively used in the generation of heat and power. The code consists essentially of the standards adopted by other societies, pertaining to the particular characteristic under investigation. Following is a list of the codes so adopted:

Methods of Collecting Samples: D270–27T, A.S.T.M.
Calorific Value: D240–27, A.S.T.M.
Gravity: Circular No. 154, National Standard Petroleum Oil Tables, Bureau of Standards; Bureau of Mines, Bull. No. 207.
Sulphur Content: D90–29T, A.S.T.M.; D129–27, A.S.T.M.
Water and Sediment: D95–28, A.S.T.M.; D96–28, A.S.T.M.
Viscosity: D88–26, A.S.T.M.
Distillation Range: D86–27, A.S.T.M.; D158–28, A.S.T.M.
Flash and Fire Points: D56–21, A.S.T.M.; D93–22, A.S.T.M.; D92–24, A.S.T.M.
Cloud and Pour Points: D97–28 A.S.T.M.
Color: D156–23T A.S.T.M.
Corrosion: D130–27T A.S.T.M.
Acidity: Method 510.0, Bureau of Mines, Technical Paper No. 323B.
Burning Quality of Wick Burners: D187–27, A.S.T.M.
Carbon Residue: D189–28, A.S.T.M.
Quantity Measurements: Circular No. 154, Bureau of Standards, National Standard Petroleum Oil Tables.

6. TEST CODE FOR STATIONARY STEAM-GENERATING UNITS

Approved, 1930

DEFINITION.—A steam-generating unit is a combination of apparatus for producing, furnishing, or recovering heat, together with apparatus for transferring the heat so made available to the fluid being heated and vaporized. Such a unit will include boiler, water walls, water floor, water screen, superheater, reheater, economizer, air heater, furnace and fuel burning equipment. The economizer and air heater are not included when the heat absorbed by them is not returned to the unit. This code applies to all of the component parts as above defined but not to the apparatus required for their operation.

Economizers may be classified as: *a*. Separate economizers, with their own housing and connected to the boiler by flues; *b*. integral economizers contained within the boiler setting and through which a part of the boiler circulating water may or may not pass.

When testing steam boilers equipped with class *a* economizers, observations may be separated either to include or exclude the economizer in the test results. With class *b* economizers, it is practically impossible to separate the economizer from the boiler, and tests of units so equipped should be conducted and reported as if the economizer was a part of the boiler.

PRECISION OF RESULTS.—The absolute accuracy of the results of a steam-generating unit test is doubtful. There is as yet no possible basis upon which to determine what the probable limit of errors might be. The more important of several sources of indeterminate error are discussed below. The limits of accuracy of a test reasonably may be taken to be within $\pm 3\%$.

SOURCES OF ERROR.—One source of probable error is the sampling of coal. Another source of error is the moisture contained in the coal. Despite the greatest care taken to obtain a representative sample, there may be an indeterminate error in the heating value of the coal, even though the laboratory determination is substantially correct as regards sample tested.

Similarly, it is problematical whether or not samples collected for determination of moisture in steam, and for gas analyses, are representative of the bulk.

While heat balances often are reported to the nearest B.t.u. and to the nearest 1/100 of 1%, the present state of the art does not provide means for attaining such accuracy. In general, results should be reported only to the nearest significant figure.

MEASUREMENTS listed below are the principal ones which must be made in a performance test of a stationary steam-generating unit: *a*. Area of heating surfaces; *b*. grate surface; *c*. furnace volume and dimensions; *d*. analysis and heating value of fuel; *e*. steam pressure; *f*. quality of steam; *g*. analysis of gases; *h*. draft pressures; *i*. steam temperatures; *j*. superheat; *k*. air temperatures; *l*. gas temperatures; *m*. feed-water temperatures; *n*. weight of fuel; *o*. weight of refuse; *p*. analysis of refuse; *q*. weight of water.

INSTRUMENTS AND APPARATUS required for boiler tests are: *a*. Scales for weighing coal, oil or other fuel, ashes, furnace refuse, etc.; *b*. graduated scales for water level measurements; *c*. tanks and scales for volumetric or weight measurement of water; *d*. meters or other apparatus for measuring gaseous fuels; *e*. pressure and draft gages; *f*. thermometers and pyrometers; *g*. calorimeter for determining quality of steam; *h*. gas sampling and analyzing apparatus. As no two plants are alike, the location of the various instruments only can be suggested.

Fuel Weighing Apparatus should be near point where fuel is to be used, and under direct observation of person in charge of test. Refuse may be weighed at any convenient point.

Water-level Scales should be so attached that breaking of water-glass will not disturb scales.

Water Weighing Apparatus, or apparatus for volumetric measurement, should be easily accessible and under direct observation of person in charge of test.

Gas Meters or other apparatus for measuring gaseous fuels may be located as conditions dictate.

Gages.—Pressure gages should be away from disturbing influences, such as extreme heat, and in a position to be read easily. Draft gages should be at not less than two points: (1) After the flue gas has passed beyond contact with any part of the boiler, and before it has passed the damper, or entered the outlet duct if there is no damper; (2) in the furnace immediately before the flue gas comes in contact with the heating surface of the boiler proper. Draft gages may be located at such other points as may be necessary to ascertain draft in various parts of the boiler.

Temperatures.—Feedwater temperatures should be measured as close to boiler inlet as possible. The pipe between boiler and thermometer should be protected with heat insulation. Saturated steam temperatures may be measured at any point in steam pipe where pressure is same as that at the point where the temperature is desired. Condensate must not be allowed to cool the thermometer well. Temperature and pressure of superheated steam should be measured as close to outlet of superheater as possible. Pyrometers must have the part on which heat impinges so located that temperature which it is desired to measure actually is obtained. Thermometers for determining atmospheric temperatures should be so placed as to give average indication, away from cold or hot air currents, surfaces, etc. For design of thermometer wells, methods of calibrating thermometers and pyrometers, see pp. 3–05 to 3–09.

Steam Calorimeter sampling tubes should be as close as possible to point at which quality of steam is desired. Usually, quality of steam leaving boiler or entering superheater is determined.

Flue Gas Analysis usually is made at point of exit of the gases. Frequently, analyses are desired at other points. Sample tubes must be so located that only the gas to be analyzed enters. The apparatus should be readily accessible and provided with good light.

STARTING AND STOPPING.—Combustion, fuel, draft and temperature conditions, water level, rate of feeding water, rate of steaming, and steam pressure should be as nearly as possible the same at the end as at the beginning of the test. If an economizer is included, the average temperature of the water in it should be the same at the start and end of the test.

Hand Firing.—To obtain equality of conditions with hand fired units, the following method should be used:

Heat the furnace by a preliminary run at the same combustion rate that will prevail during the test, and sufficiently long to thoroughly heat the setting. Burn the fire low and thoroughly clean it, leaving from 2 to 4 in. of live coal spread evenly over the grate. Estimate thickness of coal bed, note water level, steam pressure and time. Record the latter as starting time of test. Fresh coal then should be fired from that weighed for the test, the ashpit thoroughly cleaned and the regular test observations begun.

To end test, burn fire low and so clean it as to leave on the grate the same amount of live coal as at the start. When this condition is reached, note water level, steam pressure and time. Record the latter as stopping time. If water level is lower or higher than at beginning, make correction by computation and not by feeding additional water. Remove ashes and refuse from ashpit.

If several boilers are under test and it is impracticable to clean them simultaneously, fires should be cleaned one after another as rapidly as possible, and each one, after cleaning, charged with enough coal to maintain a thin fire in good working condition. After last fire is cleaned, burn all fires to 4 to 6 in. thick. Note thickness of each, the water levels, steam pressure and time. The latter is the starting time. To stop test, repeat procedure and make final observations.

Mechanical Stokers require a modification of the above procedure as follows:

Stokers should be in operation at approximately the same rate as will prevail during test for at least 12 hr. before starting test. At start and finish of test, level coal in stoker hopper. Make starting and stopping observations as in hand-fired tests.

With continuous dumping stokers, desired operating conditions should be maintained as nearly constant as possible for at least 1 hr., and preferably for 2 hr., before starting and stopping test. With intermittent dumping stokers, proceed as above, except that stokers should be cleaned about 1 hr. before starting and before stopping test.

Pulverized, Liquid or Gaseous Fuel.—Boiler to be tested should be operated for not less than 3 hr. before start of test, under the same fuel, furnace and combustion conditions that are to be maintained throughout. Fuel temperature, fuel pressure and draft conditions to be kept as nearly constant as possible during this period and throughout the test. The same observations as are made for starting and stopping hand-fired tests are made for pulverized, liquid and gaseous fuel tests.

DURATION of test to determine efficiency of a steam-generating unit burning coal, either hand- or stoker-fired, preferably should be 24 hr. Where operating conditions do not permit, the length of test may be reduced to not less than 10 hr. When rate of combustion is less than 25 lb. of coal per sq. ft. of grate surface per hr., the test should continue until 250 lb. per sq. ft. of grate surface has been burned, except that where a type of stoker is used that does not permit either or both quantity of fuel and the condition of the fuel bed to be accurately estimated, duration of test should not be reduced below that required to minimize the error.

Duration of tests of units using pulverized fuel should be not less than 6 hr.; with liquid or gaseous fuels, not less than 4 hr.

Duration of test of waste heat boilers or steam-generating units in connection with an industrial furnace, whose operation is continuous with constant furnace conditions, should be not less than 6 hr. If the industrial furnace operates in cycles, duration of the test should cover at least one cycle of furnace operation, with start and end of test at same point in cycle.

Duration of tests conducted under plant operation conditions where the service requires 24 hr. operation, with frequent shifts of firemen, should be at least 24 hr. Duration should be not less than 24 hr. when the unit operates regularly a certain number of hours and during the remainder of the day is banked.

Duration of test to determine maximum evaporative capacity, when efficiency is not determined, should be not less than 2 hr.

RECORDS.—Readings of instruments at 15 min. intervals usually are sufficient. With sudden and wide fluctuations, readings should be taken at 10 min. intervals, or intervals short enough to determine a true average.

Fuel.—Approximate quantity of fuel needed each hour should be determined and, if possible, delivered on firing floor at beginning of the hour. If the whole amount cannot be delivered at

beginning of the hour, convenient quantities should be weighed out at appropriate intervals. Quantity of fuel left on floor at end of the hour should be estimated.

When hopper scales are used, receiving coal from bunkers and discharging directly into furnace hoppers, hourly quantities may be roughly determined by estimating furnace conditions.

Hourly quantities should be properly noted on the log sheet, but only totals are to be used in final calculations.

Steam Rate.—Records should be so kept as to ascertain the approximate consumption of feed-water each hour and thereby determine the degree of uniformity of evaporation.

Sampling of Fuel should be done regularly throughout the test for purposes of analysis. See Test Code for Solid Fuels, p. 16–09.

Ashes and Refuse withdrawn from the furnace and ashpit during and at the end of the test should be weighed, if possible, in dry condition. If wet, the amount of moisture should be ascertained and allowed for, a sample being taken and dried for this purpose.

Ash sampling at best is subject to large errors and precautions should be taken to obtain as representative a sample as possible. If ash is sufficiently hot to allow combustion, it should be quenched with water immediately after dumping. Ash should not be weighed until heat of the refuse has driven off most of this moisture. If possible, ash should be crushed, mixed, and reduced to a laboratory size sample by successive quartering. If crushing is impracticable, clinkers and fines should be separated and each pile weighed and sampled separately. The two samples are then combined in proportion to the relative weights of the respective piles.

Where loss in cinders, soot and fly ash is important, amount and heat value of such materials should be determined separately from ashpit refuse.

Flue Gas Analyses should be made by the Orsat apparatus or some modification thereof. Gas samples preferably should be taken continuously. If momentary samples are obtained, analyses should be made as frequently as possible, noting furnace and firing conditions at time samples are drawn. Where firing is intermittent, samples should be taken at such intervals that the complete firing cycle will be covered by the average of individual readings.

Smoke Observations, when required, should be made regularly throughout the test at intervals of 5 min. or, if necessary, of 1 min.

DATA AND RESULTS should be reported in accordance with the following form. Items of data not provided for may be added, or if certain items are not required, they may be omitted. Unless otherwise indicated, quantities recorded should be the average of the observations.

Computations for Test of Stationary Steam-generating Unit

Test may be on an "as fired" or "dry" basis. If on an "as fired" basis the word "dry" should be eliminated wherever it appears in the report form and *vice versa*. The basis chosen must be followed throughout the computations.

Notation.—CO_2, CO, O_2, N_2 = respectively percentage, by volume, in gases of combustion of carbon dioxide, carbon monoxide, oxygen and nitrogen. C = carbon content per lb. of fuel gas = ($^3/_7$ item 47 + $^3/_4$ item 49 + $^{12}/_{13}$ item 50 + $^6/_7$ item 51 + $^4/_5$ item 52 + $^3/_{11}$ item 56) (by weight); H = total heat of saturated steam at boiler outlet pressure; H_1 = total heat of superheated steam at superheater outlet pressure; H_2, H_3 = total heat of steam at reheater inlet and outlet pressures, respectively; h = total heat in feedwater at boiler inlet; h_1 = total heat in feedwater at economizer inlet; L = latent heat in steam at pressure in steam main. All heats are in B.t.u. per lb. t_s = temperature of steam after expansion in calorimeter; t_1 to t_{12} = (see items 88 to 99); kB. = 1000 B.t.u. Italic figures below refer to item numbers in the Data and Results form p. 16–15.

Item No.

30–4 Solid Fuels = dry-analysis items × {1 − (item *33*/100)}

33–44 Liquid Fuels = dry analysis items × {1 − (item *33*/100)}

46–60 Liquid Fuels. Should be reported, and B.t.u. value calculated, on dry basis. Calorimeter determination should be corrected for moisture. If $t_{12} > t_1$, add to calculated B.t.u. value, mean specific heat × $(t_{12} - t_1)$. Standard conditions are 29.92 in. Hg and 68° F. Use data items *61–64*

58 = Item *57*/item *59*

60 = Item *48* + $^1/_4$ item *49* + $^1/_{13}$ item *50* + $^1/_7$ item *51* + $^1/_5$ item *52* + $^1/_{17}$ item *53*

65–68 Solid Fuels = $[\{11CO_2 + 8O_2 + 7(CO + N_2)\}/\{3(CO_2 + CO)\}]$ × item *126*

Liquid Fuels = $[\{11CO_2 + 8O_2 + 7(CO + N_2)\}/\{3(CO_2 + CO)\}]$ × (item *39*/100)

Gaseous Fuels = $[\{11CO_2 + 8O_2 + 7(CO + N_2)\}/\{3(CO_2 + CO)\}] \times C$

69 Solid Fuels = 12.52 × item *126* + {(26.56 × item *40* + 5.325 × item *44* + it

Liquid Fuels = (12.52 × item *39* + 26.56 × item *40* + item *42* + 5.325 × item

Gaseous Fuels = {(3.46 × item *47* + 26.56 × item *48* + 16.03 × item *49*)/100}
+ {(13.60 × item *50* + 14.52 × item *51* + 15.33 × item *52*)/100}
+ {(6.57 × item *53* + item *55* + item *56*)/100} (by weight)

70 Solid Fuels = Item *65* + {(9 × item *40*)/100} − {(100 − item *124*)/100}

Liquid Fuels = Item *65* + {(9 × item *40*)/100} − 1

Gaseous Fuels = Item *65* + (9 × item *60*) − 1

84 Determined by charts or throttling calorimeter. Formula used with latter is
$100 \times \{H - 1150.4 - 0.47 \times (t_s - 212)\}/L$

112 = (combined weight of ashes and cinders collected from all sources during test) ÷ item *78*, or,
= {Item *32*/(100 − item *125*)} × item *101* (or *102*)

115 = $(h - h_1)$

116 = $(H - h)$

117 = $(H_1 - h)$

118 = $(H_3 - H_2)$

119 = (Item *113* × item *115*)/1000

120 = (Item *113* × item *116*)/1000

121 = (Item *113* × item *117*)/1000

122 = (Item *114* × item *118*)/1000

123 = (Item *119* + item *120* + item *121* + item *122*)

124 = Item *112*/item *101* (or *102*)

126 = (Item *39*/100) − (item *124* × item *125*/10,000)

Gaseous Fuels = {Item *127* (or *128*) × 1000/item *58* (or *57*)} × 100

132 Solid and Liquid Fuels = (Item *127*×1000×100)/{item *34*+(t_4-70) × (item *70* × 0.24)}, or
= (Item *128*×1000×1000)/{item *35*+(t_4-70)×(item *70*×0.24)}

Gaseous Fuels = (Item *127* × 1000 × 100)/{item *58* + $(t_4 - 70)$ × (item *70* × 0.24)}, or
= (Item *128* × 1000 × 100)/{item *57* + $(t_4 - 70)$ × (item *70* × 0.24)}

HEAT BALANCE—SHORT FORM

NOTE. The code gives additional more elaborate heat balance forms for units comprising boiler, superheater and reheater, with or without integral economizer; for units comprising boiler, superheater, reheater and economizer; for units comprising boiler, superheater, reheater, economizer and air heater. These are omitted here, and the reader is referred to the code for them. For all except the most elaborate tests, the short form is sufficiently comprehensive.

148	...	...	{(Item *124* − item *32*)/100} $\times$ 14,600
149	...	...	Item *34* (or *35*) − {(items *134* + *135* + *136* + *137* + *138* + *139* + *141* + *143* + *144*)}
...	150	...	Item *34* (or *35*) − {(items *134* + *135* + *136* + *137* + *138* + *139* + *141* + *143* + *144*)}
...	.	151	Item *58* − {items (*134* + *135* + *136* + *137* + *138* + *140* + *142* + *143* + *144*)}

NOTES: *a*. If economizer is installed without air heater, substitute t_7 for t_6; if air heater is installed, substitute t_8 for t_6 in items *139*, *141*, *143*, *144* (for items *140*, *142*, *143*, *144* with gaseous fuels). *b*. This loss is small and often is included in item *144*. *c*. If boiler and superheater, use item *66*; if economizer, use item *67*; if air heater, use item *68*. *d*. If boiler alone, use analysis from item *62*; if economizer, use item *63*; if air heater, use item *64*.

7. TEST CODE FOR FEEDWATER HEATERS

Approved, 1925

This code applies to open and closed boiler feedwater heaters and, with slight modifications, it may apply to heaters for heating water for any purpose when the heating element is either live or exhaust steam.

OBJECT usually is to determine: *a.* Whether heater meets design conditions. *b.* The variation, with capacity, of temperature rise of water and friction drop in water in closed heaters. *c.* The closeness with which outlet water temperature approaches steam temperature corresponding to pressure in the open heater.

INSTRUMENTS AND APPARATUS required for a heater test comprise:

a. Barometer, preferably mercurial. *b.* Mercury columns for measuring vacua and low pressures, having scale variations not greater than 0.01 in. with vernier attachments. *c.* Bourdon gages for measuring pressures too high for mercury columns. *d.* Thermometers graduated by 1/2 deg., with scale readings from 32° to 350° F. for determining temperatures of feedwater, condensate and vapors, and graduated by 1 deg., with scale readings from 32° to 350° F. for determining steam temperatures. *e.* Tanks and platform scales for measuring water, or water meters cali-

DATA AND RESULTS OF TEST OF OPEN FEEDWATER HEATERS

28	Duration of test	
29	Barometer	in. Hg
30	Room temperature	deg. F.
31	Quantity of water admitted to heater	lb. per hr.
32	Inlet-water temperature	deg. F.
33	Outlet-water temperature	deg. F.
34	Steam pressure in heater, gage............lb. per sq. in., or	in. of Hg
35	Steam temperature in heater, by thermometer	deg. F.
36	Steam temperature at inlet, by thermometer	deg. F.
37	Steam used per hour	lb.
38	Total water discharged from heater	lb. per hr.
39	Volume of water in mixing compartment of heater	cu ft.
40	Volume of water in storage compartment of heater	cu ft.
41	Pressure drop from steam end of heater to vent end	
42	Time lag between occurrence of steam deficiency and change of outlet temperature	
43	Analysis of water entering heater	
44	Analysis of water leaving heater	
45	Oxygen content of water entering heater	
46	Oxygen content of water leaving heater	
	COMPUTED AND DEDUCED DATA	
47	Steam temperature corresponding to absolute pressure	deg. F.
48	Quality of steam supplied to heater	percent moisture or deg. superheat
49	Temperature difference between steam temperature corresponding to heater pressure and outlet water temperature	deg.F.
50	Lb. steam theoretically required per lb. water	
51	Lb. steam used per lb. water, actual	
52	Time required to empty heater when operating at rated capacity	
53	Steam lost up stack	lb. per hr.

brated in place under conditions of use. *f.* Steam calorimeter, throttling or separating. *g.* Apparatus for testing oxygen content of water.

It is desirable that wherever possible rate of water flow, pressures and temperatures be obtained by continuous recording instruments, in addition to observations made by instruments for instantaneous measurement.

OPEN HEATERS may be designed to heat water within a few degrees of the steam temperature corresponding to pressure in heater. Since in most open heaters water is filtered or treated as well as heated, arrangements should be made to obtain analyses of water entering and leaving heater. When these heaters are used for partial deaeration of water, means should be provided to sample water and determine its oxygen content.

51	Steam temperature in heater corresponding to absolute steam pressure	deg. F.
52	Quality of steam supplied to heater	percent moisture or deg. superheat
53	Temperature rise	deg. F.
54	Logarithmic heat-transfer coefficient, B.t.u. per hour per sq. ft. of surface, per degree of logarithmic mean temperature difference.	
55	Weight of steam theoretically required per lb. of water, computed from heat balance	lb
56	Weight of steam used per lb. of water	lb.
57	Water-pressure drop in heater	lb. per sq. in.
58	Steam lost up stack	lb. per hr

It is important to determine time required to empty heater under normal operating conditions in event of failure of water supply to heater, in order to establish rated capacity and size of heater. Equally important in establishing capacity is time lag between occurrence of insufficient steam for a desired outlet temperature and appearance of improper temperature at water outlet. The test, if possible, should determine these items in terms of definite rates and temperatures.

CLOSED HEATERS have a definite relation between capacity and outlet water temperature, determined by ability of the surface to transfer heat as measured by the heat transfer coefficient. The principal items affecting value of this coefficient are tube type, length and arrangement, water velocity, condition of tubes as regards presence of a film of scale, oil or dirt, and presence of accumulated air in steam space of heater. During tests, the shell should be thoroughly drained of condensate and vented air. Accessories necessary for good operation are pressure gages, thermometers, safety valves, vacuum breaker, water gage glass and trap. The thermometer in the steam space must not be installed where there is liable to be an air pocket or near a cold water manifold. If near cold tubes, it must be shielded for radiation.

CALCULATION OF RESULTS.—Logarithmic heat transfer coefficient is computed by

$$K = (w/S)\log_e\{(T - T_i)/(T_s - T_o)\}$$

where K = heat transfer coefficient, B.t.u. per hr. per sq. ft. of surface per deg. F. of logarithmic mean temperature difference; w = water per hr., lb.; S = heating surface measured on outside of tubes, sq. ft.; T_s = steam temperature in heater, deg. F. (if superheated steam is supplied, use temperature of saturated steam at pressure in heater); T_i, T_o = inlet and outlet water temperatures, respectively, deg. F.

Heat transfer coefficient when plotted against velocity of water in the tube gives a straight line on logarithmic paper, from which data may be obtained for determining constants in the equation $K = av^n$, where v = velocity of water, ft. per sec.

Friction drop when plotted against velocity usually gives a straight line on logarithmic paper, which serves to determine constants in friction drop formula, $H = bLv^m$, where H = total friction drop, lb. per sq. in., L = length of tube, ft. (if multi-pass, length of total path of travel of water in heater); v = velocity of water ft. per sec. Constants obtained in these formulas may be used to compare performance of heater under test with that of other heaters.

Record.—Observations and computed and deduced data should be recorded in the accompanying forms, for open and closed feedwater heaters, respectively.

8. TESTS FOR STEAM TURBINES AND TURBO-GENERATORS

Tentative,

The object of the tests may be to verify guarantees as to output, steam or heat consumption, or emergency governor operation. The Code provides rules for the tests of complete expansion and of other types of turbines.

Before tests are started, the two parties should enter into a written agreement regarding the object of the test, the methods to be employed in conducting the test, particularly where the Code permits the use of alternate methods, the magnitude of the corrections to be applied for variations from test conditions, and the method of applying these corrections; and upon the party who shall direct and carry out the test. Acceptance tests should be made within two months after the turbine enters commercial service. Preliminary tests may be run to determine whether the turbine is in suitable condition for the test, to check instruments, and to train personnel.

Conditions shall be caused to become as nearly constant as possible before the test begins and shall be so maintained during the test within limitations specified. No tests shall be made if the steam is not superheated where the initial pressure is measured.

Only accurate and reliable instruments shall be used, and these shall be calibrated both before and after the tests. Duplicate instruments shall be provided for those liable to breakage or failure. Only such observations are needed that apply and are necessary for the object of the test.

Condenser leakage during a test shall be determined when the condensate is measured, by silver nitrate, electrolytic conductance, or direct weight methods. The limit of permissible leakage with turbines over 1000 kw. is 0.3%.

Among the apparatus and instruments required for a performance test of a steam turbine or turbo-generator are: 1. A dynamometer (for a turbine alone); 2. Electrical instruments to measure the output of a turbo-generator; 3. Weighing or volumetric tanks for a condenser; 4. Water weighing and measuring tanks to an isolated boiler for a noncondensing turbine; 5. Bourdon gages; 6. Mercury manometers; 7. Thermometers or other temperature measuring instruments; 8. Speed indicators; 9. Clock or synchronized

watches; 10. Steam tables and charts (preferably Keenan's); 11. Nozzles or orifices for tests on certain types of turbines.

In general the rules of the A.I.E.E. governing the measurement of output of generators shall be followed in turbo-generator tests.

The duration of tests shall be: 1. Six hours in the case of measurement of feedwater to a boiler; 2. One hour for tests with weighed or measured condensate; 3. Seven consecutive sets of simultaneous readings for nozzle or orifice methods.

In tests involving the measurement of condensate, any leakage around pump glands or elsewhere must be carefully checked. The Code provides detailed instructions for methods of measuring electrical output, weight of condensate, leakage, and measurements of high and low pressures, temperatures, speed, and time.

HEAT CONSUMPTION of a turbine in B.t.u. per kw-hr. is expressed:

For a complete expansion, heat rate $= W_1(h_1 - h_4)/\mathrm{kw}_g$

For reheating without feedwater heating, heat rate $= \{W_1(h_1 - h_4) + W_3(h_3 - h_2)\}/\mathrm{kw}_g$.

For a regenerative turbine, heat rate

$$+ \{(h_8 - h_7) - \frac{144V(p_8 - ?}{778.6} \quad \frac{W_7}{2}$$

For a regenerative-reheating turbine, heat rate

778.6

where W_1 = weight of steam entering turbine; W_3 = weight of steam from reheater to turbine; W_6 = weight of feedwater discharged from final heater; W_5 = weight of condensate discharged from condenser; W_7 = weight of feedwater through any pump intermediate the condenser and final heater; h_1 = total heat of steam supplied; h_4 = heat of liquid at temperature corresponding to exhaust pressure; h_3 = total heat of steam returned from reheater; h_2 = total heat of steam to reheater; h_6 = heat in feedwater discharged from final heater; h_5 = heat of water of condensate; h_7 = heat of feedwater at inlet of pump; h_8 = heat of feedwater at outlet of pump; V = specific volume of 1 lb. of feedwater at mean temperature at pump, cu. ft. per lb.; p_7 = pressure at the inlet to the pump; p_8 = pressure at the discharge to the pump; kw_g = output measured at the generator terminals, kw.

All weights are in lb. per hr.; all heats in B.t.u. per lb. and all pressures in lb. per sq. in., abs.

Heat rates for bleeder and mixed pressure turbines are based on the energy from adiabatic heat drops of the various sections. See Code.

COMPUTATION OF RESULTS.—a. Complete Expansion Turbines may have their performances expressed alternatively as a *steam* or a *heat rate*. In the steam rate test, the turbine is charged with the net steam quantity supplied. In the heat rate test, the turbine is charged with the total heat supplied, and credited with the total heat of the water at the boiling temperature corresponding to the exhaust pressure.

b. Condensing Turbines Combined with Reheating have their performances expressed only as a heat rate, the turbine being charged with the initial total heat of the steam supplied plus the heat added by the reheater, and credited with the total heat of the water at the boiling temperature corresponding to the exhaust pressure.

c. Condensing Regenerative Turbines with Extraction for Heating Feedwater have their performances expressed: 1. As a heat rate, the turbine being charged with the total heat of the steam supplied, and credited with the total heat of the feedwater leaving the final heater, with an allowance should the temperature of the condensate be below that corresponding to the exhaust pressure, and also allowance for pump energy, or (2) as a steam rate in the same manner as for type *a*, the test being carried out with the heaters blanked off.

d. Condensing Turbines with Both Reheating and Extraction for Heating Feedwater have their performances expressed only as a heat rate, the turbine being charged with the initial total heat of the steam supplied plus the heat added by the reheater, and credited with the total heat of the feedwater leaving the final heater, with an allowance should the temperature of the condensate be below that corresponding to exhaust pressure, and also allowance for pump energy.

e. Non-condensing and Back-pressure Turbines have their performances expressed as a steam rate, the turbine being charged with the net steam quantity supplied.

f. Bleeder and Mixed-pressure Turbines have their performances expressed only as a heat rate, the turbine being charged with the sum of the calculated adiabatic heat drops of the quantities of steam at the respective flows.

Total steam chargeable to the turbine shall be only that which passes through the turbine throttle.

The Code gives complete directions regarding the corrections that may be applied to tests to reduce them to standard conditions and on how these shall be applied.

The following tabulation presents in abstract certain of the data and results that are shown in the complete Report of Tests in the Code, to which reference should be made for the complete form.

DATA AND RESULTS OF CONDENSING TURBINE TESTS

Item

Date of test..

Location..

Owner..

Builder..

Test conducted by..

Object of test..

Statement describing installation as regards type of turbine, condensing or non-condensing, bleeder or mixed-pressure (impulse or reaction), steam flow, number and arrangements of cylinders, reheating, regenerative feedwater heating (number and arrangement of feed heating stages), etc.

Specified operating conditions and guarantees for the particular turbine under test, together with a complete statement of the agreed corrections and whether each applies to steam or heat consumption.

Statement of conditions prevailing during the test including remarks as to test operating conditions, load at which test is made and its percent of maximum continuous rating, character of load, number of governor-controlled valves and extent of opening, disposition of any manually-operated valves and extent of opening, description of method of sealing shaft glands, stating origin of sealing steam, and disposition of leak-off steam.

10 Description of methods of measurement employed for the determination of steam quantities, output, and exhaust pressure, of methods of measurement differing from the rules prescribed in the Code, which methods have been agreed to by the parties to the test, alternative method employed where alternative methods are permissible, identification of calibration certificates and by whom made, and steam tables employed in the calculation of test results.

MEAN OBSERVATIONS DERIVED FROM LOG SHEETS

(All Calibrations Having Been Applied)

11 Duration of test.. hr.

12 Initial steam pressure.. lb. per sq. in., abs.

13 Initial steam temperature.. deg. F.

14 Barometric pressure as observed.. in. Hg

15 Vacuum at exhaust flange as observed by mercury columns.. in. Hg

16 Temperature of mercury columns.. deg. F.

17 Vacuum at exhaust flange, corrected.. in. Hg

18 Absolute pressure at exhaust flange.. lb. per sq. in., abs.

19 Temperature corresponding to the absolute exhaust pressure at exhaust flange (from steam tables).. deg. F.

20 Temperature of condensate leaving condenser.. deg. F.

21 Temperature of feedwater leaving final heater.. deg. F.

22 Pressure of feedwater leaving last heater.. lb. per sq. in., abs.

23 Speed.. r.p.m.

24 Reheater observations at test load including conditions at inlet and outlet, of absolute pressure, temperature, B.t.u. per lb., quantity in lb., and pressure drop through reheaters.

MEASUREMENT OF STEAM

25 Quantity of steam abstracted between initial admission and reheater (if any).. lb. per hr.

26 Total condensate or feedwater quantity as measured.. lb. per hr.

27 Additions to or deductions from the measured quantity, such as condenser leakage, condensate pump leakage, steam from ejectors, make-up water, steam from auxiliaries, sealing water, etc.. lb. per hr.

28 Total net condensate or steam conumption (Item 26 ± algebraic sum of Item 27).. lb. per hr.

MEASUREMENT OF OUTPUT

29 Mean output at electrical terminals..........kw......, ...kva. at.... power factor

30 Mean output at turbine coupling.. kw.

DATA AND RESULTS OF CONDENSING TURBINE TESTS (*Continued*)

Item

CORRECTIONS

31 Corrections to reduce the measured steam (or heat) consumption to that conditions, including corrections for: *a*, Initial steam pressure; *b*, initial steam temperature; *c*, exhaust pressure; *d*, superheat of steam entering turbine from reheater; *e*, pressure drop between turbine outlet and inlet from reheater; *f*, feedwater discharge temperature; *g*, speed; *h*, power factor; *j*, load correction.
Aggregate correction divisor ....

STEAM CONSUMPTION

33 Steam consumption under test operating conditions:
a, at electrical terminals .... lb. per kw-hr.
b, at turbine coupling .... lb. per kw-hr.
34 Steam consumption corrected to specified operating conditions except for load correction:
a, at electrical terminals .... lb. per kw-hr.
b, at turbine coupling .... lb. per kw-hr.
35 Steam consumption with load correction applied:
a, at electrical terminals .... lb. per kw-hr.
b, at turbine coupling .... lb. per kw-hr.

HEAT

36 Total heat of initial steam supplied .... B.t.u. per lb.
37 Total heat of water at temperature corresponding to exhaust pressure .... B.t.u. per lb.
38 Total heat of condensate at measured temperature .... B.t.u. per lb.
39 Total heat of feedwater at discharge from final heater at the measured temperature and pressure .... B.t.u. per lb.
40 Total net heat supplied under the operating conditions of the test .... B.t.u. per hr.
41 Heat consumption under the operating conditions of the test:
a, at electrical terminals .... B.t.u. per kw-hr.
b, at turbine coupling .... B.t.u. per kw-hr.
42 Heat consumption corrected to the specified operating conditions except for load correction:
a, at electrical terminals .... B.t.u. per kw-hr.
b, at turbine coupling .... B.t.u. per kw-hr.
43 Heat consumption with load correction applied:
a, electrical terminals .... B.t.u. per kw-hr.
b, at turbine coupling .... B.t.u. per kw-hr.

TESTS OF EMERGENCY GOVERNOR OPERATION

44 Turbine speed at which emergency governor operates .... r.p.m.
45 Emergency speed of turbine. The extreme speed of the turbine when accelerated from below normal speed with internal pressure corresponding to that of the maximum continuous rating, not exceeding specified exhaust pressure, no load, and without main governor control .... percent
46 Percentage overspeed of the turbine at which the emergency governor operates .. percent
47 Percentage emergency overspeed reached by the turbine when accelerated with specified initial and exhaust pressure, no load, and without main governor control .... percent

The Code also gives tables and methods for reporting tests of bleeder turbines and mixed-pressure turbines, which are not abstracted here. Useful appendices to the Code give numerical examples of test data and corrections, and show in detail how the final results are computed. These include: 1. A simple condensing turbine; 2. A turbine with one stage of reheating and three stages of feedwater heaters; 3. A condensing bleeder turbine with steam extracted for industrial or other purposes at two pressures; 4. A mixed-pressure turbine with two admission points for lower pressure steam than at the throttle.

9. TEST CODE FOR RECIPROCATING STEAM ENGINES

Approved, 1935

OBJECT AND SCOPE of test should be recorded as the verification of manufacturer's guarantees, or determination of: *a.* thermal-economy characteristics of the engine (heat rate, steam rate, or both); *b.* capacity in brake or indicated horsepower or kilowatt output; *c.* verification of special guarantees or other data, which are subjects of written agreement by both parties to the test.

DEFINITIONS.—**Throttle Pressure** is average pressure on boiler side of, and directly preceding, throttle valve during steam admission period, *i.e.*, from start of admission to cut-off.

Exhaust Pressure is average pressure at outlet side of, and adjacent to, exhaust nozzle during exhaust period, *i.e.*, from dead-center point immediately after release to beginning of compression.

Engine Output is power developed, expressed in indicated or brake or shaft horsepower. Output at coupling may be expressed in kilowatts.

Electrical Output is net output of generator in kilowatts at generator terminals. For a direct-current generator this is (corrected terminal volts × amperes) ÷ 1000. For an alternating current generator, it is {(electrical power output of generator, kw.) − (excitation power separately supplied, kw.) − (power for ventilation separately supplied, kw.)}.

PREPARATIONS.—The engine should be put in proper operating condition by the manufacturer; all unused connections should be blanked off or connections so broken that outlets are under constant supervision.

Cylinder Dimensions should be taken when engine is cold, and suitable corrections applied to conform with mean working temperature, which is the mean of saturation temperatures corresponding to throttle and exhaust pressures. Average diameter of much-worn cylinders should be found. Clearance volumes need not be found unless they are guaranteed or test conditions require them.

Leakage of pistons and valves is included in total steam consumption and need not be found. Valve stem and piston rod leakage should be measured and included in steam consumption. Condenser leakage must be determined if steam is measured by weighing or measuring condensate (see p. 16–31). Maximum permissible condenser leakage, in percentage of flow at rated load as stated in steam rate guarantee, is:

Engine capacity, Hp......	Under 700 (500 kw.)	700–1400 (500–1000 kw.)	Over 1400 (1000 kw.)
Maximum leakage, percent	0.5	0.4	0.3

Preliminary Tests may be run to determine whether engine is in suitable condition for test, to check all instruments, and to train personnel.

DURATION OF TEST, when surface condenser method is used, shall cover not less than four successive 15-minute records, during which the uncorrected steam rate for each period shall check within 3.0%. When steam consumption is measured by feedwater supplied to a boiler, duration of test shall be 8 hr. Each test should be preceded by a period adequate to establish constant conditions. In capacity tests, operating conditions including output, initial and exhaust pressures, quality or superheat, vacuum and speed shall be held sensibly constant for not less than 15 min.

Constant Conditions shall be maintained as nearly as possible throughout preliminary and test periods. Steam pressure may be adjusted by proper boiler control or by throttling (with correction for changed superheat). Superheat may be adjusted by boiler control. Reduction of superheat by spraying water into steam line is not permissible. Exhaust pressure can be raised by admitting air to condenser or suction line of air pump. Back pressure in non-condensing engines may be raised by throttling, or decreased by using a test condenser or by providing free atmospheric exhaust. Constant load may be obtained by limiting governor or cut-off. The load on engine-generator sets can be adjusted by changing electric circuit conditions, terminal voltage being held within ±5% of specified value.

INSTRUMENTS AND MEASUREMENTS.—The following instruments are required for a heat-rate acceptance or performance test:

For an engine running alone, a dynamometer; for an engine-generator set, instruments for measurement of net kilowatt output, including that for excitation and ventilation; for an engine exhausting to a surface condenser, weighing tanks and scales, or volumetric measuring tanks, and suitable instruments to determine condenser leakage; for an engine exhausting to a jet condenser, to a heating line, or simply non-condensing, water weighing or measuring tanks and boiler isolated for a feedwater test, orifices or nozzles to measure steam quantity as water in condenser tests, upon agreement in writing by the parties to the test.

For all classes of engines, the following are necessary: Steam engine indicators to measure power developed in cylinder, throttle and exhaust pressures (by agreement in writing, a Bourdon or deadweight pressure gage may be used to determine throttle pressure, and mercury manometers to determine vacuum or exhaust pressure); calipers and scales to determine dimensions; temperature measuring instrument to determine steam temperature on boiler side of throttle valve; if steam is wet, a throttling calorimeter to determine steam quality; thermometers to determine exhaust temperature, temperature of mercury columns, manometers, barometers, exposed stems of glass high-temperature thermometers, temperature of water in volumetric measuring tanks, and tem-

perature of condensate; clock, or synchronized watches or signaling system from a central point; steam tables and charts; planimeters to measure indicator cards; graduated scales for gage glasses of boilers and hotwells. All instruments shall be calibrated before and after test.

Indicators to measure power developed in the cylinder need be used only when performance guarantees are based on I.Hp., or when it is desired to measure points of cut-off, etc.

Observations of instruments shall be made and indicator cards taken from each end of each cylinder at least every 15 min. when conditions are uniform, and oftener if possible. Each indicator card shall be marked with number, date, time, scale of spring and end of cylinder.

Indicated Horsepower (I.Hp.) shall be calculated for each working end of cylinder by

$$\text{I.Hp.} = (pLAn)/33{,}000,$$

where p = mean effective pressure, lb. per sq. in.; L = length of stroke, ft.; A = area of piston, minus area of piston- or tail-rod, sq. in.; n = rev. per min. Total horsepower of a cylinder is the sum of horsepower developed in the two ends.

Brake Horsepower (B.Hp.) shall be measured by dynamometer or other loading device. With absorption dynamometers, such as water brakes, the operating fluid shall enter and leave in substantially a radial direction. In electric absorption dynamometers, admission and emission of cooling air shall be sensibly radial in direction. Dynamometers shall be examined before and after test and deadweight determined. In absorption dynamometers, effective-radius arm shall be measured with an accuracy within 1 part in 2000; weighing means shall be effective within 2 parts in 1000. Dynamometer readings shall be taken with such frequency that average of all observations will not differ from average of all alternate observations by more than 1%. A test shall be deemed unsatisfactory if a condition exists that gives variations in dynamometer readings exceeding 2%. Brake horsepower is calculated by

$$\text{B.Hp.} = 2\pi LFn/(550 \times 60) = 6.2832\, LFn/33{,}000$$

where F = net force on brake arm, lb. (gross weight − tare weight on scales); L = horizontal distance between center of shaft and bearing point at end of brake arm, ft.; n = rev. per min. of brake shaft.

Output at coupling may be expressed in kilowatts (1 kw = 736.5 ft.-lb. per sec.).

ELECTRICAL OUTPUT.—For a 3-phase generator with grounded neutral, power output of main unit shall be measured by 3-wattmeter method; with isolated neutral, power output shall be measured by either 2-wattmeter or 3-wattmeter method. For single-phase generators, power output shall be measured by the 1-wattmeter method. Power output of direct-current generators shall be measured by the direct-current voltmeter-ammeter method. Single-phase wattmeters or watt-hour meters are preferable for measuring polyphase loads at high voltage. If generator leads are connected solidly to power transformers, and it is necessary to connect instruments on secondary side of transformers, the calculated losses in transformers and leads shall be added to transformer output to give generator output.

Calculations.—Average kilowatt output of any run is the sum of the corrected average reading of wattmeters.

$$\text{Coupling or shaft kw.} = \{(\text{kw. at generator terminals})/(\text{generator efficiency})\}$$

$$\text{B.Hp or shaft Hp.} = 1.34 \times (\text{coupling kilowatts}).$$

Generator efficiency shall be as defined in the current A.I.E.E. rules.

STEAM QUANTITY MEASUREMENT always shall be in terms of liquid water, either after it is condensed or before it has evaporated. Measurements shall be made as follows:

a. Measurements of condensate from a surface condenser, including steam discharged by drips and glands of engine proper. *b.* For engine with jet condenser, or a non-condensing or back-pressure engine, measurement of feedwater delivered to the boiler, whose only outlet is to the engine under test, after making any necessary corrections for leakage, water level, etc.; accuracy in quantity of steam so determined cannot be expected within 3%. *c.* If engine is steam jacketed, all steam condensed in jackets and not passing directly through the cylinder, but discharged to traps or drains, shall be recovered and weighed; this weight is to be added to weight under (*a*) to determine total quantity of steam chargeable to engine.

The steam shall be measured by one of the following methods: *a.* Actual weighing by means of tanks and scales. *b.* Calibrated volumetric measuring tanks. *c.* By agreement in writing, and with understanding that accuracy cannot be expected within 2%, a Venturi tube, nozzle or orifice, with means for accurate measurement of pressure differences, may be used for measurement of condensate or feedwater, if supplied at constant rate.

Water level in condenser hotwell or in boiler should be the same at beginning and end of test. If any variation exists, the necessary corrections shall be made.

Condenser Leakage shall be determined by one of the following methods: *a.* Silver nitrate method, suitable only for circulating water containing an appreciable amount of salt; preferred

URE
sures above 25 lb. per s
gages or their equivalent m
shall be of such size
they may not have

by steam engine indicator for pres-
calibrated Bourdon or dead weight
shall not be used. The Bourdon
of the total scale easily can be
% of the absolute pressure.

Throttle Pressure shall be measured
diameter of throttle valve. Average thro
ordinate of a pressure curve plotted against
from end of stroke to point of cut-off. Thi
indicator operated from reducing motion o

indicator within, if possible, one
all be obtained by determining
ment during steam admission period
obtained from a card drawn by an
pipe on boiler side of

lemiscus or capillarity; c. Gravity to reduce reading to
ıtion of instrument had International Standard value
c.; d. Difference in elevation between the barometer and the mercury
barometer reading shall be corrected for this difference, having first been
capillarity and gravity.

Exhaust ... e by means of a steam engine indicator attached to exhaust pipes at specified point and operated from reducing motion of engine. Exhaust pressure shall be obtained by determining mean ordinate of a pressure curve plotted against piston position during steam-exhaust stroke, *i.e.*, from a piston displacement diagram. Exhaust period shall extend from dead center point to instant of closure of exhaust valve or port, as determined with exhaust pipe diagrams.

Temperature Measurements shall be made by mercury-in-glass thermometers with etched stems. Thermometer wells (see p. 3–08) may contain fused solder, sodium nitrate or mercury for higher temperature ranges, or oil if temperature is so low as not to evaporate the oil.

For high temperatures, measurements may be made, under written agreement, by an electric resistance thermometer or an iron-constantan or other suitable thermocouple with nul-reading potentiometer. Important temperature readings should be the mean of readings taken at two points close together. Discrepancies in excess of 1% above the ice point should be investigated.

QUALITY OF STEAM shall be determined by throttling calorimeter, when the engine operates without superheat; calorimeter sampling tube to be inserted in steam pipe on boiler side of, and adjacent to, throttle valve.

SPEED MEASUREMENTS may be made by: *a*. Hand counter; *b*. Hand tachometer of mechanical weight type; *c*. Belted or positively-driven tachometer of mechanical weight type; *d*. Frequency meter connected to generator circuit; *e*. Electric tachometer; *f*. Mechanical integrating counter; all except *a* to be calibrated prior to test.

For steam or heat consumption tests involving measurement of brake or indicated horsepower speed shall be determined by a mechanical integrating revolution counter, positively geared or con-

nected to some portion of engine or driven machine. Average speed per unit of time shall be determined from total number of revolutions during entire test. Time of counter observation at beginning and end of test shall be accurate within 1 sec.

MAXIMUM VARIATION IN OPERATING CONDITIONS shall be as follows: *a.* Throttle pressure, ±8% of absolute pressure. *b.* Initial steam superheat ±25° F. *c.* Throttle quality, 2% from guarantee. *d.* Exhaust pressure not exceeding 2 lb. per sq. in., abs. Actual absolute pressure not more than 150%, nor less than 75%, of absolute pressure corresponding to specified exhaust pressure. From 2.01 to 5 lb. per sq. in., abs., ±10% of absolute pressure. Above 5 lb. per sq. in., abs., ±5% of absolute pressure. *e.* Speed ±5%. During any one test, not more than ±2% of average speed of test. *f.* Power factor, from unity P.F. to 5% below specified value. *g.* Load fluctuation ±5%. *h.* Output (mean) ±5% from specified value.

DATA AND RESULTS should be reported on a suitable form. The form on p. 16–28 is suggested in the code, but can be modified to suit conditions.

10. TEST CODE FOR CONDENSING APPARATUS

Approved, 1926

This code covers surface-, low-level jet-, barometric-, and ejector-condensing apparatus.

OBJECT of test usually is: *a.* To determine fulfilment of manufacturer's guarantee; *b.* To determine performance of the apparatus in part or as a whole.

INSTRUMENTS AND APPARATUS required comprise: *a.* Mercurial barometer. *b.* Mercurial columns for measuring vacua, the smallest scale graduations being not greater than 0.1 in., with vernier attachment reading to 0.01 in. *c.* Bourdon gages for measuring pressures too great for mercury manometer tubes. *d.* Thermometers graduated to 1/2 deg. F., with maximum scale readings from 32 to 150 deg. F. for determining temperatures of circulating water, condensate and vapors; thermometers graduated by degrees, with maximum scale readings from 32 to 250 deg. F. for determining steam temperature. *e.* Tanks and platform scales for measuring water, or water meters calibrated in place under conditions of use. *f.* Appliances for tests of auxiliary pumps, such as steam engine indicators, electrical instruments, speed indicators, etc. *g.* Air measuring devices, gasometer or calibrated orifices.

Amount of Circulating Water may be estimated by the heat balance method, using the equation

$$F_w = h_c w_s/(t_2 - t_1)$$

where F_w = circulating water, lb. per hr.; h_c = B.t.u. per lb. of steam absorbed by condenser; w_s = steam discharged to condenser, lb. per hr.; t_1, t_2 = respectively, inlet and outlet temperatures of circulating water.

Location of Thermometers within the steam space should be such that they are shielded from direct impact of steam currents and from radiation from cold tubes. It usually is best to insert bare thermometers through rubber stoppers. Thermometers measuring temperature of discharge water should be located as far as practicable, but not more than 100 ft., from the condenser. At least three thermometers uniformly spaced should be used to determine the temperature of discharge circulating water.

Inlet Pressure shall be measured by mercury columns accurate to 0.01 in. mercury, corrected for all observable causes of error. Each column shall be mounted as near as practicable to the pressure hole in the conduit or casing. Extreme care shall be exercised to make piping and joints between the column and pressure hole air-tight. Each column must be so mounted as to be as free as possible from vibration.

If conduit connecting turbine exhaust nozzle and condenser inlet nozzle is approximately straight, inlet pressure shall be measured as far as possible from turbine exhaust flange (toward the condenser) and at a distance from the condenser inlet flange (toward the turbine) not to exceed three diameters of a circle of area equal to that of the inlet conduit. Each column shall be connected to a static pressure hole normal to the inner wall of the conduit and not smaller than 1/2-in. standard iron pipe size. There shall be approximately one such hole and column for each 16 sq. ft. of inlet conduit area, but not less than 2 nor more than 6 columns. Pressure holes shall be distributed uniformly around the periphery of the conduit.

If there is no straight conduit between turbine and condenser, pressure holes shall be located within 12 in. of the plane of the face of the condenser inlet flange at that plane where steam flow is most likely to be smooth.

Readings of all Mercury Columns, corrected to inches of mercury at 32 deg. F., shall be averaged and subtracted from a similarly corrected reading of a mercury barometer to give absolute exhaust pressure. Correction must be made for any difference in elevation of barometer and mercury columns.

PREPARATIONS.—Dimensions and physical condition of condenser and auxiliaries should be ascertained. All foul tube surfaces, both inner and outer, should be thoroughly cleaned. Quantity of leakage from water to steam spaces of surface condensers should

be determined by measuring water discharged from condensate pump with all steam shut off from entering condenser, the normal quantity of circulating water being in use and all other conditions normal. Leakage so revealed should be rectified before proceeding with test, unless precluded by the object in view.

Leakage test should continue for at least one hour after normal conditions are established. Leakage so determined should be deducted from total condensate measured on main test. If leakage exceeds 1% of the normal capacity of condenser, test should be stopped until it is reduced to the stated figure. The average of a leakage test made before and after the main test may be considered as condenser leakage.

By filling a surface condenser shell and its connections with water at a temperature approximately that of surrounding air, and under slight pressure, air leaks will be revealed. The quantity of air removed from the condenser shall be measured by gasometer or other approved apparatus. The tightness of steam valves and pistons of steam-driven auxiliaries may be ascertained by standing leakage tests.

OPERATING CONDITIONS, such as speed of auxiliaries, degree of vacuum to be carried, quantity of circulation or injection water needed, should be determined prior to beginning of main test; these conditions should prevail throughout the test. Since condenser performance depends on amount of air leakage, which the condenser manufacturer does not fully control, a definite air handling capacity of the air-removing apparatus must be assumed. Separate or shop tests of such apparatus often are desirable.

STARTING, STOPPING AND DURATION of a condenser test should follow the same rules that govern a steam engine or turbine test.

Surface Condenser Tests should determine the quantity of steam condensed by collecting and weighing the condensate and correcting the total as measured for leakage.

Jet Condenser Tests, including those of the barometric type, may be made by measuring feedwater consumption and correcting for drips, leakage of boilers and piping, and for steam which is not supplied to the condenser.

Such steam preferably should be taken from isolated boilers. It may be determined approximately by steam meter measurement if the meter is calibrated in place and under conditions of use, or by calculation of the heat given to the injection water if determined.

Circulating water may be measured by discharge into an open tank with a V-notch or rectangular weir, or by an orifice inserted in a discharge pipe. These indirect methods must be considered as only approximate.

Quantity of steam consumed by auxiliaries may be found by connecting them to a surface condenser and measuring the condensate, or by water glass tests made at a time when they can be operated independently and preferably taking steam from a single boiler.

CALCULATION OF RESULTS.—**Heat Supplied to Condenser** per hour depends on heat content of steam as delivered to condenser. Heat supplied to condenser is heat supplied to prime-mover exhausting into the condenser, less that converted into work and that lost by generator losses, friction, radiation and other wastes not readily determined. It is expresed by the following formulas (where condenser is bolted direct to turbine exhaust opening):

For a simple non-bleeding, non-reheating turbine

$$h_x = h_t - (3413/f_s\, e_{me}) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [1]$$

For a reheat, non-bleeder turbine

$$h_r = h_t + (h_2{}^1 - h_1{}^1) - (3413/f_s\, e_{me}) \quad . \; . \; . \; . \; . \; . \; . \; . \quad [2]$$

in which the expression ($h_2{}^1$ — is repeated for each stage of reheating.

For a bleeder non-reheat turbine

$$h_x = (h_t\, F_d/X) - (3413\ K \qquad {}_1 h_1 + \qquad + \qquad {}_i h_n)/X\} \qquad [3]$$

For a bleeder and reheat turbine

$$h_x = [\{(h_t\, F_d/X) + (F_d - w)(h_2{}^1 - h_1{}^1)\}/X] - (3413\ K/e_{me}\, X)$$
$$\{(w_1\, h_1 + w_2\, h_2 + \; . \; . \; . \; w_n\, h_n)/X\} \quad . \; . \; . \; . \; . \; . \quad [4]$$

where h_x = B.t.u. per lb. of steam at prime-mover exhaust; h_t = B.t.u. per lb. of steam at prime-mover throttle; F_s = steam supplied to throttle of prime-mover, lb. per kw.-hr.; e_{me} = mechanical and electrical efficiency of prime mover complete including all losses; $h_2{}^1$ = B.t.u. per lb. of steam at point of re-entrance to turbine after reheating; $h_1{}^1$ = B.t.u. per lb. of steam after partial expansion in turbine, at point of extraction for reheat. F_d = total steam supplied to throttle of prime mover, lb. per hr.; $w_1, w_2 \; . \; . \; . \; w_n$ = respectively, steam bled from first, second and nth bleeder point of turbine, lb. per hr.; w = total steam bled from turbine at all bleeding points between throttle and point of reheating, lb. per hr., in a bleeder and reheat turbine; $h_1, h_2 \; . \; . \; . \; h_n$ = B.t.u. per lb. of steam at first, second and nth bleeder point of the turbine; K = load on prime-mover, kw.; $X = \{F_d - (w_1 + w_2 \; . \; . \; . + w_n)\}$.

CONDENSING APPARATUS TESTS *(Continued)*

Item		
	GENERAL RESULTS OF TESTS—*Continued*	
105	Temperature corresponding to test pressure (Item 59)...........	deg. F.
106	Temperature of condensate in hotwell:	
	(*a*) Guarantee...............; (*b*) Test (Item 71).....................	deg. F.
107	Temperature of entering condensing water:	
	(*a*) Guarantee...............; (*b*) Test (Item 70*a*).....................	deg. F.
108	Quantity of condensing water: (*a*) Guarantee........; (*b*) Test........	gal. per min.
109	Amount of free air handled by air pump:	
	(*a*) Guarantee......; (*b*) Test (Item 93).....cu. ft. per min. at 60° F. and 14.7 lb.	
110	Total heat delivery to prime mover: (From Items 48 to 52)..............	B.t.u. per hr.
111	Total heat:	
	(*a*) Carried to condenser by exhaust steam (Formulas 1 to 4).........	B.t.u. per hr.
	(*b*) Carried from condenser by condensate (Items 67 to 71)...........	B.t.u. per hr.
	(*c*) Absorbed by condensing water (Items 70 to 74)..................	B.t.u. per hr.
112	Steam supplied to auxiliaries:	
	(*a*) Absolute pressure at throttle................................	lb. per sq. in.
	(*b*) Quality of steam....................percent moisture or deg. F.	superheat
113	Steam consumed by auxiliaries: (*a*) Guarantee........; (*b*) Test..........	lb. per hr.
	(*c*) Percent of steam delivered to condenser..............................	percent
114	I.Hp. or B.Hp. of auxiliaries: (*a*) Guarantee........; (*b*) Test..................	Hp.
115	Mechanical efficiency of circulating or tail pump (Items 74 to 85)..............	percent
116	Mechanical efficiency of condensate pump (Items 98 to 102)..................	percent
117	Mechanical efficiency of air removal pump..................................	percent
118	Volumetric efficiency of air removal pump..................................	percent
119	Average velocity of circulating water through tubes......................	ft. per sec.
120	Heat transfer per deg. difference of temperature per sq. ft. per hr. (based on total surface):	
	(*a*) Using arithmetical mean.....; (*b*) Using logarithmic mean...............	B.t.u.
121	Steam condensed per sq. ft. of total surface per hr. (Item 52 ÷ Item 14)..............	lb.
122	Circulating water per lb. of steam condensed (Item 74 ÷ Item 69*a*)..................	lb.
123	Circulating water per sq. ft. of total condenser surface (Item 74 ÷ Item 14)..	lb.

In using the above formulas to determine heat absorbed by the condenser, the heat carried away by the condensate should be subtracted from the heat absorbed by the condenser.

$$h_c = h_x - (t_c - 32) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [5]$$

where h_c = B.t.u. per lb. of exhaust steam absorbed by condenser and carried away by circulating water; t_c = temperature of condensate.

If prime-mover steam rate is given in lb. per Hp.-hr., the constant 2545 must be substituted for constant 3413. Value of e varies with type and size of prime mover and should be obtained from the turbine manufacturer.

HEAT TRANSFER IN SURFACE CONDENSER is the measure of performance and is expressed in B.t.u. transmitted per sq. ft. of tube surface per hr. per degree mean difference in temperature between the two sides of the tube.

Arithmetical mean difference $= t_s - \{(t_2 + t_1)/2\}$

Logarithmic mean difference $= (t_2 - t_1)/\log_e \{(t_s - t_1)/(t_s - t_2)\}$

where t_s = temperature in steam space, t_1, t_2 = respectively, temperature of incoming and outgoing circulating water. Both arithmetical and logarithmic mean temperature differences should be calculated in order to make comparison possible with all other tests.

Data and Results should be reported in accordance with the form on p. 16–33.

11. TEST CODE FOR RECIPROCATING STEAM-DRIVEN DISPLACEMENT PUMPS

Approved, 1925

This code applies to tests to determine performance of pump and engine, including reheaters, heaters and jackets, if any, and jacket pumps, circulating pumps, condensate pumps, and vacuum pumps which are concerned in their operation.

MEASUREMENTS.—*a*. Amount of water pumped, lb. *b*. Average total head, ft. *c*. Amount of steam supplied, lb., or amount of heat supplied, B.t.u.

Standard units for volume, head and power are the same as those used for centrifugal pumps. See p. 16–41.

INSTRUMENTS AND APPARATUS required for performance tests include:

a. Tanks and platform scales for weighing water. *b*. Graduated scales attached to water glasses of boilers if feedwater is measured. *c*. Pressure gages, vacuum gages, thermometers with suitable wells. *d*. Steam calorimeter. *e*. Barometer, *f*. Revolution counter or other speed measuring device. *g*. Indicators. *h*. Planimeter. *i*. Deadweight gage tester.

Gage on discharge main should be attached near pump discharge nozzle; that on suction main near suction nozzle. Gages should be at an angle of 90° to direction of flow, and should be provided with valves and pet cock air vents. When a suction or discharge surface condenser forms part of the unit under test, water-head readings should be made outside of and beyond condenser.

LEAKAGE TEST to determine tightness of suction and discharge valves and plunger packing should be made by applying specified discharge pressure and observing leakage through a handhole or manhole on suction side. If leakage is sufficient to affect capacity, conditions should be corrected before proceeding with test.

QUANTITY OF WATER PUMPED should be determined by computing actual plunger displacement in gallons or cubic feet. If possible, total pumpage should be checked by Venturi tubes, pitometer, weir, calibrated orifice, etc. In direct-acting pumps, actual stroke of each plunger must be determined by graduated stroke scales.

DURATION OF TEST should be not less than 8 hr. when surface condenser measurement is used, and 10 hr. if steam consumption is determined by measuring feedwater to the boiler.

RECORDS.—Instruments should be read at least every 15 min., and indicator cards taken from each end of each cylinder once each hour with uniform conditions, and oftener if conditions vary.

Throttle Pressure in steam pipe is that shown by a calibrated gage on the steam pipe, $1^1/_2$–2 diameters from the throttle.

CALCULATION OF RESULTS.—Steam Rate is reported as the actual steam rate as measured. *Estimated steam* also is reported as corrected for pressure, quality or vacuum in accordance with correction factors based on data obtained from engine under test.

Heat Supplied is the total heat content of steam entering the engine and its auxiliaries, less total heat returnable from engine and auxiliaries to the boiler as follows: *a.* In condensate from air pump. *b.* In any feedwater heater using exhaust steam or steam from working charge of the engine. *c.* In high-temperature jacket and other drain water.

Total Head is the sum of the discharge head and suction head when suction main is under vacuum, and the difference between discharge head and suction head when suction main is under pressure.

Discharge Head is the sum of the head in ft. shown by the gage on the discharge main and the vertical distance between the center of the gage (Bourdon spring type) or lower surface of the mercury (mercury type) above center line of pump cylinder. If gage be located below the center line, the distance is to be subtracted instead of added.

Suction head is the difference between pressure, in feet, shown by suction gage and vertical distance, in feet, between center of gage on suction main (Bourdon type), or lower surface of the mercury (mercury type), and the datum line.

Suction lift is the sum of the reading, in feet, shown by gage on suction main and the vertical distance, in feet, between datum line and point of connection of gage to suction pipe. Should point of connection be above datum line, distance should be subtracted instead of added.

CAPACITY by displacement is found by

$$Q = A \times L \times n \times 1440 = \text{cu. ft. per 24 hr.}; \quad Q_1 = 7.48\,Q = \text{U. S. gal. per 24 hr.}$$

where A = net or effective area of all plungers, sq. ft.; L = length of stroke, ft.; n = number of discharge strokes per min.

WATER HORSEPOWER is found by

$$\text{Hp.}_w = (w \times H)/1{,}980{,}000$$

where w = weight of water pumped, lb. per hr., H = average total dynamic head, ft.

ENGINE INDICATED HORSEPOWER for entire test is found by dividing average water horsepower by average hydraulic and mechanical efficiency of the entire unit.

DUTY FOR 1000 LB. OF STEAM in foot-pounds of work done is

$$W_s = \{(W \times H)/w_s\} \times 1000$$

where W_s = duty per 1000 lb. of steam, ft.-lb.; W = weight of water pumped during test, lb.; H = average total dynamic head, ft.; w_s = steam supplied during test, lb.

DUTY PER 1,000,000 B.T.U. in foot-pounds of work done is

$$W_h = (W \times H)/H_s \times 1{,}000{,}000$$

where W_h = duty per million B.t.u.; H_s = total number of B.t.u. supplied. Other notation as before.

FRICTION AND MECHANICAL EFFICIENCIES.—Average combined hydraulic and mechanical efficiency of the entire unit is 100 times the average of the ratios of instantaneous water horsepower to engine indicated horsepower shown by all normal indicator cards taken during test.

DATA AND RESULTS should be reported in accordance with the form on p. 16–38.

* The correction factor used shall be stated in percentage, and the basis and method of determining it described.

12. TEST CODE FOR CENTRIFUGAL AND ROTARY PUMPS

Approved, 1927

This code applies to tests for determining performance of pump only. It does not apply to performance of piping, driving apparatus or other auxiliaries, except as they may affect results of pump test.

INSTRUMENTS AND APPARATUS required for measuring the head of water and speed of pump are:

a. Water column or gage glass. *b.* Pressure gage. *c.* Vacuum gage. *d.* Mercury column. *e.* Revolution counter. *f.* Tachometer.

Instruments and apparatus for measuring the quantity of water and amount of power input depend on methods to be used.

OPERATING CONDITIONS are: *a.* Quantity of water delivered by pump. *b.* Total dynamic head. *c.* Speed in r.p.m.

Speed always should be maintained as nearly constant and as nearly equal to nominal designed speed as possible. Prevailing total dynamic head under operating conditions may not be the designed head. If possible it should be brought to designed value by throttling by means of a valve in the discharge line, or other methods applicable to the local conditions. Throttling by a valve in the suction line close to the pump is not permissible. If operating head is greater than design head, additional delivery openings in discharge mains at a lower elevation will lower the operating head. Side outlets between pump and point of measurement of discharge should be blanked off.

Each of the various measurements for a given run shall be computed by averaging a series of instantaneous readings taken simultaneously at equal time intervals. Extreme fluctuations at any instant should be noted. The number of readings shall be such that the elimination or addition of a single reading, representing a maximum swing of the instrument, shall not affect the average by more than 1%.

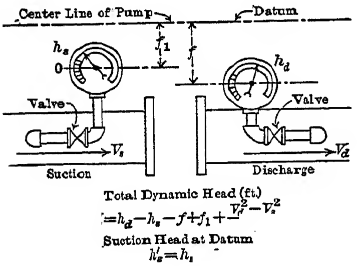

FIG. 1

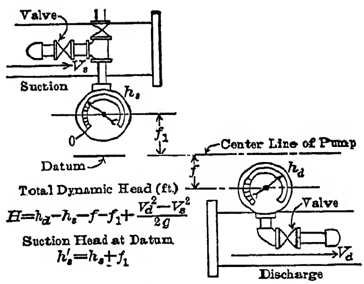

FIG. 2

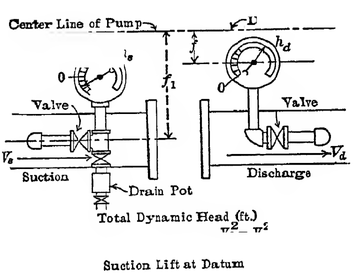
Bourdon Gages. Absolute Suction Head above Atmospheric Pressure



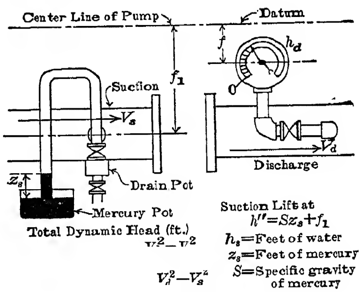


FIG. 3 FIG. 3A. Alternative to Fig. 3

Bourdon Gages. Absolute Suction Head below Atmospheric Pressure

HYDRAULIC AND MECHANICAL CONDITIONS.—The unit shall be in the best possible mechanical condition with bearings, stuffing boxes and internal running clearances properly adjusted. The water to be handled shall be clear cold water, free of air, gases or suspended solids. Unless otherwise stipulated, temperature of water during test shall not exceed 85° F.

For pumps handling fluids other than water, suitable corrections shall be made, depending on characteristics of the fluid; specific gravity and viscosity, referred to water, and boiling point, shall be determined. The dry weight and volume of solids in suspension, and the total weight and volume of the mixture shall be determined. Formulas in the code are based on the use of water whose specific gravity is unity.

DURATION OF TEST depends on method of driving pump, on method used to measure discharge, and also on how completely pump characteristic is determined. In determining characteristic, capacity should be varied in steps covering a range of at least 10 to 15% above and below normal tested delivery of pump, and curves plotted of the results.

STANDARD UNITS FOR VOLUME HEAD AND POWER.—The Standard Unit for Volume is the U. S. gallon or the cubic foot. The gallon unit is expressed in gallons per min. (g.p.m.) or million gallons per day of 24 hours (m.g.d.).

The cubic foot unit is expressed in cu. ft. per sec. One U. S. gallon = 231 cu. in. For temperatures not exceeding 85° F, specific gravity of water may be taken as unity. (For more exact computations, the specific gravity may be calculated by means of the weights of water at various temperatures as given in Table 2, p. 2–04.)

In computations, the following relations shall be used. 1 cu. ft. = 7.4805 gal.; 1 cu. ft. per sec. = 448.83 gal. per min.; 694.45 gal. per min. = 1,000,000 gal. per day of 24 hr.

The Unit for Measuring Head shall be the foot. 1 lb. per sq. in. = 144 ÷ weight of 1 cu. ft. of liquid. For water whose specific gravity is unity, 1 lb. per sq. in. = 2.307 ft.

When the temperature of water is such that the weight per cubic foot varies from 62.43 lb., or when liquid other than water is handled, the reading of gages calibrated in lb. per sq. in. must be corrected by dividing the reading by the specific gravity and multiplying by 2.307.

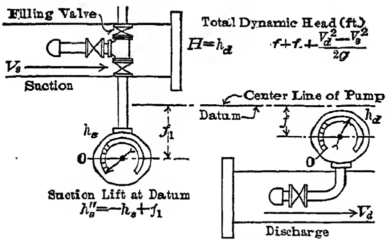

FIG. 4. Bourdon Gages. Absolute Suction Head below Atmospheric Pressure

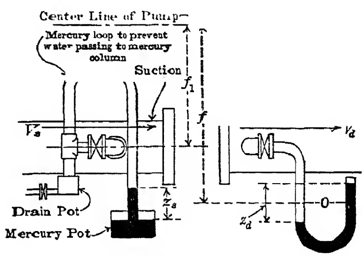
z_s, z_d = Feet of mercury

S = Specific gravity of mercury



Suction Head at Datum

$H = (S - \frac{1}{2})(z_d) + Sz_s - f + f_1 + \frac{V_d^2 - V_s^2}{2g}$

Suction Lift at Datum, $h''_s = Sz_s + f_1$

FIG. 6 FIG. 6A. Alternative to Fig. 6

Mercury U-tubes. Absolute Suction Head below Atmospheric Pressure

The Unit of Power shall be the horsepower (550 ft.-lb. per sec.) delivered to the pump ed as shaft-horsepower. (S.Hp.)

NTS OF QUANTITY OF WATER are primary or secondary. The .easurement by volume or weight. Secondary methods, more nt by weir, Venturi meter, nozzle, or Pitot tube. istalled as to change either the coefficient of th ump.

·Net total head is the total dynamic head produced by the pump. It is the between the absolute head at discharge and suction nozzles, taking into acco nce in elevation of these nozzles with respect to a fixed datum, and any differe velocity heads at points of measurement. The standard method of measuring use of a water column or gage glass giving direct reading of surface elevation. If ble, indirect methods may be used, as a mercury or other fluid gage very gage or pressure measuring device must be attached by a smooth- 1/4 in. diam., whose axis is at right angles to the direction of flow, with the inside of the conduit. For great accuracy when the h operates is 50 ft. or less, ometers instead of Mercury gages shall under actual co aili comparison with the height of the water column.

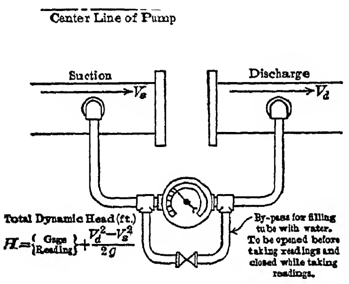


FIG. 7. Differential Gage, Bourdon Type

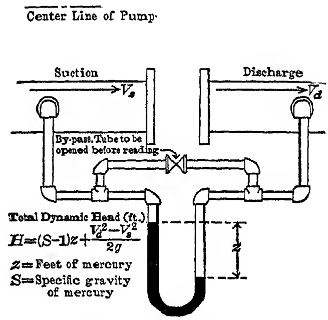

FIG. 8. Differential Gage, Mercury U-tube. Suction Head above or below Atmospheric Pressure. Discharge Head above Atmospheric Pressure

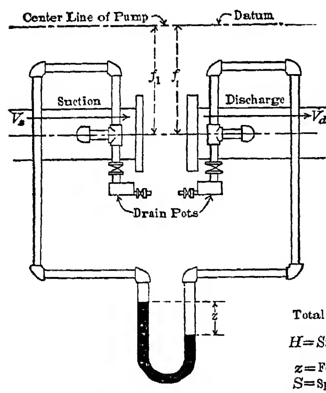
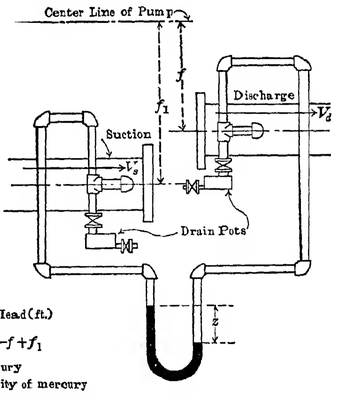




Total Dynamic Head (ft.)

$$H=Sz+\frac{V_d^2-V_s^2}{2g}-f+f_1$$

z = Feet of mercury

S = Specific gravity of mercury

Suction and Discharge Heads below Atmospheric Pressure

FIG. 10. Suction and Discharge at Different Levels

Differential Gage Mercury U-tube

Total Dynamic Head may be expressed by the formula

where H = total dynamic head; H_d = absolute discharge pressure head, ft.; H_s = absolute suction pressure head, ft.; V_d, V_s, = respectively mean discharge and suction velocity, ft. per sec., g = acceleration due to gravity, = 32.2.

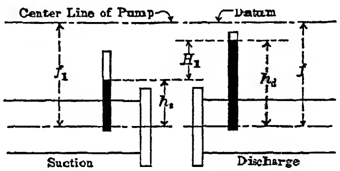
$$H_d = h_d' + h_a; \quad H_s = h_s' + h_a = -h_s'' + h_a$$

where h_a = atmospheric pressure head, ft., corresponding to barometer; h_d = discharge gage reading, ft., h_d' = discharge gage reading, ft., corrected to datum; h_s = suction gage reading, ft., positive when above, negative when below, atmospheric pressure; h_s'' = suction lift or negative suction pressure (below atmosphere), ft., corrected to datum $= - h_s'$.

The use of the various types of measuring instruments is shown in Figs. 1 to 13.

MEASUREMENT OF SPEED shall be taken by a revolution counter or an accurately calibrated tachometer.

MEASUREMENT OF POWER INPUT *i.e.*, shaft-horsepower of the pump, may be made by some form of transmission dynamometer or calibrated electric motor. Other methods involve measurement during the pump test of power input to the driving element and the previous or subsequent determination of the relation of power input to power output of this driving element under the identical conditions of the pump test.



Total Dynamic Head, ft., =

Suction Head at Datum = $h'_s = h_s - f_1$

FIG. 11. Water Gage. Suction and Discharge Pressures Above Atmospheric Pressure

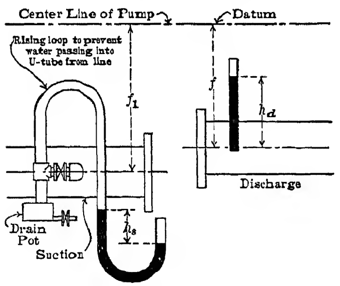
CALCULATION OF RESULTS.—Water Horsepower is found by the formula

$$\text{W. Hp.} = \{Q \times W \times (\text{Total head, ft.})\}/550$$
$$= \{\text{g.p.m.} \times (\text{total head, ft.})\}/3960$$

where W. Hp. = water horsepower; Q = cu. ft. per sec.; W = weight of water, lb. per cu. ft.; g.p.m. = gallons per minute. It is here assumed that the weight of water is 62.318 lb. per cu. ft.

Efficiency of a pump is ratio of energy converted into useful work to energy supplied to pump, or E = (W.Hp./S.Hp.)

RECORDS.—Test results usually are presented in the form of a single sheet upon which are drawn three curves showing respectively relation between efficiency and capacity,

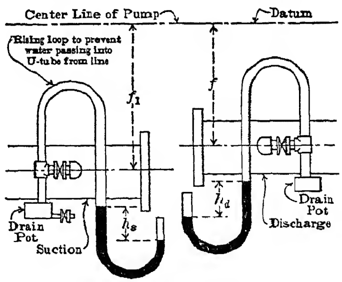


Total Dynamic Head, ft., =
$H = h_d + h_s + f_1 - f + \{(V_d^2$

Suction Lift at Datum =
$h''_s = h_s + f_1$

Water cannot be used if h_s is greater than height of rising loop.

FIG. 12. Water Gage. Absolute Suction Pressure below Atmospheric Pressure. Absolute Discharge Pressure above Atmospheric Pressure



Total Dynamic Head, ft., =
$H = h_s - h_d + f_1 - f +$ $V_s^2)/2g\}$

Suction Lift at Datum =
$h_s'' = h_s + f_1$

Water cannot be used if h_s is greater than rising loop. Read H, h_d, h_s, f and f_1 in feet.

FIG. 13. Absolute Suction and Discharge Pressures below Atmospheric Pressure

head and capacity, and shaft-horsepower and capacity. The values used in plotting these curves are those computed for a given definite speed of the pump, usually the speed of best efficiency, or that at which it was designed to operate.

If pump under test is of the rotary displacement type, its volumetric displacement corresponding to the speed developed in the test may be computed, and the difference between this displacement and the quantity actually pumped may be stated as slip, expressed as a percentage of displacement.

35	Pump efficiency .... percent
36	Specific speed of pump = r.p.m. $\times$ ($\sqrt{Q}/H^{3/4}$) at maximum efficiency point (from characteristic curve)

13. TEST CODE FOR INTERNAL COMBUSTION ENGINES

Approved, 1929

This code applies to all forms of internal combustion engines, but is limited to the engines alone. Separately-driven auxiliaries, essential to the operation of the engine, may be included in the test, but tests of such units must follow codes appropriate to them. Internal combustion engines vary widely in character and service, and operate under a wide range of conditions. No single code can prescribe tests in detail equally applicable to all conditions. Many details of the test must be left to the judgment of the engineer. The code includes:

a. Stationary engines and electric generating sets burning gaseous or liquid fuels including scavenging pumps of 2-cycle engines and injection air compressors, if used and separately driven. *b.* Marine engines, exclusive of propeller, and burning light or heavy liquid fuels. *c.* Aircraft engines, limited to block tests, exclusive of propeller, and burning light liquid fuels. *d.* Land vehicle engines, limited to block test and burning light and heavy liquid fuels. The code excludes: All sets where engine and driven unit are so combined that determination of the performance of the engine itself is impossible; all internal combustion engines whose construction or operating conditions prevent an output determination in terms of either brake horsepower or kilowatts;

internal combustion engines combined with vehicles, as vessels, air craft, motor cars, etc.; tests forming part of experimental investigations, research or development. The code is limited to tests in which the object is of a commercial nature.

MEASUREMENTS REQUIRED are:

a. Bore, stroke and clearance of power cylinders. *b.* Diameters of piston- and tail-rods of power cylinders of double-acting engines. *c.* Brake- or shaft-horsepower output. *d.* Kilowatt output if direct connected to a generator. *e.* Speed. *f.* Horsepower to drive independent cooling, water pump and fuel pump. *g.* Horsepower to drive independent scavenging pump or blower. *h.* Horsepower to drive independent injection air compressor. *i.* Cubic feet of gas supplied to gas burning engines, or pounds of liquid fuel supplied to liquid fuel engines. *j.* High calorific value of fuel.

Additional measurements that may be required are: 1. Cylinder diameters and strokes of injection air compressor, diameters of piston- and tail-rods. 2. Two-cycle engine scavenging pump, diameter and stroke and diameters of piston- and tail-rod. 3. Indicated horsepower of engine. 4. Explosions or fuel injections per minute. 5. Spray air pressure and temperature of air injection oil engines. 6. Exhaust back pressure at common exhaust nozzle. 7. Scavenging air pressure and temperature of 2-cycle engine. 8. Manifold vacuum of carburetor engine. 9. Jacket water or oil supply pressure and temperature at engine supply and main outlet; if jackets are divided, with separate supplies and discharges, the pressure at each. 10. Temperature, pressure, vacuum or hydraulic head, positive or negative, of supply of liquid fuel at carburetor connection of carburetor engine, at injection pump suction of injection oil engines, and pressure or vacuum of gas at stop valve of gas burning engine. 11. Total, static and velocity pressure, and temperature of cooling air supply of air-cooled engines. 12. Atmospheric pressure, temperature and humidity. 13. Pressure and temperature of lubricating oil supply to bearings at as many points as there are different supplies of pump-circulated lubricating oil, or in the crankcase of engines without pump, or having pump deliveries that do not permit of temperature measurement. 14. Amount of lubricant consumed. 15. Quantity of jacket water or oil supplied to engine as a whole or to separate jackets. 16. Quantity of cooling air supplied to air-cooled engines. 17. Quantity of jacket water evaporated in hopper-cooled engines. 18. Pounds of injection water supplied internally as liquid or steam, to cylinders of some oil engines. 19. Compression pressure in cylinders, when hot and cold, at normal speed at wide open air throttle.

INSTRUMENTS AND APPARATUS REQUIRED include:

a. Scales with or without tanks for weighing liquid fuel. *b.* Gas meters for measuring gaseous fuels, or gas metering methods with indirect observation apparatus. *c.* Gas calorimeters to determine heating value of gaseous fuel. *d.* Baumé oil hydrometer for petroleum liquid fuel and for indirect determination of calorific power. *e.* Pressure gages, mercury or water column. *f.* Thermometers. *g.* Barometers. *h.* Gas engine and oil engine indicators for working cylinders, and steam engine indicators for cylinders of 2-cycle scavenging pump, and low-pressure cylinders of injection air compressors. *i.* Pressure indicating or recording instruments for compression pressures or injection pressures in cylinders. *j.* Planimeters. *k.* Tachometers, revolution counters, or other apparatus for measuring speed or number of fuel admissions per minute. *l.* Absorption dynamometers of appropriate type, especially hydraulic brakes and electric dynamometers. *m.* If engine is direct connected to a generator, appropriate electrical instruments and apparatus, to provide suitable electrical load and measure it.

Dynamometers for testing all aircraft and land vehicle engines must be electric dynamometers. For brake-horsepower test of marine engines, hydraulic or electric dynamometers shall be used. For stationary engines and electric generating sets, electric or hydraulic dynamometers or other forms of brake may be used. For brake horsepower measurements, only a brake driven by direct coupling to, or mounted on, the engine shaft may be used.

With due precautions and under proper provisions, brake horsepower may be determined by substitution. The engine may be tested with a load such as a propeller, club or fan, which later may be tested for its speed-torque characteristic curve. The horsepower of the engine then is found by reading from this curve the horsepower and speed.

Tachometers of the centrifugal, liquid pumping, or magnetic type may be used after careful calibration. They must be connected by tachometer shaft or positive gearing to engine shaft. Continuous speed counters may be used if constant speed of considerable duration is maintained. Hand speed-counters placed directly against engine shaft may be used if handled carefully and well-made.

Calorimeters.—Unless otherwise agreed in advance, heating value of fuels to be used in calculations of results must be the *high value* products condensed, or the direct reading of a water calorimeter properly used. The following recommendations are made:

a. For gaseous fuel a standard form of gas calorimeter shall be used, and its determination used as heating value of gas as supplied. Heating value shall not be calculated from gas analysis. *b.* Heating value of liquid fuel shall be determined, in condition in which it is delivered to engine, in a standard bomb calorimeter, by a recognized physical or chemical laboratory. *c.* If previously agreed, heating values of gasoline may be estimated from the Baumé reading, by the Sherman and Kropf formulas, modified by Strong. These formulas (U. S. Bureau of Mines, Bull. No. 43) are:

Gasoline, $H = 18{,}320 + 40\,(B - 10)$; Kerosene, $H = 18{,}440 + 40\,(B - 10)$, where H = high heating value, B.t.u. per lb.; B = deg. Baumé.

Gas Measurements must be made with Venturi or drop-holder meter. Proportional meters, or anemometer-type meters are not satisfactory. Large capacity measurements are best made by some type of flow rate measurement. Physical or chemical properties of a mixed gas, determined for use in a metering calculation, shall be made by a recognized chemical laboratory previously agreed upon.

Liquid fuel must be weighed directly as used. Meters shall not be used.

PREPARATIONS.—Dimensions and physical conditions of all parts of engine shall be determined and recorded, and also of all parts external to engine, whose condition might affect test. Among external conditions so investigated may be included jacket water supply, external electric current supply for ignition system of electrically-ignited engines, sufficiency of fuel supply of liquid fuel engines, and sufficiency of lubricating oil supply.

DIMENSIONS.—In addition to those given in paragraph on measurement, the following data may be useful to identify an engine or to increase the value of future comparative analyses:

Dimensions of scavenging pump and injection air compressor, and of other fixed and running parts; diameter and length of all important bearings and pins, and of minor parts, such as valve lift, port area, area through mixing valves in gas-burning engines, carburetor choke area and nozzle sizes, injection pump plunger diameter and stroke, push rod or valve rocker clearances; all items of adjustment and timing, all nameplate information; dimensions of importance in judging the condition of engine as a machine, and useful in judging value of test, including all items of alignment, bearing clearances, pins, rods and slides, pistons and cylinders, rings in grooves, valve stems in guide, etc.

Internal Inspection should cover:

Jacket surface on the heat receiving side to insure freedom from water scale, rust or other deposits; combustion chamber walls including piston heads and all inward facing parts, which should be free from deposits; lubricating oil system, to insure freedom from deposits and cleanness of all flow passages; exhaust system, including expansion chambers, mufflers and pipes, to insure cleanness and arrangement that will not develop excessive back pressure; fuel supply and regulating system must be clean and free of all foreign matter, with passages fully open.

Leakage Tests should locate and correct all leakage. The more important leakages to be investigated are:

a. Cylinder leakage outward, best checked by an indicator. When there is clear space between compression and expansion lines of a diagram, taken when there is no combustion and when cooling water is not running, it may be assumed that leakage is excessive. In such case, and also if an indicator cannot be used to check leakage, the possible sources of leakage must be checked separately, *i.e.*, piston ring, cylinder, cylinder head gasket, air starting valve, relief valve, spray valve or spark plug seat, inlet or exhaust valve of 4-cycle engine, air scavenging valves of 2-cycle engines. *b.* Leakage from jackets through bad joints, cracks or porous spots, compressed air through leaky air starting valve, fuel oil past spray valve, and high pressure spray air. *c.* Miscellaneous leakages outside of cylinders, as in manifold system of carburetor engines between carburetor and inlet valve; fuel oil in injection oil engines at pump valves, pump plunger, oil delivery pipe, or spray valve; lubricating oil at pumps, tanks or in piping; spray air at compressor storage bottles, valve or piping; starting air at compressor storage reservoir, valves or piping; insulation of electrical circuits.

OPERATING CONDITIONS of the test should be agreed upon and defined. Such an agreement is regarded as essential to all internal combustion engine tests. The definition should include all of the items necessary in regard to service and to test procedure.

Variation.—Operating conditions to be maintained during test often are the ones that are most uncertain; thus, aircraft engines in service must work under a wide range of atmospheric temperature and pressure, and at any angle of inclination. Engines for land vehicles must operate on a fixed supply of jacket water or oil, with an air-cooled radiator, and external wall temperature varies with engine load, vehicle speeds, weather and climate. A statement of normal horsepower and speed for such engines is impossible. Marine engines always operate with a propeller load, under service conditions that cannot be reproduced in block tests. Even stationary engines in service operate under conditions that differ widely from those obtaining in a block test. Agreement on conditions of test is important, but details must be left to the judgment of the test engineer.

EFFECTIVE LOAD AND SPEED.—Operating conditions during test include mainly load and speed to be maintained. The agreement in all details should not be inconsistent with:

a. Stationary engines including generator sets shall be tested at constant speed under governor control, or as near constant as the governor will maintain it, and at whatever load may be required by agreement, or by specific object of the test. *b.* All land vehicle engines, except tractor engines fitted with speed governors and operating normally under governor control, shall be tested with throttle wide open, with brake torque regularly varied from zero to maximum and back to zero at whatever speeds may result. The horsepower-speed curve typical of the engine shall be determined

instead of horsepower at any given speed. Safe speed designated by engine builder must not be exceeded. If highest speed used is the safe limit, so state. Maximum torque applied in all cases shall be greater than that which will produce maximum horsepower, unless speed required exceeds safe speed. *c*. Marine and aircraft engines may be tested according to conditions prescribed for land vehicles, except that speed shall be maintained by brake torque and not by a governor. Marine engines may be tested at constant speed for full load operation fixed by their propellers.

Special attention should be given to questions of safety, such as safe speed or torsional vibration at a given speed within the normal range. Procedure in such cases should be by agreement.

STARTING, STOPPING AND DURATION.—Engine with all attachments shall be brought to a condition of steady operation, which shall continue long enough to permit preliminary observations to prove that steady state has been attained. If successive runs are to be made under different conditions, preliminary observations must be repeated for each run. An engine shall not be regarded as having attained its steady state until jacket and lubricating oil temperatures are substantially constant, nor until one hour after operating conditions have been imposed before the test observations are started.

For successive runs, under other conditions, minimum time for any engine shall be 10 min., actual time being determined by extent to which conditions are changed in each successive run. Maximum time to reach steady state shall not be greater than 24 hr.

Duration of test after establishment of steady operating conditions shall be by previous agreement. It should be greater for engines where reliability is important, and which require longest time to reach a steady state. Length of run shall be not less than period required to reach steady state, subject to the condition that length of run shall be great enough to insure accuracy of fuel measurement within 1%, except when metering of gaseous fuels is not improved by lengthened runs.

CALCULATION OF RESULTS.—**Fuel Consumption** for liquid fuel engines is stated in pounds of actual fuel measured and is subject to no correction.

For gaseous fuel engines, cubic feet of gas at prevailing pressure and temperature indicated or recorded by meter, or calculated from reading of flow rate devices, is stated in the report. This is to be corrected for pressure and temperature at which gas was delivered to calorimeter by the formula

$$Q_1 = Q \times (p_1/p_2) \times (t_2/t_1)$$

where Q_1 = corrected quantity of gas, cu. ft.; Q = quantity of gas as measured; p_1, p_2 = absolute pressure of gas at meter and calorimeter, respectively; t_1, t_2 = absolute temperature of gas at meter and calorimeter, respectively.

Heat Consumption is the product of heating value of fuel by fuel consumed per hour. Heating value for gaseous fuels is that found by the gas calorimeter, B.t.u. per cu. ft., high value. Heating value of liquid fuels is that given in report of physical or chemical laboratory, B.t.u. per lb., high value.

Indicated Horsepower if specified in agreement, shall be the gross I.Hp. as determined from indicator diagrams from working cylinders alone.

For 4-cycle engines, I.Hp. = $PLAN/(2 \times 33{,}000)$;

For 2-cycle engines, I.Hp. = $PLAN/33{,}000$,

where P = mean indicated pressure, lb. per sq. in.; L = length of stroke, ft.; A = area of piston, minus area of piston- or tail-rod, sq. in.; N = rev. per min. Total indicated horsepower of a double-acting cylinder is sum of the horsepowers developed in the two ends. Total indicated horsepower of a multi-cylinder engine is sum of the horsepowers developed in all cylinders.

Brake Horsepower is found by the formula

$$\text{B.Hp.} = 2\pi LWN/33{,}000$$

where W = net force on brake arm, lb.; L = distance between center of shaft and bearing point or weight center at end of brake arm, ft.; N = rev. per min. of shaft. If brake horsepower is calculated from electric measurements, 2% of full load capacity of generator at applicable speed shall be added to measured electric output to cover windage, friction and undetermined losses. Correction shall be made for conventional efficiency of generator.

Brake Mean Effective Pressure must be calculated from brake horsepower by the formulas

For 4-cycle engines, B.M.E.P. = $(\text{B.Hp.} \times 33{,}000 \times 2)/(LAN)$;

For 2-cycle engines, B.M.E.P. = $(\text{B.Hp.} \times 33{,}000)/(LAN)$.

Symbols have the same meaning as in formula for indicated horsepower.

Electrical Horsepower is kilowatt output at terminals divided by 0.746. With alternating-current generators, output shall be net output. When power for excitation or ventilation is taken directly from engine shaft, output indicated at terminal is net output.

*According to actual contractual conditions, the B.Hp. will be either Item 54 or Item 59.

When exciting current is obtained from the generator through a motor, or from some outside source, net output is current delivered at terminals minus current supplied for excitation.

Thermal Efficiency is the fraction of the heat consumption converted into work according to the formulas

$$\text{Brake thermal efficiency, } e_b = 2545/Q_b$$

$$\text{Indicated thermal efficiency, } e_i = 2545/Q_i$$

where Q_b and Q_i = respectively, high heating value of the fuel multiplied by the pounds or cubic feet of fuel supplied per brake horsepower hour or per indicated horsepower hour.

DATA AND RESULTS should be reported in accordance with the form on p. 16–48. for horsepower tests made at constant speed, and on the form below for horsepower tests made over the whole speed range of a variable speed engine.

DATA AND RESULTS OF INTERNAL-COMBUSTION ENGINE TEST AT VARIABLE TORQUE AND SPEED

14. TEST CODE FOR GAS PRODUCERS

Approved, 1928

This code is intended primarily for tests of producers whose gas is to be used for power purposes; it also may be used for producers generating gas for metallurgical and other heating purposes. The term fuel in the code includes all possible fuels.

OBJECTS for which tests of producers are made include:

a. Maximum and most efficient capacities of the producer plant and of its several elements. *b.* The efficiency of the producer as a whole in making gas, and that of its several elements. *c.* Ability of the producer to use a particular fuel in a particular way. *d.* Labor and power required for operation. *e.* Quantity of cooling water required. *f.* Cleanness of gas delivered. *g.* Results obtained by using different kinds and sizes of fuel in different ways. *h.* Amount of manual and skilled labor and of power required to operate producer and each of its auxiliaries. *i.* Reliability of producer and of its several elements and auxiliaries. *j.* Causes for faulty operation of the producer.

MEASUREMENTS depend somewhat on the object of the test, but in general include:

a. General data relative to type of producer and of each of its auxiliaries and their principal and important dimensions. *b.* Sizes and weights of each of the solid fuels, weight of oil, and weight of tar supplied to producer, and their physical characteristics and rates of firing; weight of ashes and refuse; weight of unburned carbon recovered therefrom. *c.* Ultimate and approximate analyses and calorific values of fuel and tar supplied to producer, and of hot gas, clean gas and tar delivered by producer plant; the specific gravity of each, and the analyses of ashes and refuse. *d.* Weights of water and their total heats above or below 68° F. supplied to producer and to each of its auxiliaries and their rates of supply. *e.* Volume, pressure, temperature and humidity of air delivered to producer. *f.* Temperatures of water delivered to producer and each of its auxiliaries; of the steam generated, and its quality; of gas delivered to and by each unit of the plant wherever change of temperature occurs. *g.* Barometric pressure and temperature of atmosphere, pressures of steam at the steam jet, in evaporator or jacket in the boiler, and elsewhere; the suctions and pressures of the gas before and after passing each auxiliary, and on being measured for calorific value and quantity. *h.* Humidity of air and steam delivered to producer. *i.* Quantity of gas of ...ure, absolute pressure, analysis, humidity, and calorific value delivered, and the rate of generation. *j.* Amounts of gross power used in operating scrubbers, purifiers, pumps, exhausters, and each of the other auxiliaries, and in charging, rotating, poking, and cleaning

producer. *k.* Amounts of manual and skilled labor used in operating the producer and each of its auxiliaries. *l.* Scaling properties of the water. *m.* Wear and tear and length of life of fuel-feeding devices, grates, valves, cleaning materials used, and of engines, motors, and other auxiliaries. *n.* Size of coal as determined by screening a sample.

AND APPARATUS required for producer tests are:

a. Measuring rods, rules, or tapes. *b.* Platform scales and weighing vessels for weighing fuels, ashes and water. *c.* Fuel-sampling and analyzing appliances and hydrometers. *d.* Fuel calorimeter. *e.* Steam calorimeter. *f.* Gas calorimeter, both sampling and continuous. *g.* Gas analyzing apparatus. *h.* Tar determinator. *i.* Soot determinator. *j.* Moisture determinator. *k.* Gas meter, Venturi meter, pitometer, or orifice meter for measuring gas output, together with the necessary thermometers, thermometer wells, manometers or pressure gages. *l.* Manometers, draft and pressure gages. *m.* Water meters, or other water measuring apparatus for measuring feed and scrubber water, and steam meters or equivalents for measuring steam used by each unit. *n.* Thermometers and wells. *o.* Instruments for measuring or determining power required to rotate and poke producer, to operate water- and oil-fuel pumps, tar extractor, scrubber, purifier and each of the other motive appliances. *p.* Necessary connections for each instrument or apparatus. *q.* Necessary instruments, etc. for calibrating above apparatus and instruments.

DURATION OF TEST in full time and complete tests should be such that probable error in weighing coal does not exceed 2%, or that total consumption of fuel is at least twice the weight of fuel in the producer when in normal operation. No test should be shorter than 24 hours, after the producer has attained desired and constant operating temperatures and conditions. Determination of clinkering tendency of fuel and quality of ash in large producers will require tests of five or more days duration.

Intermittent producers require the fuel bed to be entirely removed and rebuilt at regular intervals. Duration of test then should be that of one or more of the regular commercial operating cycles. Or if a complete cleaning and renewal occurs before total fuel consumption stipulated above occurs, the duration of test should be time elapsing between a corresponding number of successive renewals of the fuel bed.

STARTING AND STOPPING should occur at the conclusion of the time of regular cleaning. Both starting and stopping should be preceded for a period of not less than 8 hr. by the same regular working conditions as will characterize the test as a whole. Nc clinker should be on the walls or in the producer at beginning and end of test.

Continuous Producers with Grate and No Ash Bed.—Remove ashes and clinker from grate and lower part of furnace space. Stir fuel bed by means of a poker introduced through poker holes. Replenish producer with fuel to working depth; fill hopper level full. Note time and consider it as starting time. Then clean ash pit and proceed with regular work of the test, using weighed fuel.

To stop test, repeat cleaning operations, bring ash zone to the same depth and uniformity of content as at start, replenish producer with fuel to the same measured working depth as at start, and end test by filling hopper level full and noting time. Remove ashes and refuse from ash pit, weigh and sample.

Continuous Producers with Supporting Ash Beds.—Remove ashes until top of ash bed is lowered to normal working point. Introduce poker and break down any bridge or crust that may have formed, and make fuel bed homogeneous. Replenish producer with fuel to the working depth, which should be measured; fill hopper level full. Note time and consider this starting time. Then proceed with regular work of test, using weighed fuel.

To stop test, repeat above operations, ending with replenishing producer and filling hopper with weighed fuel. Note time and consider this as stopping time. Ashes and refuse finally removed, unless already dry, are to be dried before weighing. They may be weighed both wet and dry, and the water accredited to the water used during the test.

Intermittent Producers.—Thoroughly clean producer of its entire contents. Introduce a weighed supply of fuel, ignite it and build fuel bed to working condition, using weighed fuel. Note time and consider it as starting time. Proceed with regular work of the test.

When time approaches for ending test, burn fuel bed as low as practicable to prepare for cleaning. Note time and consider this stopping time. Completely empty producer, quench fire remaining in live coals, separate and weigh coke and ashes, and deduct weight of the coke from fuel as charged. Dry, weigh, and sample for analysis, the ashes and refuse. Analyze them for their contents of moisture, carbon, iron and earthy inorganic matter, making allowance for moisture in determining net weight of dry ashes.

THICKNESS OF FUEL BED AND ASH BED may be determined by the simultaneous use of several rods inserted vertically through observation holes in top of producer. The rods should be of $^3/_4$-in. pipe, with a stop-pin 3 in. long, 2 ft. from the upper end and long enough to extend down to the ash pit.

Top level of the green coal zone and height of fuel in producer at each place will be shown by distance rod is inserted below observation hole when resting on the fuel. When rod is forced down

to the ash pit, the depth of ash zone, thickness of incandescent and of green-fuel zones may be determined by length and position of red-hot portion of the rod. The gas zone may be noted by e sooty deposit on the upp ... results from the several rods should be reported.

NOTATION.—The following notation is used in the discussion below:

Standard Conditions are a temperature of ° F. and a pressure of 29.9212 in. of mercury at 32° F. (approximately 14.70 lb. per sq. in.).

$A_1, A_2 \ldots A_n$ = percentage of each combustible constituent of gas (standard conditions)

c_1, c_2 = sum of proportions, by volume, of constituent gases containing 1 atom and 2 atoms, respectively, of carbon

C_1 = carbon in 1 lb. of coal as fired

C_2 = carbon in 1 lb. of ashes and refuse

C_3 = carbon in ashes from 1 lb. of coal

C_4 = carbon gasified per 1 lb. of coal

C_5 = carbon in 1 cu. ft. of gas (standard conditions)

C_c = carbon in 1 cu. ft. of clean, dry gas, lb.

C_f = carbon in 1 lb. of fuel

$C_{p1}, C_{p2} \ldots C_{pn}$ = respectively, specific heat of each combustible constituent gas at constant pressure

C_n = percentage of net carbon in fuel

C_s = lb. of carbon per lb. of fuel in soot

C_t = lb. of carbon per lb. of fuel in tar

$d_1, d_2 \ldots d_n$ = respectively, density of each constituent gas

E = efficiency

E_c = cold gas efficiency

E_h = hot gas efficiency

$G_1, G_2 \ldots G_n$ = respectively, percentage of each constituent in gas delivered (standard conditions)

H_a = heat lost in combustible in ashes and refuse

H_c = B.t.u. per lb. of coal

H_g = B.t.u. per 1 cu. ft. of dry gas

H_m = Heat in moisture leaving producer

H_o = desired B.t.u. output of producer per hr.

H_r = Heat of scrubber water

H_s = Sensible heat in gas as delivered

H_w = Total heat above 68° F. of water vapor in gas at partial pressure due to its temperature

$h_1, h_2 \ldots h_n$ = respectively, calorific value of constituent gases (Standard conditions)

h_f = higher calorific value of 1 lb. of fuel, B.t.u.

h_g = higher calorific value of 1 lb. of dry gas

h_h = higher calorific value of gas, B.t.u. per cu. ft. (Standard conditions)

h_r = total heat of 1 lb. of superheated steam above 68° F. at temperature of gas leaving producer, and at its partial pressure

h_s = higher heat value of fuel (or equivalent heat) used to generate steam supplied from outside source

m = percentage of moisture in gas

P = absolute pressure of gas, lb. per sq. in. (Standard conditions)

P_a = standard atmospheric pressure

P_w = pressure of saturated water vapor at temperature t

t = temperature of gas as delivered, deg. F.

t_a = absolute temperature of gas, deg. F.

t_i = temperature of scrubber inlet water

t_o = temperature of scrubber outlet water

V = gas delivered per 1 lb. of fuel, cu. ft.

V_b = volume of gas generated per 1 lb. of dry fuel burned, cu. ft.

V_c = volume of clean gas per 1 lb. of fuel, cu. ft.

V_d = volume of dry gas, cu. ft.

V_e = equivalent volume (standard conditions)

V_m = measured volume

V_s = observed volume of gas leaving scrubber

W_a = weight of combustible in ashes, lb.

W_b = weight of dry gas per 1 lb. of fuel burned

W_c = weight of coal per hour to generate desired output

W_d = weight of dry gas per 1 lb. of net carbon gasified

W_f = weight of dry fuel

W_g = gross weight of dry gas delivered

W_r = weight of scrubber water

$w_1, w_2 \ldots w_n$ = weight of each of constituent gases, lb. per cu. ft. (standard conditions)

w_a = weight of ash in 1 lb. of coal, by analysis

w_c = weight of carbon per 100 cu. ft. of gas

w_g = weight of 1 cu. ft. of dry gas

SPOT TESTS are made where the cost of making full time test is prohibitive, or where frequent check is desired on the capacity, efficiency and character of output of producer at any time. Spot tests require an appliance for continuously sampling gas or for taking a series of spot samples, apparatus for analyzing gas produced and a continuous gas calorimeter or equivalent.

Average calorific value of gas may be calculated from volumetric analysis under standard conditions by using appropriate values of calorific value of the constituent gases. Average volumetric analysis for test period then is converted into an analysis by weight from which the total weight of carbon in 1 cu. ft. of standard gas may be determined.

Total weight of carbon in 1 cu. ft. of gas standard is $C_5 = 0.03127\ c_1 + 0.06298\ c_2$

Determine ultimate analysis and calorific value of the coal as actually fired, and also the analysis of the carbon content of the dried ash. Then weight of carbon lost in ashes per 1 lb. of coal as fired is $C_3 = w_a\{C_2/(1 - C_2)\}$.

Weight of carbon gasified per 1 lb. of coal is $C_4 = C_1 - C_3$

Cu. ft. of gas per 1 lb. of coal is $V = C_4/C_5$

Cold gas efficiency is $E_c = (C_4 \times \text{B.t.u. per cu. ft. of gas})/(C_5 \times H_c)$

B.t.u. output per lb. of coal is cu. ft. gas per lb. of coal × B.t.u. per cu. ft. of gas

Weight of coal to be fired per hour to generate desired output is $W_c = H_o/(E_c \times H_c)$. Weighing the coal input over any desired period of steady load, therefore, will permit determination of output capacity.

Spot Test with Tar Producing Fuels may be made if tar and soot per cu. ft. of outlet gas are determined. The above methods will apply only where cooling water is recirculated and tar and soot either are gasified, or separated and determined per cu. ft. of gas delivered. If tar is wasted, it first must be collected, weighed and sampled, and its weight compared with weight of fuel used during the same time, to determine amount of tar lost per lb. of coal gasified. If water is not recirculated, considerable CO_2 will be absorbed by the cold water washing the gas. Carbon so lost can be determined by comparing CO_2 content of gas samples taken simultaneously before and after passing the coolers, or by metering cooling water and analyzing it to determine the amount of carbon carried away as CO_2 in the water.

Short Tests may be made by determining items indicated in the record, p. 16–55. In such tests, it is unnecessary to meter steam used or gas made. Volume of gas made is determined by knowing amount of carbon gasified per hr., and average amount of carbon in 1 cu. ft. of gas as it leaves producer, including carbon in tar and soot. Amount of water vapor coming from all sources must equal water equivalent to hydrogen, free and combined, in gas, tar and water going into the gas-main from the producer. The amount of hydrogen coming from the fuel and from moisture in the air are known. The balance of the hydrogen enters producer as steam from boiler and as vapor from ash pit, water seal and elsewhere. From these data, gas and tar produced per ton of coal, total heat in gas, both sensible and potential, and thermal efficiency can be calculated.

Analyses and Calorific Test of Gas Output * should be determined by chemical analysis, calorimetric tests, or both. Continuous samples should be taken from delivery pipe at point nearest producer and other points as needed. Condensible tarry vapors and soots should be filtered out and their weights determined. Calorimetric tests of clean gas should be made with a Junkers type of calorimeter. Approximate determination of the composition of clean gas may be made with an Orsat apparatus and a complete determination with a Hempel apparatus. Determinations should be made not more than one-half hour apart, the time for collecting sample being not less than one quarter hour. If results of averages only are desired, taking of the sample may be made continuous and extended to several hours.

Measurement of Steam may be by weighing the water before it is evaporated, providing there are no leaks or other uses made of the steam; by a suitable steam meter; or by the Rateau or Napier formulas.†

CALCULATIONS. Total Volume of Gas Delivered should be calculated from chemical analyses of fuel and gas, or measured by the pitometer or orifice meter. With the latter it will be the continued product of the effective area, sq. ft., of the delivery pipe at the Pitot tube, or of the orifice, the average velocity of gas over that area, ft. per min., and the duration of the test in minutes. With unclean gases, calculation from chemical analysis is more likely to give correct results.

Equivalent volume of gas at standard atmospheric pressure is

$$V_e = (V_m \times P \times 35.89)/t_a$$

Gas leaving the scrubber is saturated with water vapor at the pressure due to its temperature. Volume of dry gas is

$$V_d = V_s \times \{(P - P_w)/P_a\} \times \{527.6/(t + 459)\}$$

The weight of dry gas per lb. of net carbon gasified in the producer is

$$W_d = \frac{11CO_2 + 8O_2 + 7(CO + N_2 + C_2H_4) + 4CH_4 + 0.5H_2}{3(CO_2 + CO + CH_4 + 2C_2H_4)}$$

where CO_2, O_2, etc. are the percentages by volume of the dry gas per lb. of net carbon gasified.

Dry gas per pound of fuel burned is

$$W_b = (W_d \times C_n)/100; \quad C_n = C_f - (C_t + C_s + C_1)$$

C_f, C_t, C_s and C_1 are taken in percent.

Volume of gas per 1 lb. of fuel is $V = W_b/w_g$. Values of w_g may be calculated from the values in Table 1 as shown below.

Weight of carbon per 100 cu. ft. of gas at standard conditions is

$$w_c = 0.03127\ (CO + CO_2 + CH_4) + 0.06284\ C_2H_4 + 0.6313\ C_2H_6$$

where CO, CO_2, etc. = percentage by volume of each constituent gases containing carbon; the numerical factors are the pounds of carbon in 1 cu. ft. of the several constituent gases.

Volume of clean gas delivered per lb. of fuel is

$$V_c = \{C_f - (C_t + C_s + C_a)\}/C_c$$

The percentage of tar and soot, C_t and C_s, is total weight of tar and soot including that collected from tar drips, soot catchers and scrubber water, divided by total weight of dry fuel used.

* See Analysis of Fuel Gas, S. W. Parr and F. E. Vandaveer, Univ. of Ill. Bull., vol. xxii, No. 8, Oct. 20, 1924.

† Rateau formula, $Q = 3.6P(16.3 - 0.96 \log P)$; Napier formula, $Q = PA/70$ (approx); Q = lb. steam per sec.; A = orifice area, sq. in.; P = absolute pressure, lb. per sq. in.

MOISTURE IN GAS is found by passing a sample of gas through a chloride of calcium tube and weighing the amount of moisture collected and absorbed, the gas first passing through a heater to raise its temperature to that of gas leaving producer, or to not less than 250° F. The gas first should have all tarry vapors removed by inserting a plug of cotton in the inlet end of the sampling tube, providing the temperature of the gases is below 212° F., and at the exit end of the tube. The tube should be kept at a temperature above the dewpoint of the gas, if the gas is extremely hot. The sample of gas from which tarry vapors have been removed should be metered.

Net Volume of Dry Gas Delivered is the difference between the volume delivered by the producer and that used by gas engines or other gas-consuming auxiliaries in the plant. If steam is generated in a special boiler instead of by waste heat from the producer, fuel and labor costs of the boiler should be charged to the producer. If the producer and its auxiliaries use purchased electric or other power, the cost of such power should be charged to the producer.

Gross Weight of Dry Gas may be obtained by

$$W_g = (G_1 w_1 + G_2 w_2 \ldots . G_n w_n)/100$$

Values of $w_1, w_2 \ldots . w_n$ should be at standard conditions. (See column 2, Table 1.)

Calorific Value of Dry Gas per cu. ft. should be obtained by a Junkers type of calorimeter. It also may be obtained by

$$H_g = A_1 h_1 + A_2 h_2 \ldots . A_n h_n$$

For values of $h_1, h_2 \ldots . h_n$, see Table 2.

Sensible Heat of the gas as delivered may be obtained by

$$H_s = (t - 68)\ (A_1 d_1 C_{p1} + A_2 d_2 C_{p2} + \ldots . A_n d_n C_{pn}) + H_w$$

Results may be calculated and reported per cubic foot of gas (saturated, moist or dry), either at specified or at standard temperature and pressure, or they may be reported per pound of fuel gasified (either as fired or dry). Sensible heat of fuel is product of its specific heat per lb. (0.20 to 0.24 for coal) and temperature difference between the fuel and the surrounding air, above or below 68° F. (*Continued on page 16–58*)

DATA AND RESULTS OF GAS-PRODUCER TEST

Only items marked * are used in report of short test

Item		
	Type of producer	
	Rated size, power, or capacity of producer	
9	Duration of test	
10	Trade name, kind, and size of solid fuel	
11	Trade name and kind of oil fuel	
	(a) Oil fuel, specific gravity at 68 deg. F	deg. A.P.I.
	(b) Oil fuel, specific gravity	referred to water
	(c) Oil fuel, weight per gal. at 68 deg. F	lb.
12	Outside diameter and height of producer	ft.
13	Inside diameter at hearth	ft.
14	Maximum inside diameter of lining of producer	ft.
15	Minimum inside diameter of lining of producer	ft.
16	Actual net diameter of gasification zone	ft.
17	Height from lowest level of grate to top of crown	ft.
18	Height from lowest level of grate to center of gas outlet	ft.
19	Vertical distance between highest and lowest levels of inclined grate	ft.
20	Gross dimension of grate, or of area upon which fuels and ashes are supported	ft.
21	Corresponding projected area of grate	sq. ft.
22	Gross diameter of central air-inlet through grate	ft.
23	Corresponding area of same	sq. ft.
24	Gross area of grate, if inclined	sq. ft.
25	Area of air spaces in grate	sq. ft.
26	Ratio of air spaces in grate to net, or gross, grate area	
27	Diameter of steam-blast inlet, or blower	in.
28	Corresponding area of same	sq. in.
29	Type of blower used	
30	Diameter of steam pipe to blast inlet, or blower	in.
31	Diameter of gas outlet	in.
32	Corresponding area of same	sq. in.
33	Area of fuel bed at maximum diameter	sq. ft.
34	Actual net area of fuel bed at gasification zone	sq. ft.
35	Area of water-heating surface in vaporizer, or jacket	sq. ft.
36	Method of poking producer	
37	Method of rotating producer	
38	Method of generating steam for producer	
39	Method of cooling gas	
40	Method of scrubbing and purifying gas	
41	Method of supplying water for cooling and cleaning	

TEST DATA AND RESULTS

Pressures

Item		
*42	Steam pressure, gage, lb. per sq. in. (a) in boiler .... (b) in vaporizer .... (c) as delivered to producer..	
43	Gas pressure, or suction, in main at point where gas is measured	in. of water
44	Pressure, or suction, at top of producer	in. of water
45	Pressure, or suction, beyond scrubber	in. of water
46	Pressure, or suction, beyond purifier	in. of water
47	Draft pressure, or suction, in ash pit, or in bottom of producer	in. of water
48	Barometric pressure of atmosphere .... in. of mercury at	deg. F.
49	Corresponding barometric pressure of atmosphere at 32 deg. F	in. Hg
50	Corresponding barometric pressure of atmosphere at 68 deg. F	in. Hg

Miscellaneous

Item		
*51	Relative humidity of air	percent
	Humidity of steam as delivered to the producer	percent wet
53	Average depth of fuel bed	
54	Average depth of ash bed	
55	Number of cleanings	
56	Average length of cleanings	
57	Average intervals between cleanings	
58	Average intervals between pokings	
59	Average length of pokings	
60	Ashes, clinkers, and refuse, wet or dry	lb.

Temperatures

Item		
61	Temperatures of feedwater entering vaporizer of producer	deg. F.
62	Temperature of feedwater entering outside steam generator or waste-heat boiler	deg. F.
63	Temperature of air in room	deg. F.
*64	Temperature of air entering producer	deg. F.
*65	Temperature of gas leaving producer	deg. F.
66	Temperature of tar and soot as delivered	deg. F.

(*Continued on following page*)

EFFICIENCIES.—The hot gas efficiency of the producer is the ratio of the total heat carried by the gas (heat of combustion + sensible heat above 68° F.) to the sum of the heat supplied in its production. The total heat of hot unclean gases includes: Heats of combustion of the constituent gases and of the carbonaceous and tarry vapors, liquids

and solids, their superheat above the temperatures corresponding to their partial pressures. the latent heats of the constituent vapors, including water vapor, and their sensible heats above 68° F. In determining efficiency, total heat used to generate steam supplied to the producer from an outside source, must be added to heat of the fuel supplied in the same time.

Gross-dry-fuel is 1 lb. less weight of moisture in 1 lb. as determined by analysis. Net-dry-fuel is gross-dry-fuel less weight of unburned carbon in ashes and refuse produced by 1 lb. of fuel-as-fired. Gross combustible is 1 lb. less sum of weights of moisture and ash in 1 lb. as determined by analysis. Net combustible is gross combustible less weight of unburned carbon in ashes and refuse produced by 1 lb. of fuel-as-fired.

Efficiency may be referred to gross or net gas delivered (saturated, moist or dry), to fuel-as-fired, to gross-dry- or net-dry-fuel, or to gross or net combustible. The calorific value used must be that of the fuel as stated. The gases may be taken as saturated, moist or dry under standard conditions. Efficiency may be calculated by

$$E = h_h \times V/(h_f + h_s)$$

Efficiency of conversion and cleaning, or gross efficiency, is found by using total gross volume of gas delivered. Efficiency of plant, or net efficiency, is found by using net volume of gas delivered. Net volume is gross volume less the actual gas used, or its equivalent, to operate the auxiliaries. If total heat of cold gas be taken, the efficiency is the cold gas efficiency. If the total heat of the hot gas be taken, the efficiency is the hot gas efficiency. Cold gas efficiency and hot gas efficiency are determined by the following formulas:

$$E_c = (A_1 h_1 + A_2 h_2 \ldots + A_n h_n)/(h_f + h_s)$$
$$E_h = \{(A_1 h_1 + A_2 h_2 \ldots + A_n h_n) + H_s\}/(h_f + h_s)$$

$A_1, A_2 \ldots A_n$ are taken as percentages of cold gas delivered per lb. of fuel; $h_1, h_2 \ldots h_n$ are based on cold gas. Unless otherwise stated, higher calorific value always should be used. Cold and hot gas efficiencies, both gross and net, however, may be determined for both higher and lower calorific values of the gas.

HEAT BALANCE quantities based on dry gas are computed as follows:

Heating value of dry gas $= H_g = V_b \times h_g$.

Sensible heat $= H_s = V_b \times C_{p(\text{mean})} \times (t - 68)$. (See also p. 16–54.)

Heat carried off by scrubber water $= H_r = W_r \times (t_o - t_i)/W_f$.

Heat in moisture leaving producer $= H_m = W_b \times m \times h_r$.

Heat lost in combustible in ashes and refuse $= H_a = (W_a/W_f) \times 14{,}544$. The calorific value of the combustible in the ashes may be checked by calorimeter or by chemical analysis.

If excess steam is generated in a waste heat boiler by waste heat of the producer, and if tar, soot and ammonia are recovered along with the gas, their amounts should be included and reported in the output, and their net values deducted in the financial report of the cost of making gas.

DATA AND RESULTS should be reported in the form p. 16–55, using only those items that conform to the object of the test.

15. TEST CODE FOR CENTRIFUGAL COMPRESSORS AND EXHAUSTERS

Approved, 1934

This code covers the conducting and recording of tests on centrifugal compressors and exhausters, whose purpose is to determine all or some of the following essential quantities, reduced to some specified conditions:

1. Inlet and discharge pressures, expressed as total pressures in inches of water for fans, and pounds per square inch for compressors and exhausters.

2. Quantity of air or gas compressed and delivered, expressed in units of volume per unit of time, under the specified conditions of density, temperature, and pressure at the intake of the machine. The unit for this quantity usually is the cubic foot per minute.

3. Power applied to the shaft of the compressor or exhauster or fan. The unit for this quantity usually is the horsepower.

4. The rate at which steam, electrical energy or fuel, depending upon the method of drive, is consumed by the driving element. The unit for this quantity usually is pounds of steam per hour, kilowatts, or pounds of fuel per hour. This also may be expressed as the pounds of steam, kilowatt-hours, pounds of fuel, or available B.t.u. per 100 cu. ft. of air or gas at contract inlet conditions.

PREPARATIONS FOR TESTS.—Dimensions and physical condition of the machine to be tested, as listed in the report form, should be ascertained and reported, and also similar information concerning all associated parts of the plant which may have a bearing on the results of the test.

Items which should be recorded in this connection are: Internal condition, particularly with reference to clearance in wearing rings, presence and extent of deposits on impellers and casing, and other factors that can affect the performance of the machine; dimensions of inlet and discharge openings, particularly where pressure readings are taken; number of stages in the machine and whether it is uncooled or provided with internal or external cooling. A sketch showing the location of the various instruments and testing apparatus in relation to the machine under test should be prepared.

Preliminary Tests may be run to: *a.* Determine whether the machine is in suitable condition for conduct of acceptance test. *b.* Check all instruments. *c.* Train personnel.

OPERATING CONDITIONS.—The most important factors affecting operating conditions are: *a.* Inlet gas temperature, pressure and composition. *b.* Quantity of air or gas handled by machine. *c.* Total pressure rise or pressure ratio. *d.* Speed of the machine.

Operating conditions should be as near as possible to those specified. Test results with gas having practically the same value of C_p/C_v as specified, may be corrected to specified conditions when volume, speed and density at inlet are within 3%, 5% and 10%, respectively, of the corresponding specified conditions, and when the combined variations result in (*inlet volume rate/speed*) differing by not more than 4% from the specified values.

STARTING AND STOPPING.—The machine should be operated under test conditions sufficiently long to establish uniform conditions of pressure, volume, temperature and speed. The duration of the test depends on method of driving the machine, on how completely the compressor characteristic is to be determined, and on the uniformity of the various readings. Each test in which volume, pressure and speed are intended to be constant shall run for at least 30 minutes. During this period at least six readings of all instruments which have an important bearing in the calculation of results shall be taken. The readings of each set should be taken as nearly simultaneously as possible. The test must be continued until a period of 30 consecutive minutes produces a consistent set of records.

INSTRUMENTS AND APPARATUS required are: *a.* Barometer. *b.* Thermometers. *c.* Pressure gages, or mercury or water U-tubes. *d.* Differential gages. *e.* Impact tubes, pitot tubes, manometers. *f.* Flow nozzles. *g.* Tachometers, revolution counters, or other speed counting devices. *h.* Appropriate electrical instruments. *i.* Appropriate instruments for measuring total steam flow, pressure, temperature, vacuum, etc., if performance of a turbine or engine is to be determined. *j.* Hydrometer or psychrometer. *k.* Gas analysis apparatus. *l.* Dynamometer for determining power absorbed at coupling of machine, if separate performance data are required for driving and driven elements.

Power delivered to the compressor or exhauster shaft, when direct connected, shall be the power output of the driving element. When not direct connected, corrections shall be made for the losses between driving element and the machine under test. Without special precautions, the electric dynamometer may be an unreliable instrument. It is recommended that the machine under test be driven by a direct-current dynamometer and that the dynamometer horsepower be checked by the calculation of horsepower from the electrical readings by the method of losses. It is recommended further that a dynamometer should not be used for less than 33% of its rated

horsepower. If a transmission dynamometer is not available, the preferred method of determining power input to the compressor shall be the use of a direct connected calibrated electric motor, provided the calibration tests of this motor are made in accordance with the standard rules of the A.I.E.E. and are frequently re-checked. Curves shall be made up from the calibration tests, translating kilowatt input into shaft horsepower output. Power input to the motor during a compressor test then shall be measured in accordance with the standard rules of the A.I.E.E. and the corresponding power output as shown on the calibration curve shall be taken as the power input to the compressor.

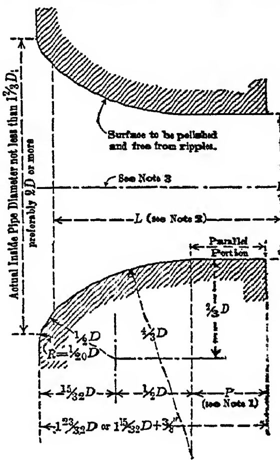
COMPUTATION OF RESULTS.—Pressure Rise shall be the difference between the absolute discharge total pressure and the absolute total pressure at the inlet to the machine. If the difference between the velocity pressure at the inlet and discharge is less than 0.2% of the pressure rise, as defined above, static pressures given by pressure gages may be used.

Pressure Ratio shall be the absolute discharge total pressure divided by the absolute inlet total pressure.

The Volume Rate discharged by compressors and exhausters shall be computed by the flow nozzle method.

EFFICIENCY of a compressor or exhauster is the ratio of the energy converted into useful work to the energy supplied. Efficiency $= (P_g/P) \times 100$, where P = shaft horsepower input, as determined by dynamometer or calibrated electric motor, and P_g = gas horsepower output as explained below.

Efficiency may be computed on the basis either of adiabatic or isothermal compression. Overall efficiency is the ratio of theoretical (adiabatic or isothermal) horsepower to the horsepower input of the driving element.



Note 1. $P = {}^3/_4\ D$ for nozzles $1\ {}^1/_2$ in. and over $= {}^1/_2 D + {}^3/_8$ in. for smaller nozzles.

Note 2. For pipe diameters of $1.66D$ to $1.9D$, L is to be made such as to make diameter of intersection of inlet curve with nozzle face equal to $1.05\times$ actual inside pipe diameter.

Note 3. Nozzle to be centered with pipe by means of close fitting bolts, dowels or counterbore, or careful setting and checking; within ${}^1/_{25}\ D$ for pipe diameters $3D$ to $4D$, and within $0.01D$ for pipe diameters less than $4D$.

FIG. 1. Flow Nozzle

Gas and Air Horsepower for Adiabatic Compression and Delivery is determined as follows:

$$P_g = [144\ k/\{33{,}000\ (k-1)\}]\ p_i\ q_i\ X_k \quad \ldots\ldots\ldots \quad [1]$$

where $k = C_p/C_v$ (specific heat ratio); p_i = total pressure at nozzle inlet, lb. per sq. in., abs.; q_i = volume rate at inlet, cu. ft. per min.; X_k = a constant $= r^{(k-1)/k} - 1$; r = pressure ratio. For normal air, or any gas where $(k-1)/k = 0.283$, formula [1] becomes

$$P_g = 0.01542\ p_i\ q_i\ X \quad \ldots\ldots\ldots\ldots \quad [2]$$

where $X = r^{0.283} - 1$.

Gas Horsepower for Isothermal Compression and Delivery is determined by

$$P_g = (144\ p_i/33{,}000) \times q_i \times \log_e (p_f/p_i) = 0.01005\ p_i\ q_i \times \log_{10} (p_f/p_i) \quad \ldots \quad [3]$$

where p_f = discharge pressure. Other notation as before.

Conversion of Test Results to Conditions Specified may be necessary when it is not possible to maintain the same speed for each of the series of tests, or where conditions make tests impractical at the speed at which characteristic curves are desired, or where it is not possible to have conditions of pressure, temperature and gas density in accordance with specified conditions. Test readings then may be corrected to specified conditions by the method given below. Corrections should be applied only within a reasonably narrow range. It is desirable to maintain the ratio (*inlet volume rate/speed*) as nearly as possible the same as when compressor is operating under specified conditions.

Table 1.—Formulas for Flow of Air and Gas through Nozzles

ı the formulas below, the various symbols have the following significance: efficient of discharge = 0.97 for nozzle throat diameter of 0.5 to 1.0 in.; 0.98 above 1 to 2 in.; 0.99 above 2 up to 6 in.; 0.995 above 6 in. C_p, C_v = specific heat at constant pressure and constant volume, respectively. D diam., in. $k = C_p/C_v$. $K = (k-1)/k$ = 0.283 for air and diatomic gases. p_1 at nozzle inlet. p_s = static pressure at nozzle inlet. p_2 = static pressure at nozzle outlet absolute pressure to which volume flow is to be computed or referred. p_b = barometric e. q_1 = volume of flow at conditions in inlet pipe corresponding to p_s and T_1. flow corresponding to conditions p_3 and T_3. $r = p_1/p_2$ for inlet total pressure static pressure. T_1 = absolute temperature at nozzle inlet. T_3 = absolute tem hich volume flow is to be computed or referred. V = velocity, ft. per sec., in inlet p_s is measured. w = flow, lb. per sec. $X = (r^{0.283} - 1)$. Δ = differential pressure across nozzle = $p_1 - p_2$, or $p_s - p_2$. ρ_1 = density in inlet pipe, lb. per cu. ft. corresponding to a given gas at T_1 and p_1 or p_s. All pressures are in lb. per sq. in. absolute. All temperatures are absolute = deg. F. + 459.6.

AFFECTED FLOW.—Absolute Pressure of Low-pressure Region more than 50% of Inlet Pressure.

* Divisor for any perfect gas, or air, with Δ less than 2% of p_s, and D/D_1 less than 1/3.
† Divisor for any perfect gas, or air, with Δ less than 10% of p_s, and any D/D_1.

Note 1.—When inlet pressure is measured as static pressure use the proper formula for inlet total pressure with the following changes: 1. Substitute p_s for p_1; 2. Divide the right-hand term of the formula by the divisor given by the formula in the static inlet pressure column.

Table 1.—Formulas for Flow of Air and Gas through Nozzles.—*Continued*

UNAFFECTED FLOW.—Absolute Pressure of Low Pressure Region Less than about 56% of Inlet Pressure.

Inlet Total Pressure	Inlet Static Pressure
FORMULAS FOR ANY PERFECT GAS	First compute approximate flow by using p_s for p_1 in formula for total inlet pressure. Then compute approximate velocity V by one of the following:
$w = 0.5250\,cD^2\sqrt{p_1\rho_1}\{2/(k+1)\}^{1/(k-1)}\sqrt{k/(k+1)}$	$V = 144\,q_1/60\,D_1^2(\pi/4)$
$q_3 = 31.50\,cD^2\,(T_3 p_1/p_3\,T_1)$ $\times\sqrt{p_1/\rho_1}\{2/(k+1)\}^{1/(k-1)}\sqrt{k/(k+1)}$	$= 144\,w/\rho_1\,D_1^2(\pi/4)$.
FORMULAS FOR ANY PERFECT DIATOMIC GAS	ρ_1 = density in inlet pipe corresponding to T_1 and p_s. Then
$w = 0.2539\,cD^2\sqrt{p_1/\rho_1}$	$(p_1 - p_2) = \rho_1 V^2/144\,(2g)$
$q_3 = 15.23\,cD^2(T_3 p_1/p_3\,T_1)\sqrt{p_1/\rho_3}$	$= \rho_1\,V^2/9266$.
FORMULAS FOR AIR	This is added to p_s, giving p_1, which is used in the proper formula for total inlet pressure.
$w = 0.4165\,cD^2\,p_1/\sqrt{T_1}$	
$q_3 = 9.284\,cD^2\,p_1\,T_3/p_3\sqrt{T_1}$	

In the following formulas, subscript c denotes specified conditions, subscript t denotes test conditions, subscript tc denotes values which the test shows that the machine will give when operating under specified conditions.

The corrected value X_{tc} is found from the test value X_t by the formula

[4]

where the symbols have the same significance as in formulas [1] to [3] and where n = revolutions per minute of the machine under test and ρ = density of gas. $r_t = p_{ft}/p_{it}$, from which the value of X_t may be found.

The corresponding pressure ratio, $r_{tc} = p_{ftc}/p_{ic}$ then is found from the corrected value X_{tc} and compared with specified ratio $r_c = p_{fc}/p_{ic}$. The corrected pressure rise $(p_{ftc} - p_{ic})$ should approximate the specified pressure rise $(p_{fc} - p_{ic})$.

If the gas analysis under specified and test conditions is the same, so that molecular and gas constant R are the same, formula [4] reduces to

[5]

Corrected power P_{tc} is given by

$$P_{tc} = \ldots (k/k - \ldots \times \frac{\ldots}{p_{it}} \times \frac{\ldots}{q_{it}} \times \ldots$$

If the specified and test gas analysis is the same, then

$$P_{tc} \ldots \qquad [7]$$

The above formulas give the power which the machine will consume when operating at specified inlet conditions of volume, pressure, temperature and density, and speed, and on the basis of the corrected pressure ratio, r_{tc} actually produced by the machine.

If the corrected discharge pressure, p_{ftc}, produced approximates specified discharge pressure, p_{fc}, the specified power, P_c, shall be multiplied by the ratio (X_{tc}/X_c). The product, $P_c \times (X_{tc}/X_c)$, should approximate the power P_{tc}.

When tests are conducted to obtain the complete characteristics of the machine, a series of tests should be conducted as follows: *a*. Inlet suction or discharge pressure (not both), and speed are held constant while the volume is changed for each point on the curve. *b*. Similar series are run for different speeds.

The performance of the unit or its characteristic is best presented in curves using inlet volume as abscissa and discharge pressure, horsepower and efficiency as ordinates. Curves should show the relation between each of the following pairs of quantities for each constant speed: 1. q_i and p_f, or $(p_f - p_i)$. 2. q_i and P. 3. q_i and efficiency. Steam consumption in pounds per hour or kilowatts may be used as ordinate, instead of the horsepower, in presenting the q_i and P relations, and the efficiency then should represent that of the overall unit, including the driving element.

FLOW-MEASUREMENT WITH NOZZLES.*—Flow may be measured by means of the nozzle shown in Fig. 1, with an accuracy within 2%, with thoroughly experienced personnel. The formulas given in Table 1 are used to calculate results.

* Tentative, 1935.

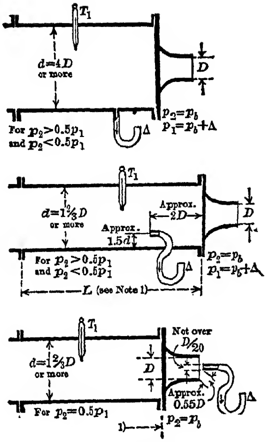
Nozzle Outlet Pressure, where it affects the flow, is the static pressure of an unrestricted region into which the discharge takes place. For example, when a nozzle under pressure discharges to atmosphere, the nozzle outlet pressure is that of the atmosphere as given by the barometer reading. When a nozzle discharges into a reservoir so large that the pressure on the walls is the same wherever measured, the nozzle outlet pressure is the static pressure in the reservoir.

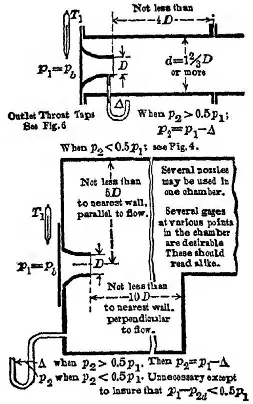
Nozzle Inlet Total Pressure in an inlet pipe whose diameter is $4D$, or more (D = nozzle diameter), may be taken as either the static or total pressure. Static or total pressure also may be used where the fluid enters nozzle from a large space, as when air flows from outside into an exhausted reservoir. If inlet pipe is less than $4D$, total pressure is higher than static pressure. It may be taken with an impact tube, pointing upstream, either in the pipe just ahead of the nozzle or in the jet outside. The reading will be the same in either position. See Fig. 2 for arrangement of apparatus.

Nozzle Inlet Static Pressure may be used instead of inlet total pressure, but the formulas are more complicated. See Fig. 3 for an arrangement of apparatus.

Affected and Unaffected Flow.—When p_2 is more than about 0.5 p_1, flow increases with decrease of p_2. The flow then is *affected.* When p_2 is less than about 0.5 p_1, a change of p_2 does not change the flow, which then is *unaffected.* In either affected or unaffected flow, the pressure rise of the machine under test may be wasted in order to make the flow measurement test, or the flow may be measured while the machine is in service. See Figs. 2 to 5 for arrangement of apparatus for the several classes.

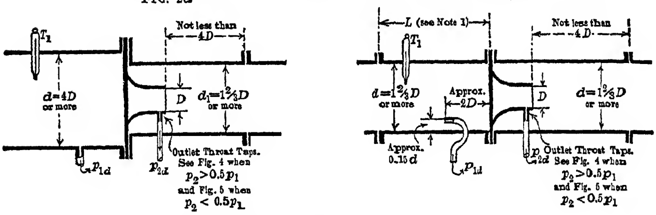
Pressures.—With affected flow, if discharge is into an unrestricted region, nozzle throat pressure is the same as outlet pressure, *i.e.*, pressure in unrestricted region. If nozzle outlet pressure is observed with throat taps, nozzle discharge coefficient is practically the same as for unrestricted discharge. Throat pressure observations should be made with at least two, and preferably four, sets of pressure holes, each with its own dif-





where pressure rise is wasted in order to make flow measurement test.

Fig. 2a Fig. 2b



Arrangements for measuring flow with machine in service.

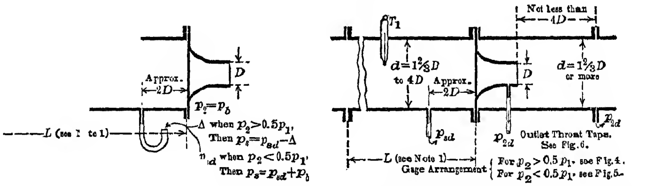
Fig. 2c

Note 1. $L = 10\,D$ where there is a preceding symmetrical irregularity in the pipe, as a reducer; $L = 20\,D$ if there is a preceding unsymmetrical irregularity, as an ell or tee.

Fig. 2. Flow Measurement with Inlet Total Pressure

ferential U-tube, whose readings should agree within 1.5%. Apparatus set-up and operating conditions should be refined until this agreement is attained.

Nozzle diameters should be selected that will give pressures ranging from 10 to 40 in. of water or 10 to 28 in. of mercury. High-pressure air discharging to atmosphere may be measured with high initial pressure, giving unaffected flow, or a throttle may be used to give affected flow, and nozzle diameters selected accordingly. Throttle valves should be of the butterfly or globe type (not a gate) and should be at least 20 nozzle diameters upstream from nozzle.



Note 1. $L = 10\,D$ where there is a preceding symmetrical irregularity in the pipe, as a reducer; $L = 20\,D$ where there is a preceding unsymmetrical irregularity, as an ell or tee.

Fig. 3. Flow Measurement with Inlet Static Pressure

TEMPERATURES less than 300° F. should be measured with a mercury-in-glass thermometer with bare bulb exposed to the fluid, and located 6 to 10 nozzle diameters upstream from the nozzle. T_1 = thermometer reading + 459.6.

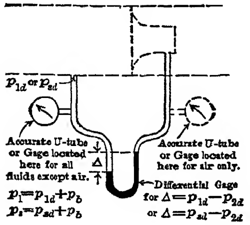


FIG. 4

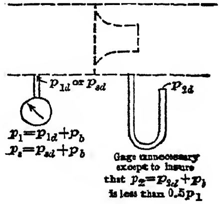

FIG. 5

Gage Arrangements for Flow Measurement with Machine in Service

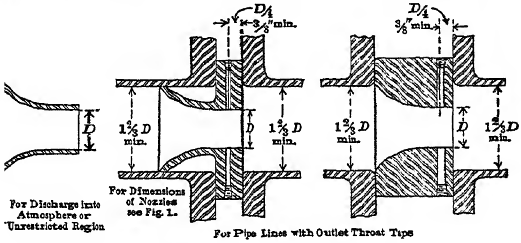

FIG. 6. Forms of Nozzles

ROTARY MOTION of the fluid should be eliminated by guide vanes or straighteners (Fig. 7) whose discharge ends are 5 to 15 nozzle diameters upstream from nozzle.

SELECTION OF FORMULA, when result desired is in volume instead of weight of fluid, should be on the basis of: 1. *Inlet volume* at conditions of pressure and temperature at inlet of machine under test, invariably used for tests of compressing and circulating apparatus; substitute values of inlet temperature and pressure for p_3 and T_3 in the formulas. 2. *Atmospheric conditions*, substitute values of p_b and T_b for p_3 and T_3. 3. *Volume under any conditions*, substitute values for such conditions for p_3 and T_3.

STANDARD CONDITIONS OF AIR are taken as 14.7 lb. per sq. in. pressure, 68° F. temperature, and 0.075 lb. per cu. ft. density. These conditions represent average air and make some allowance for humidity.

DENSITY OF PERFECT GASES.—Where the density in the inlet pipes is unknown, it may be calculated by one of the following formulas. These formulas also may be combined with the formulas in Table 1 to form new formulas in terms of factors such as specific gravity, etc., which are known or can be determined, instead of in terms of the inlet density ρ_1. This is done by substituting for ρ_1 in the formulas of Table 1, the values given by one of the formulas below.

Based on density ρ_0 at 68° F. and 14.7 lb. per sq. in.

$$\rho_1 = 527.6\, p_1\, \rho_0 / 14.7\, T_1.$$

Based on specific gravity G, compared to air without moisture

$$\rho_1 = \{(527.6 \times 0.752)/14.7\}\{p_1\, G/T\}$$

on specific heat C_p

$$\rho_1 = (144/J)(p_1/T_1)\,[1/\{C_p(k-1)/k\}]$$

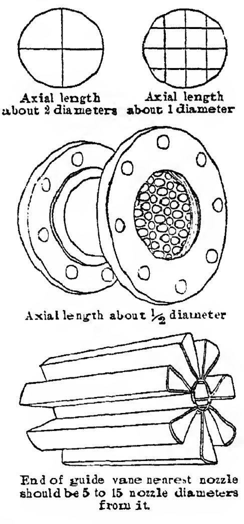

FIG. 7. Guide Vanes to Prevent Rotary Motion

Based on R, from equation, $144\ pv = RT$

$$\rho_1 =$$

Based on molecular weight M

$$\rho_1 = (527.6 \times 0.752\, p_1\, M)/(14.7 \times 28.989\, T_1).$$

For a mixture of gases, density at standard conditions ρ_0, or specific gravity, may be computed from analysis and the first or second formula used.

If the gas contains water vapor,

$$\rho_1 = \rho_g\, \{1 - (Hp_w/p_1)\} + H\rho_w,$$

where ρ_1, ρ_g = density, lb. per cu. ft., of moist and dry gas, respectively, at p_1 and T_1; ρ_w = density, lb. per cu. ft., of saturated water vapor at T_1; H = relative humidity of gas at nozzle inlet = 1.00 when gas is saturated at T_1; p, p_w = saturation pressure of water vapor at T and T_1 respectively; p_1 = absolute pressure at nozzle; T = dewpoint of water vapor at inlet, where gas is saturated at some temperature T less than T_1; T_1= temperature at nozzle inlet.

In some cases gas, saturated at a given temperature, may decrease in temperature to T_1 at nozzle inlet, with certainty of complete removal of the condensed moisture. Under some such circumstances, H may be inferred to be 1.00 at T_1. Pressures and temperatures may be in any units, if the same units are used throughout.

DATA AND RESULTS should be reported in the form shown on p. 16–64.

LOGARITHMS

Logarithms (abbreviation *log*).—The log of a number is the exponent of the power to which it is necessary to raise a fixed number to produce the given number. The fixed number is called the *base*. Thus if the base is 10, the log of 1000 is 3, for $10^3 = 1000$. There are two systems of logs in general use, the *common*, in which the base is 10, and the Napierian, or *hyperbolic*, in which the base is 2.718281828. . . . The Napierian base is commonly denoted by e, as in the equation $e^y = x$, in which y is the Napierian log of x. The abbreviation $\log_e$ is commonly used to denote the Napierian log.

In any system of logs, the log of 1 is 0; the log of the base, taken in that system, is 1. In any system the base of which is greater than 1, the logs of all numbers greater than 1 are positive and the logs of all numbers less than 1 are negative.

The modulus of any system is equal to the reciprocal of the Napierian log of the base of that system. The modulus of the Napierian system is 1, that of the common system is 0.4342945. The log of a number in any system equals the modulus of that system $\times$ Napierian log of the number. The *hyperbolic* or *Napierian* log of any number equals the common log $\times$ 2.3025851.

Every log consists of two parts, an integral part called the *characteristic*, or index, and the decimal part, or *mantissa*. The mantissa only is given in the usual tables of common logs, with the decimal point omitted. The characteristic is one less than the number of figures to the left of the decimal point in the number whose log is to be found. The characteristic of numbers from 1 to 9.99+ is 0, from 10 to 99.99+ is 1, from 100 to 999+ is 2, from 0.1 to 0.99+ is −1, from 0.01 to 0.099+ is −2, etc. Thus,

log of 2000 is 3.30103;	log of 0.2	is −1.30103,	or	9.30103 − 10
" " 200 " 2.30103;	" " 0.02	" −2.30103,	"	8.30103 − 10
" " 20 " 1.30103;	" " 0.002	" −3.30103,	"	7.30103 − 10
" " 2 " 0.30103;	" " 0.0002	" −4.30103,	"	6.30103 − 10

The minus sign is frequently written above the characteristic thus: log 0.002 = $\bar{3}.30103$. The characteristic only is negative, the decimal part, or mantissa, being always positive.

When a log consists of a negative index and a positive mantissa, it is usual to write the negative sign over the index, or to add 10 to the index, and indicate the subtraction of 10 from the resulting logarithm. Thus log 0.2 = $\bar{1}.30103$, may be written 9.30103−10. The difference between a logarithm and 10 is its *arithmetical complement* or **cologarithm**.

In tables of logarithmic sines, etc., the −10 is generally omitted, as being understood.

RULES FOR USE OF THE TABLE OF COMMON LOGARITHMS.—To Find the Log of a Decimal Fraction or of a Whole Number and a Decimal.—First find the log of the quantity as if there were no decimal point, then prefix the index according to rule; the index is one less than the number of figures to the left of the decimal point.

EXAMPLE. log of 3.14159.	log of 3.141 =	0.497068.	Diff.	138.
From proportional parts	5 =	690		
" " "	09 =	1242		
	log 3.14159	0.4971494		

If the number is a decimal less than unity, the index is negative and is one more than the number of zeros to the right of the decimal point. Log of 0.0682 = $\bar{2}.833784$ = 8.833784 − 10.

To Find the Number Corresponding to a Given Log.—Find in the table the log nearest to the decimal part of the given log and take the first four digits of the required number from the column N and the top of the column containing the log which is the next less than the given log. To find the 5th and 6th digits subtract the log in the table from the given log, and multiply the difference by 100, and divide by the figure in the Diff. column opposite the log; annex the quotient to

the four digits already found, and place the decimal point according to the rule; the number of figures to the left of the decimal point is one greater than the index. The number corresponding to a log is called the anti-logarithm.

Find the anti-log of.............................. 0.497150
Next lowest log in table corresponds to 3141........ 0.497068 Diff. = 82.

Tabular diff. = 138; 82 ÷ 138 = 0.59+

The index being 0, the number is therefore 3.14159+.

Multiplication by Means of Logarithms.—Add together the logs of the two numbers to be multiplied. The sum is the log of the product.

a. Where both factors are greater than unity.

EXAMPLE. $31 \times 1274 = 39{,}494$.

Solution. $\log 31 + \log 1274 = 1.491362 + 3.105169 = 4.596531 = \log 39{,}494$.

b. Where one or more factors are less than unity, the logs with a negative characteristic can be handled most conveniently by adding and subtracting 10.

EXAMPLE. $.000028961 \times .084507 = .0000024474$.

Solution. $\log .000028961 + \log .084507 = \bar{5}.461814 + \bar{2}.926893.$

$$= (5.461814 - 10) + (8.926893 - 10) = 14.388707 - 20 = \bar{6}.388707$$
$$= \log .0000024474.$$

Division by Means of Logarithms.—Subtract the log of the divisor from the log of the dividend. The remainder is the log of the quotient.

a. When the divisor is smaller than the dividend.

EXAMPLE. $2987 \div 63 = 47.41284$.

Solution. $\log 2987 - \log 63 = 3.475235 - 1.799341 = 1.675894 = \log 47.41284$.

b. When the divisor is larger than the dividend, add and subtract as many tens as may be necessary to the log of the dividend and proceed as before.

EXAMPLE. $.000672 \div 263 = .00000255513$.

Solution. $\log .000672 - \log 263 = \bar{4}.827369 - 2.419956$
$$= 6.827369 - 2.419956 - 10 = \bar{6}.407413 = \log .00000255513.$$

c. The log of a fraction is obtained by subtracting the log of the denominator from the log of the numerator. Thus,

$$\log \frac{a}{b} = \log a - \log b.$$

To Raise a Number to Any Given Power.—Multiply the log of the number by the exponent of the number, and find the number whose log is the product.

a. Where the exponent consists of one figure.

EXAMPLE. $16.2^3 = 4251.528$.

Solution. $3 \times \log 16.2 = 3 \times 1.209515 = 3.628545 = \log 4251.528$.

b. Where the exponent consists of two or more figures, it is best to multiply the characteristic and mantissa separately.

EXAMPLE. $.005624^{.37} = .147067$.

Solution. $.37 \times \log .005624 = .37 \times \bar{3}.750045 = .37 \times (-3) + .37 \times .750045$
$$= -1.11 + .277517 = \bar{1}.167517 = \log .147067.$$

c. Where the number is a fraction, first find the log of the fraction and then multiply it by the exponent.

EXAMPLE. $\left(\frac{276}{.032}\right)^{.72} = 681.9396$.

Solution. $.72 (\log 276 - \log .032) = .72 \{2.440909 - (8.505150 - 10)\}$
$$= .72 \times 3.935759 = 2.833746 = \log 681.9396.$$

To Extract Any Root of a Number.—Divide the log of the number by the index of the root, and find the number whose log is the quotient.

To extract the root of a decimal: *a.* When the root index is positive and evenly divisible into the negative characteristic of the log of the number, the division may be performed with the negative characteristic written in its usual place.

EXAMPLE. $\sqrt[4]{.0006954} = .16239$.

Solution. $\log .0006954 \div 4 = \bar{4}.842235 \div 4 = \bar{1}.210559 = \log .16239$.

b. When the root index is positive and not even divisible into the negative characteristic, add to the log of the number, and indicate the subtraction from it, the smallest integral multiple of the root which will eliminate the negative characteristic. Divide the result by the root index and ascertain the number whose log corresponds to the quotient.

EXAMPLE. $\sqrt[3.1]{.00002785} = .03393$.

Solution. $\log .00002785 = \bar{5}.444825;\ \bar{5}.444825 \div 3.1 = \{(2 \times 3.1) + \bar{5}.444825 - 2 \times 3.1\} \div 3.1$
$$= \{1.644825 - 6.2\} \div 3.1 = \bar{2}.530589 = \log .03393.$$

c. When the root index is negative, determine the excess of the negative characteristic over the positive mantissa. Divide the result by the root index and ascertain the number whose log corresponds to the quotient.

EXAMPLE. $\sqrt[-4]{.000003976} = 22.394$.

Solution. $\log .000003976 = \bar{6}.599446 = .599446 - 6 = -5.400554;$
$$-5.400554 \div (-4) = 1.350138 = \log 22.394.$$

Solution of Exponential Equations.—In an exponential equation, the unknown quantity is the exponent; thus $a^x = b$. This may be transformed to $\log a^x = \log b$, or $x \log a = \log b$, whence $x = \log b \div \log a$.

a. When the base is greater than unity, put the equation in the form $x = \log b \div \log a$. Then $\log x = \log (\log b) - \log (\log a)$.

Example. $32.6^x = 14.632$.

Solution. $\log x = \log (\log 14.632) - \log (\log 32.6) = \log 1.165303 - \log 1.513218$
$= .066439 - .179901 = \bar{1}.886538$; $x = .77008$.

b. When both the known quantities are decimal, put the equation in the form $x = \log b \div \log a$. Subtract the positive mantissa from the negative characteristic in both divisor and dividend, obtaining negative remainders. Change the signs of divisor and dividend and proceed as in Case *a*.

Example. $.0729^x = .2693$.

Solution. $x = \log .2693 \div \log .0729 = \bar{1}.430236 \div \bar{2}.862728$
$= (-.569764) \div (-1.137272) = .569764 \div 1.137272$;
$\log x = \log .569764 - \log 1.137272 = \bar{1}.755695 - .055864 = \bar{1}.699831$
$x = .50099$.

c. When only one of the known quantities is a decimal, put the equation in the form $x = \dfrac{\text{og}}{\log a}$.
Subtract the positive mantissa from the negative characteristic of the numerator or denominator as the case may be, and rewrite the fraction with the remainder so obtained as the new numerator or denominator. Make both numerator and denominator positive, but write a minus sign in front of the fraction, to signify that the result will be a negative quantity. Solve the fraction by logarithms and write a minus sign in front of the result.

Example. $.726^x = 802.7$.

Solution. $x = \dfrac{\log 802.7}{\log .726} = \dfrac{2.904553}{\bar{1}.860937} = \dfrac{2.904553}{-.139063} = -\dfrac{2.904553}{.139063}$.

$\log x = -(\log 2.904553 - \log .139063) = -(.463079 - \bar{1}.143211) = -(1.319868)$.
$x = -20.8867$.

d. When the exponent is negative and one of the known quantities is less than unity, put the equation in the form $(-x) = \dfrac{\log b}{\log a}$. Subtract the positive mantissa from the negative characteristic, as in Case *c*, and multiply both sides of the resulting equation by (-1). Find the value of x as in Case *c*.

Example. $10.78^{-x} = .09431$.

Solution. $x = \dfrac{\log .09431}{\log 10.78} = \dfrac{\bar{2}.974558}{1.032619} = -\dfrac{1.025442}{1.032619}$.

$\log x = .010911 - .013940 = \bar{1}.996971$. $x = .99305$.

Table 3.—Natural (Napierian or Hyperbolic) Logarithms of Numbers

Table gives natural logarithms of numbers from 1.0 to 9.99 directly. To find logarithms of numbers outside that range add or subtract natural logarithm of the powers of 10 as follows:

$\log_e 10 = 2.302585$ $\qquad \log_e 10^4 = 9.210340$ $\qquad \log_e 10^7 = 16.118096$

$\log_e 10^2 = 4.605170$ $\qquad \log_e 10^5 = 11.512925$ $\qquad \log_e 10^8 = 18.420681$

$\log_e 10^3 = 6.907755$ $\qquad \log_e 10^6 = 13.815511$ $\qquad \log_e 10^9 = 20.703266$

Example.—$\log_e 679. = \log_e 6.79 + \log_e 10^2 = 1.9155 + 4.6052 = 5.5207$

$\log_e .0679 = \log_e 6.79 - \log_e 10^2 = 1.9155 - 4.6052 = -2.6897$

The common logarithm is the natural logarithm multiplied by the modulus of $\log_{10}$; $\log_{10} N = 0.434294 \log_e N$.

CIRCULAR ARCS, CHORDS, SEGMENTS AND SECTORS

Notation.—A = central angle, degrees; C = chord of arc; c = chord of 1/2 arc; D = diameter; G = area of segment; H = rise of arc or height of segment; L = length of arc; R = radius; S = area of sector.

L (exact) $= 2\pi RA/360 = 0.017453RA$

L (approx.) $= (8c - C)/3 = \{(2c \times 10H)/(60D - 27A)\} + 2c$

$= \{(\sqrt{C^2 + 4H^2} \times 10H^2)/(15C^2 + 33H^2)\} + 2c$

$C = 2\sqrt{c^2 - H^2} = \sqrt{D^2 - (D - 2H)^2} = (8c - 3L) = 2\sqrt{R^2 - (R - H)^2} = 2\sqrt{(D - H) \times H}$

$C/2 = \sqrt{H \times (D - H)}$; $c = 1/2\sqrt{C^2 - 4H^2} = \sqrt{D \times H} = (3L + C)/8$

$D = c^2/H = (1/4\,C^2 + H^2)/H$

$H = c^2/D = 1/2\,(D - \sqrt{D^2 - C^2})$ when $H < R$; $= 1/2\,(D + \sqrt{D^2 - C^2}) = \sqrt{c^2 - 1/4\,C^2}$ when $H > R$

$G = S - 1/2\,C\sqrt{R^2 - 1/4\,C^2}$ when $G <$ semi-circle; $= S + 1/2\,C\sqrt{R^2 - 1/4\,C^2}$ when $S >$ semi-circle

$= S - (C/2)(R - H) = 1/2\,\{(L - C)(D/2) + CH\}$

$S = 1/2\,LR = \pi AR^2/360 = (\pi R^2/360) \times 2[\sin^{-1}\{(C/2)/R\}]$; $R = (C^2 \cdot$

* Area of segment of any radius = factor G × square of radius

Table 6.—Areas of Segments of a Circle

Area $= F \times D^2$ where segment $<$ semicircle; $= \frac{1}{4}\pi D^2 -$ (area of segment of rise h). $H =$ ris or height of segment; $D =$ diam. of circle; $F =$ factor corresponding to H/D. $h = (D - H)$

EXAMPLE: 9 19/32 in. = 0.7500 + 0.0495 = 0.7995 ft.

FLOW AND CAPACITY EQUIVALENTS

Flow and capacity equivalents, Tables 14 and 15, and the tables of capacity of tanks and cisterns, Tables 16 to 18, are based on the following values.

1 cubic foot = 7.480519 U.S. gallons
1 U.S. gallon = 231 cu. in. = 0.13368056 cu. ft.
1 lb. of water at 62° F. = 0.01603489 cu. ft.

The British Imperial gallon = 277.418 cu. in. (U.S.) = 277.420 cu. in. (British) = 1.20094 U.S. gallons.

The flow equivalents of Table 14 are based on water at 62° F. These flow equivalents for a given weight of water can be converted to flow equivalents for any other fluid by multiplying by the ratio of the density of that fluid to the density of water. For example, the flow per minute of 20 lb. of oil of specific gravity 0.90 (water = 1.0) is

$$(1/0.90) \times 20 \times 0.1200 = 2.67 \text{ gal. per min.}$$

Table 14.—Flow Equivalents

	Cu. ft. per sec.	Cu. ft. per min.	U.S. Gallons per min.	U.S. Gals. per hr.	U.S. Gallons per 24 hr.	Lb. H_2O per min.	Lb. H_2O per hr.
1 cu. ft. per sec. =	1	60	448.83	26,929.9	646,316.8	3741.00	224,460
1 cu. ft. per min. =	1/60	1	7.4805	448.83	10,771.2	62.35	3741.00
1 gal. per min. =	0.002228	0.1337	1	60	1440	8.3350	500.1
1 gal. per hr. =	3713×10^{-5}	0.002280	1/60	1	24	0.1389	8.3350
1 gal. per 24 hr. =	1547×10^{-6}	9283×10^{-5}	6944×10^{-4}	1/24	1	0.005788	0.3473
1 lb. H_2O per min. =	2673×10^{-3}	0.01604	0.1200	7.1986	172.7658	1	60
1 lb. H_2O per hr. =	4455×10^{-5}	2673×10^{-3}	0.0020	0.1200	2.8794	1/60	1

To ascertain the contents of a tank over one-half full: Let h' = depth of unfilled portion. Find from the table the quantity corresponding to a depth h. Subtract this quantity from the contents of a full tank.

Table 18.—Capacity of Rectangular Tanks per 1 Foot of Length

Capacities given in U. S. gallons

MEASURES AND WEIGHTS COMMONLY USED IN THE UNITED STATES AND GREAT BRITAIN

Abbreviations

bbl.	= barrel	dwt.	= pennyweight	hr.	= hour	quin.	= quintal
bu.	= bushel	fath.	= fathom	Imp.	= Imperial (bu., gal.)	qr.	= quarter
chn.	= chain	ft.	= foot	in.	= inch	qt.	= quart
circm.	= circumference	fl. drm.	= fluid drachm	lea	= league	scr.	= scruple
cir. in.	= circular inch	fl. oz.	= fluid ounce	m. pace	= military pace	sec.	= second
cir. mil.	= circular mil	furl.	= furlong	min.	= minute	sq.	square (in., ft., etc.)
cwt.	= hundred weight	gal.	= gallon (U.S.)	naut. mi.	= nautical mile	stat. mi.	statute mile
deg.	= degree	grn.	= grain	pnch	= puncheon	trce.	= tierce
drm.	= drachm (dram)	hghd.	= hogshead	quad.	= quadrant	yd.	= yard

Table 19.—Measures of Length

Long Measure

12 in. = 1 ft.
3 ft. = 1 yd.
5 1/2 yd. = 16 1/2 ft. = 1 rod, pole or perch
40 poles = 220 yd. = 1 furl.
8 furl. = 1760 yd. = 5280 ft. = 1 mile
4 in. = 1 hand
9 in. = 1 span
2 1/2 ft. = 1 m. pace.

Land, Surveyors, or Gunter's Measure

7.92 in. = 1 link
100 links = 66 ft. = 4 rods = 1 chn.
10 chn. = 220 yd. = 1 furl.
8 furl. = 80 chn. = 1 mile.

Nautical Measure

6080.26 ft. = 1.15156 stat. mi. = 1 naut. mi.
3 naut. mi. = 1 lea.
60 naut. mi. = 1 deg. (at equator)
6 ft. = 1 fath.
120 fath. = 1 cable
1 naut. mi. per hr. = 1 knot.

Table 20.—Measures of Area

Square Measure

144 sq. in. = 183.35 cir. in. = 1 sq. ft.
9 sq. ft. = 1 sq. yd.
30 1/4 sq. yd. = 272 1/4 sq. ft. = 1 sq. rod
160 sq. rods
4840 sq. yd.
640 acres = 27,878,400 sq. ft. = 1 sq. mile
1 acre = $(208.71 \text{ ft.})^2$
1 cir. in. = area of circle 1 in. diam. = 0.7854 sq. in.
1 cir. mil = area of circle 0.001 in. diam. = $0.0_5 7854$ sq. in.
1,000,000 cir. mil = 1 cir. in.

Board Measure

144 cu. in. = 12 × 12 × 1 in. = 1 board ft.

The above definition of a board foot applies to rough green lumber. American practice uses a yard standard of 29/32 in. thick and an industrial standard of 7/8 in. thick for rough dry lumber; for dressed lumber the corresponding thicknesses are 25/32 in. and 13/16 in. For example, a rough dry piece 12 × 12 × 29/32 in. contains 1 board ft. Board ft. in round timber = $(1/4\, c \times d \times l)/144$. c = mean circm., d = diam., l = length, all in ft.

Table 21.—Measures of Weight

(The grain is the same in all systems.)

Avoirdupois Weight

16 drm. = 437.5 grn. = 1 oz.
16 oz. = 7000 grn. = 1 lb.
14 lb. = 1 stone
28 lb. = 2 stone = 1 qr.
100 lb. = 1 quin.
4 qr. = 112 lb. = 1 cwt.
20 cwt. = 2240 lb. = 1 long ton
2000 lb. = 1 short ton.

Troy Weight (for gold and silver)

24 grn. = 1 dwt.
20 dwt. = 480 grn. = 1 oz.
12 oz. = 5760 grn. = 1 lb.
1 Assay ton = 29,167 milligrams = Troy oz. per 2000 lb. ton avoirdupois

Carat Weight (for precious stones)

1 carat = 3.086 grn. = 0.200 gram

Apothecaries' Weight

20 grn. = 1 scr. ℈
3 scr. = 60 grn. = 1 drm. ʒ
8 drm. = 480 grn. = 1 oz. ℥
12 oz. = 5760 grn. = 1 lb.

Table 22.—Measures of Volume

Cubic Measure

1728 cu. in. = 1 cu. ft.
27 cu. ft. = 1 cu. yd.
4 × 4 × 8 ft. = 128 cu.

Liquid Measure

4 gills = 1 pint
2 pints = 1 qt.
4 qt. = 231 cu. in. = 8.3356 lb. H_2O = 1 U. S. gal. = 0.8327 Imp. gal.
1 Imp. gal. = 277.420 cu. in. = 10 lb. H_2O
1.20094 U. S. gal. = 1 Imp. gal.
7.4805 U. S. gal. = 1 cu. ft.

Old Liquid Measure

31 1/2 gal. = 1 bbl.
42 gal. = 1 trce.
2 bbl. = 63 gal. = 1 hghd.
84 gal. = 2 trce. = 1 pchn.
2 hghd. = 126 gal. = 1 pipe or butt
2 pipes = 3 pchn. = 1 tun.

Apothecaries' Fluid Measure

60 minims = 1 fl. drm.
8 drm. = 1 fl. oz.
1 fl. oz. = 1/128 U. S. gal. = 1.8047 cu. in. = 456.3 grn. H_2O at 39° F.
16 fl. oz. = 1 pint
1 fl. oz. (British) = 1.732 cu. in. = 437.5 grn. H_2O at 62° F.

Dry Measure

2 pints = 1 qt.
8 qts. = 1 peck
4 pecks = 2150.42 cu. in. = 1 bu. (struck)
1 1/4 bu. (struck) = 1 bu. (heaped)
105 qts. (struck) 7056 cu. in. = 1 bbl.
8 Imp. gal. 2218.192 cu. in. = 1 Imp. bu.
8 Imp. bu. = 1 qr.

Shipping Measure

100 cu. ft. = 1 Register ton *
40 cu. ft. = 31.143 U. S. bu. = 1 shipping ton (U. S.) †
42 cu. ft. = 32.719 Imp. bu. = 1 shipping ton (British) †

* For measurement of entire internal capacity † For measurement of cargo.

Miner's Inch

A variable unit, defined by statute in different states as the quantity of water that will flow through an orifice of 1 sq. in. area, under a head ranging from 4 1/2 to 6 in. U. S. Reclamation Service defines the miner's inch as 1 cu. in. per sec. The law governing the locality in which the measurement is to be made should be consulted.

Table 23.—Circular Measure

60 sec.	=	1 min.
60 min.	=	1 deg.
90 deg.	=	1 quad.
360 deg.	=	circm.
57.2957795 deg.	=	1 radian
	=	57° 17′ 44.806″
1 radian	=	angle of arc equal to radius.

Table 24.—Time

60 sec. = 1 min.		7 days = 1 week	
60 min. = 1 hr.		52 weeks = 1 year	
24 hr. = 1 day			

1 year (exact) = 365 days, 5 hr., 48 min., 45.6 sec.

A year divisible by 4 is a leap year and contains 366 days, except centesimal years, of which only those divisible by 400 are leap years.

365.24734 mean solar days
= 366.008515 sidereal days
24 hr. mean solar time
= 23 hr. 56 min., 49.9 sec. sidereal time
1 mean solar day
= 1 mean sidereal day + 3 min., 10.1 sec.

THE METRIC SYSTEM

The fundamental standard of length in the metric system is the International Standard Meter, derived from the Metre des Archives, Paris. Its length is defined as the distance between two lines at 0° C. on a platinum-iridium bar deposited at the International Bureau of Weights and Measures near Paris. 1 meter = 39.37 in.

The fundamental standard of mass is the International Standard Kilogram, which is a mass of platinum-iridium, deposited at the International Bureau, whose weight *in vacuo* is the same as that of the Kilogram des Archives.

The fundamental unit of volume is the liter, which is defined as the volume of a kilogram of water at the temperature of maximum density, 4° C., under a pressure of 76 cm. of mercury. The liter originally was defined as a cubic decimeter, but is slightly greater. The generally accepted relation between the cubic decimeter and the liter is 1 liter = 1.000027 cu. decimeters.

The unit of force is the **dyne**, which is the force which acting for 1 second on a mass of one gram will produce a velocity of 1 centimeter per second. 1 dyne = (1/980.665) gram. 1,000,000 dynes = 1.020 kilograms force = 2.248 lb. force. 1 lb. force = 0.4536 kilogram force = 448,800 dynes.

The unit of heat is the **gram-calorie**, which is the quantity of heat required to raise 1 gram of water 1° C. See p. 3-17.

Table 25.—Units of Metric Measures*

Length			Area		
Unit	Symbol	Value in Meters	Unit	Symbol	Value in Sq. Meters
Micron	μ	0.000 001			
Millimeter	mm.	0.001	Sq. millimeter	sq. mm.	0.000 001
Centimeter	cm.	0.01	Sq. centimeter	sq. cm.	0.000 1
Decimeter	dm.	0.1	Sq. decimeter	sq. dm.	0.01
Meter (unit)	m.	1.0	Sq. meter (centiare)	sq. m.	1.0

1. MATHEMATICAL AND PHYSICAL TABLES: Symbols and Abbreviations; Mathematical Tables; Physical Properties of Materials; Tables of Conversion Factors—Units of Weights and Measures; Gages; Standard Structural Sizes; by Ovid W. Eshbach in collaboration with J. L. Barnes, J. G. Brainerd, R. T. Kent, and H. C. Knutson.

2. MATHEMATICS: Arithmetic; Algebra; Mathematics of Finance; Geometry; Trigonometry; Plane Analytic Geometry; Solid Analytic Geometry; Differential Calculus; Integral Calculus; Differential Equations; Solution of Linear Constant-coefficient Integro-differential Equations by the Laplacian Transformation (Operational Calculus); Functions of Complex Variables; Vector Analysis; Alignment Charts (Nomograms); Precision of Measurements; by J. L. Barnes in collaboration with J. G. Brainerd, C. Eisenhart, M. J. Fish, and J. M. Rice.

3. PHYSICAL UNITS AND STANDARDS: Dimension Systems; Unit Systems; Units and Standards; Dimensional Analysis; by Ernst Weber.

4. THEORETICAL MECHANICS: Statics; Kinematics; Kinetics; by Janvier M. Rice.

5. MECHANICS OF MATERIALS: Simple Stresses; Beams; Columns; Shafts; Cylinders, Plates, Rollers, and Riveted Joints; Testing of Materials; by Jasper O. Draffin. Reinforced Concrete; by Theodore Crane.

6. MECHANICS OF FLUIDS: Properties of Fluids, Divisions of Fluid Mechanics; Fluid Statics; Fluid Dynamics; by P. E. Hemke.

7. ENGINEERING THERMODYNAMICS: Principles of Thermodynamics; Gases; Liquids and Vapors; The Steam Power Plant; The Internal-combustion Engine; Refrigeration; Gas and Vapor Mixtures, Humidity, and Air Conditioning; by Milton C. Stuart and Paul J. Kiefer.

8. ELECTRICITY AND MAGNETISM: Electron Theory; Direct-current Circuits; Electrokinetics and the Magnetic Circuit; Electrostatics and the Dielectric Circuit; Alternating-current Circuits; Transients; Conduction of Electricity in Solids and Fluids; by Charles Weyl and Irven Travis.

9. RADIATION AND LIGHT: Theory of Radiation; Geometry of Radiation; Physics of Radiation; Physiology of Radiation; by Ernst Weber. ACOUSTICS; by R. B. Lindsay. METEOROLOGY; by Edgar W. Woolard, R. J. Martin, and H. L. Dryden.

10. CHEMISTRY: General Chemistry; Industrial Chemistry; Qualitative Analysis; Electrochemistry; by Joseph Mattiello and Sidney B. Tuwiner.

11. METALLIC MATERIALS: Corrosion of Metals; by Frank N. Speller. Iron and Steel; by Bradley Stoughton. Copper and Copper-base Alloys; by members of the staff of the American Brass Co. and W. M. Corse. Zinc and Zinc-base Alloys; by W. M. Peirce. Aluminum and Aluminum Alloys; by Junius D. Edwards and Zay Jeffries. Nickel and Non-ferrous Nickel Alloys; by Robert Worthington. Magnesium and Magnesium Alloys; by John A. Gann. Tungsten; Molybdenum; by Zay Jeffries. Die-casting Alloys; by J. C. Fox. Bearing Metals; by Christopher H. Bierbaum. Welding, Brazing, and Soldering Materials; by Bradley Stoughton and D. F. Miner. Electrical Conductor Materials; by H. C. Knutson and D. F. Miner. Magnetic Materials, by J. B. Seastone. Miscellaneous Materials.

12. NON-METALLIC MATERIALS: Cement, Concrete, Lime, Mortar, and Plaster; by Theodore Crane. Stone, Brick, and Terra-cotta; by Jasper O. Draffin. Refractories; by J. Spotts McDowell and E. B. Guenther. Thermal Insulating Materials. Timber; by H. C. Knutson and H. F. Moore. Paints, Enamels, Varnishes, and Lacquers; by Joseph Mattiello. Electric Insulating Materials; Lubricants; Adhesive Materials; by D. F. Miner. Fuels and Explosives. Miscellaneous Materials.

13. CONTRACTS. By R. L. Sackett.

MECHANICAL ENGINEERS' HANDBOOK

POWER

Edited by Robert Thurston Kent

1226 Pages

SECTION

1. AIR: Properties of Air. Compressed Air, by Robert Peele. Fans and Blowers, by Robert T. Kent.
2. WATER: Properties of Water. Hydraulics, by William P. Creager. Hydraulic Turbines, by R. E. V. Sharp. Pumps and Pumping Engines, by Robert T. Kent. Centrifugal Pumps, by V. deP. Gerbereux.
3. HEAT: Measurement of Heat. Heat Transmission, by W. J. King. Evaporators and Evaporation, by W. L. Badger. Dryers and Drying, by Francis E. Finch. Kiln Drying of Lumber, by L. V. Teesdale. Heat Insulation, by P. Nicholls. Thermodynamics, by A. G. Christie.
4. COMBUSTION AND FUELS: Combustion and Solid Fuels, by Robert T. Kent. Liquid Fuels, by Harry L. Tapp. Gaseous Fuels. Illuminating Gas, by Alfred E. Forstall.
5. STEAM: Properties of Steam; The Mollier Diagram, by A. G. Christie. Flow of Steam in Pipes, by Robert K. Behr. Steam Piping. Stresses in Pipe Lines, by A. S. McCormick. Commercial Pipe and Fittings. Steam Valves.
6. THE STEAM BOILER: Boiler Construction; Superheaters, Economizers and Air Heaters; Utilization of Waste Heat; Moisture in Steam. Boiler Feeding. Feedwater for Steam Boilers. By D. S. Jacobus, Robert K. Behr and Robert T. Kent. Boiler Furnaces; Stokers; Gas and Oil Burners, by W. S. Carter. Chimneys and Draft. Smoke.
7. THE STEAM ENGINE: Capacity of Engines; By W. Trinks. Compound and Triple-expansion Engines; Steam Engine Economy; Operation of Engines; Valve Gears; Operating Data; Steam Engine Parts; Selection of Type of Engine; Cost of Engines.
8. THE STEAM TURBINE: By A. G. Christie. Types of Turbines. Steam Turbine Cycles. Nozzles. Blading. Steam Supply. Rotors. Turbine Details. Reduction Gearing. Lubrication. Turbine Governors. Casings. Erection and Operation. Correction Factors. Turbine Performance. Turbine Calculations. Reheating Turbines. Economic Selection of Operating Conditions. Mercury Turbines.
9. CONDENSING AND COOLING EQUIPMENT: By Robert T. Kent. Direct Contact Condensers. Properties of Saturated Steam below Atmospheric Pressure. Surface Condensers. Air Pumps. Cooling Towers. Cooling Ponds.
10. REFRIGERATION AND ICE MAKING: By Louis A. Harding. Refrigeration. Cold Storage. Heat Transmission. The Ammonia Absorption Machine. Vapor Condensers. Brine Circulating System. Ice Manufacture.
11. HEATING, VENTILATING AND AIR CONDITIONING: By Louis A. Harding. Estimating Heating Requirements of Buildings. Heating Systems. Rating of Heating Boilers. Design of Air Ducts. Ventilation. Air Conditioning.
12. INTERNAL COMBUSTION ENGINES: Diesel Engines, by E. J. Kates. Gas Engines, by H. A. Gehres. Gasoline Engines.
13. GAS PRODUCERS: By John Blizard. General Design and Operation of Gas Producers. Properties of Producer Gas. Design of Furnaces for Producer Gas.
14. TRANSPORTATION: Railroad Engineering, by G. E. Rhoads. Automotive Vehicles, by Ralph A. Richardson. Aeronautics, by Edward P. Warner and S. Paul Johnston.
15. ELECTRIC POWER: By E. S. Dibble. Purchased Power. Generated Power. Conversion Equipment. Switchboard Equipment. Batteries. Power Factor. Power Distribution.
16. POWER TEST CODES: Instruments and Apparatus. Test Codes.
17. MATHEMATICAL TABLES.

SECTION

1. GENERAL PROPERTIES OF MATERIALS.
2. IRON AND STEEL: Iron and Steel, by Bradley Stoughton. Ingot Iron, by R. L. Kenyon. Welding of Iron and Steel, by J. C. Hodge and R. E. Hiller.
3. CORROSION AND CORROSION-RESISTANT METALS: Corrosion of Metals, by Frank N. Speller. Corrosion-resistant Metals, by Robert T. Kent.
4. NON-FERROUS METALS AND ALLOYS: General Properties of Metals and Alloys, by Paul D. Merica and Norman B. Pilling. Copper, by W. H. Bassett (deceased). Zinc and Its Alloys, by W. M. Peirce. Brass and Bronze Sand-cast, Copper-base Alloys, by W. M. Corse. Wrought Brasses, Bronzes and Nickel-silver Alloys, by W. H. Bassett (deceased), H. G. Jennison, and W. R. Hibbard. Aluminum and Its Alloys, by Zay Jeffries. Nickel and Its Non-ferrous Alloys, by Robert Worthington. Magnesium and Its Alloys, by John A. Gann. Tungsten and Molybdenum, by Zay Jeffries. Die-casting Alloys, by J. C. Fox. Bearing Metals, by Christopher H. Bierbaum. Solders.
5. NON-METALLIC MATERIALS: Refractories, by J. Spotts McDowell. Wood, Cork, Rubber, Carbon and Miscellaneous Materials.
6. FABRICATED MATERIALS: By Robert T. Kent. Plates, Sheets, Bars, Rods and Shapes. Steel, Copper and other Wires. Ropes, Chains, and Wire Rope. Rivets, Nails and Washers.
7. STRENGTH OF MATERIALS: By Edward R. Kent and Jasper O. Draffin. Simple Stresses. Beams. Columns. Shafts. Cylinders, Plates and Rollers. Testing of Materials.
8. MECHANISM AND MECHANICS: By Robert T. Kent. Elements of Machines. Mechanics. Friction.
9. FASTENINGS: By Robert T. Kent. Screws and Screw Fastenings. Rivets and Riveted Fastenings. Fastenings for Timber Joints.
10. MECHANICAL SPRINGS: By Mortimer F. Sayre.
11. ROTATING MEMBERS: By Robert T. Kent. Axles and Shafts. Cranks and Crank-pins. Fly-wheels.
12. KEYS, COTTERS, PINS, TAPERS AND FITS: By Robert T. Kent.
13. BEARINGS AND LUBRICANTS: Oil Film Bearings, by H. A. S. Howarth. Ball Bearings, by J. S. Tawresey. Roller Bearings, by Robert T. Kent. Lubricants, by J. C. Geniesse.
14. GEARING: By Earle Buckingham. Friction Gearing. Spur Gears. Helical Gears. Bevel Gearing. Screw Gearing. Spiral Gear Drives. Worm Gear Drives.
15. CONTROL MECHANISMS: Governing, Regulation and Control, by W. Trinks. Brakes, by Robert T. Kent.
16. VIBRATION AND NOISE: By Arthur L. Kimball.
17. STRUCTURES AND BUILDINGS: Stresses in Framed Structures. Building Construction, by Theodore Crane. Properties of Structural Materials, by Robert T. Kent.
18. INDUSTRIAL HEATING PROCESSES: Industrial Furnaces, by W. Trinks. Industrial Electric Heating, by R. M. Cherry.
19. FORGING PRACTICE: By Eugene C. Clarke.
20. FOUNDRY PRACTICE: Iron Foundry Practice, by D. M. Avey. Malleable Castings, by Enrique Touceda. Non-ferrous Foundry Practice, by N. K. B. Patch.
21. THE MACHINE SHOP: Lathe Work. Single-point Metal-Cutting Tools, by Robert C. Deale. Planer Work, by Forrest E. Cardullo. Pressure Working of Metals, by H. B. Morse. Drills and Drilling; Abrasive Processes; Broaching; Metal Sawing; Machine Tool Motor Drives; Measurements, by Robert T. Kent.
22. WOODWORKING: By Thomas D. Perry. Materials. Primary Conversion Machinery. Processing. Small Tools. Machine Tools for Wood.
23. MATERIALS HANDLING: By Frederic V. Hetzel. Hoisting. Handling Materials in Bulk. Cranes and Derricks. Hoists. General Conveying and Elevating. Belt Conveyors. Screw Conveyors. Pneumatic and Hydraulic Conveying. Package Handling. Vehicles. Manufacturers of Material Handling Equipment.
24. MECHANICAL POWER TRANSMISSION: By Robert T. Kent. Shafting. Pulleys. Belt Drives. Chain Drives. Rope Driving. Couplings and Clutches. Speed Changing Mechanisms. Dynamometers.
25. ELECTRIC MOTORS AND THEIR CONTROL: By M. N. Halberg. Electric Motors. Electric Motor Control.
26. MISCELLANEOUS SHOP EQUIPMENT: Dust Collection, by M. S. Kice, Jr. Illumination, by Matthew Luckiesh.
27. SAFETY ENGINEERING: By Sidney J. Williams. Accident Prevention. Mechanical Power Transmission. Machinery. Electrical Hazards. Eye Protection and Safe Clothing. First Aid. Supervision and Education. Organizations.
28. MATHEMATICAL TABLES.

HANDBOOK FOR ELECTRICAL ENGINEERS

ELECTRIC POWER

Edited by Harold Pender, William A. Del Mar, and Knox McIlwain

1300 Pages

SECTION

1. MATHEMATICS, UNITS, AND SYMBOLS: Mathematics; by Carl C. Chambers. Mathematical Tables. Units and Conversion Factors; by J. G. Brainerd and Carl C. Chambers. Symbols and Abbreviations. Constants; by Carl C. Chambers.

2. PROPERTIES OF MATERIALS: Weights of Materials; Conductor Materials; Insulating Materials; Magnetic Materials; Thermal Properties of Materials; by D F. Miner.

3. ELECTRIC CIRCUITS AND ELECTRIC LINES: Alternating Currents; Linear Circuits; Non-linear Circuits; Polyphase Systems and Symmetrical Components; Electrical Machines; Transmission Lines; Stability of Power Systems; by Irven Travis.

4. RESISTORS, REACTORS, MAGNETS: Resistors, Rheostats; Capacitors—Condensers; Inductors; Magnets, Magnetic Devices; by A. Dexter Hinckley.

5. MEASUREMENTS AND MEASURING APPARATUS: by H. B. Brooks.

6. PRINCIPLES OF ELECTROCHEMISTRY: by H. M. Goodwin, revised by Martin Kilpatrick and Mary L. Kilpatrick.

7. BATTERIES: Primary Batteries; by C. F. Burgess. Lead-acid Storage Batteries; by J. Lester Woodbridge. Alkaline-type Storage Batteries; by E. W. Allen and F. Brehme.

8. DIRECT-CURRENT MACHINES: Direct-current Generators; Direct-current Motors; by Walter I. Slichter.

9. ALTERNATING-CURRENT MACHINES: Alternating-current Generators; Synchronous Motors; Polyphase Induction Motors; Single-phase Induction Motors; Alternating-current Commutator Motors; by Walter I. Slichter.

10. TRANSFORMERS; by Walter I. Slichter.

11. CONVERTERS AND RECTIFIERS: Energy Converters; Frequency Converters; Phase Converters and Balancers; Rectifiers; by Walter I. Slichter.

12. SWITCHING, CONTROL, AND PROTECTION: Circuit Elements; Circuit Breakers; Controllers and Regulators; Protection; Station Equipment; Station Structures and Layout; by Stephen Q. Hayes.

13. POWER STATIONS AND SUBSTATIONS: Steam Power Stations; by F. S. Bennett. Hydroelectric Power Stations; by R. A. Hopkins and A. G. Cherry. Internal-combustion Power Stations; by W. A. Sloan. Substations; by W. I. Slichter. Power Station Circuits; by R. A. Hopkins.

14. POWER TRANSMISSION AND DISTRIBUTION: Systems; Capacitance and Inductance Tables; Underground Conduits; Distribution; Bare Wires and Cables; Insulated Wires and Cables; Electrolysis of Underground Structures; by W. A. Del Mar. Electrical Design of Transmission and Distribution Systems; by W. A. Del Mar, J. H. Palmer, F. W. Peek, and R. A. Philip. Pole and Tower Lines; by Howard Enos. Wiring of Buildings; by G. W. Zink. Grounding of Electric Circuits and Accessories; by R. F. Abele.

15. LIGHTING AND HEATING: Lighting; by F. C. Caldwell. Household Heating Appliances and Cooking; by Frank Thornton, Jr. Water Heating; by C. J. Fay and J. F. Reifenberg. Heating and Air Conditioning of Buildings; by Otto W. Walter.

16. INDUSTRIAL APPLICATIONS OF MOTORS; by Francis A. Westbrook.

17. TRANSPORTATION: Electric Traction; by H. A. Currie and Robert S. Rhodes. Electrical Equipment of Internal-combustion Automobiles; by H. Chase. Electric Automobiles; by W. P. Kennedy. Electric Propulsion of Ships; by W. N. Zippler.

18. ELECTROCHEMICAL AND ELECTROTHERMAL INDUSTRIES: Electrochemical Processes; Electric Furnaces and Their Products; by M. de K. Thompson. Electric Resistance Heating; by Frank Thornton, Jr. Electrical Precipitation of Suspended Particles; by N. W. Sultzer. Electric Welding; by H. M. Hobart.

19. ELECTRICITY ON THE FARM; by Lee C. Prickett.

HANDBOOK FOR ELECTRICAL ENGINEERS

COMMUNICATION. ELECTRONICS

Edited by Harold Pender and Knox McIlwain

1022 Pages

SECTION

1. MATHEMATICS, UNITS, AND SYMBOLS: Mathematics; by Carl C. Chambers. Mathematical Tables. Units and Conversion Factors; by J. G. Brainerd and Carl C. Chambers. Symbols and Abbreviations. Constants; by Carl C. Chambers.

PROPERTIES OF MATERIALS: Conducting Materials; Insulating Materials; Luminescent Materials; Magnetic Materials; Special Properties of Dielectrics; by William F. Diehl with W. R. Dohan, H. W. Leverenz, D. G. C. Luck, and C. R. Nelson.

ELECTRIC CIRCUITS, LINES, AND FIELDS: Linear Electric Circuits; General Network Theory; Recurrent Networks; Non-linear Electric Circuits; Electromagnetic Radiation; Electromechanical Systems; by Knox McIlwain.

RESISTORS, INDUCTORS, CAPACITORS: Resistors and Rheostats; Inductors with Air Cores; Ferrous-cored Inductors; Capacitors, Condensers; by A. Dexter Hinckley.

ELECTRON TUBES: Thermionic Vacuum Tubes; by B. J. Thompson with J. M. Stinchfield, Bernard Salzberg, and E. W. Herold. Gaseous Conduction Tubes; by O. W. Livingston. Cathode-ray Oscillograph Tubes; by G. F. Metcalf. X-ray Tubes; by S. Reid Warren, Jr. Photoresponsive Devices; by H. E. Ives.

ELECTROMECHANICAL-ACOUSTIC DEVICES: Effects of the Acoustic Medium; Loud Speakers and Telephone Receivers; Microphones; by Hugh S. Knowles. Mechanical Recording and Reproducing of Sound; Optical Recording and Reproducing; Magnetic Recording and Reproducing; by H. A. Frederick and A. C. Keller.

CIRCUIT ELEMENTS: Single Mesh and Coupled Circuits; by Vernon D. Landon and Knox McIlwain. Transformers with Iron Cores; by J. I. Cornell and A. J. Rohner. Electrical Wave Filters; by T. E. Shea and C. E. Lane. Radio Antennas; by G. C. Southworth. Vacuum-tube Amplifiers; by Loy E. Barton. Modulators; Power Supply; Radio Transmitters; by J. E. Young. Detectors; Radio Receivers; by Vernon D. Landon. Oscillators; by Carl C. Chambers.

HIGH-FREQUENCY TRANSMISSION: Wire Transmission Lines; by Knox McIlwain. Transmission in Space; by John C. Schelleng. Mechanical Features of Transmission Lines; by C. H. MacDonald. Coordination of Communication and Power Systems; by C. H. MacDonald and H. A. Dambly.

ACOUSTICS: The Sense of Hearing; Speech and Music; Effects of Distortion on Speech and Music; by John C. Steinberg. Acoustic Properties of Rooms; Sound Insulation; Acoustic Design of Auditoriums; by Vern O. Knudsen.

10. ELECTRICAL MEASUREMENTS: Frequency Measurements; by W. A. Marrison. Measurement of Primary Electrical Quantities; by W. J. Shackelton and J. G. Ferguson. Wire Transmission Measurements; by F. H. Best. Measurements of Transmission through Space; by R. K. Potter. Wave Analysis; by E. Peterson and T. G. Castner.

11. TELEGRAPHY: Elements of Telegraph Systems; D-c Telegraph Systems; A-c Telegraph Systems; Printing Telegraph Systems; Local Equipment; Submarine Cable Telegraphy; by Allison A. Clokey. Radio Telegraph Systems; by J. L. Finch.

12. SOUND-REPRODUCTION SYSTEMS: Acousto-electric Equipment; Radio Telephone Broadcasting; by Howard A. Chinn. Electro-acoustic Equipment; by W. H. Bohlke and Knox McIlwain. Public Address Systems; Sound Pictures; by Knox McIlwain. Police Radio Systems; by Loren F. Jones.

13. TELEPHONY: Substation Equipment and Circuits; Central Office Systems; by Knox McIlwain. Telephone Lines; by C. H. MacDonald. Radio Telephone Systems; by A. A. Oswald.

14. FACSIMILE TRANSMISSION AND RECEPTION: Scanning Systems; Recording Systems; Transmission and Synchronization; Complete Facsimile Systems; by Maurice Artzt.

15. TELEVISION: Transmitting Point Analyzer; Transmission Channel; Receiving Point Reproducer; Scanning Systems (Electrical); Complete Television Systems; Circuit Elements Peculiar to Television Systems; by H. Branson and R. L. Campbell.

16. ELECTRONIC CONTROL AND NAVIGATION EQUIPMENT: Fundamental Electronic Control Circuits; Light-sensitive Control Equipment; Thyratron Control Equipment; by W. R. King. Radio Aids to Air and Marine Navigation; by W. E. Jackson and J. C. Hromada.

17. MEDICAL APPLICATIONS OF ELECTRICITY: Electrotherapy; Diathermy and High-frequency Surgery; Ultra-violet-ray Therapy; Physiological Electromotive Forces; Electro-acoustic Devices; Roentgen Therapy; Roentgenography and Roentgenoscopy; High-voltage Shock and X-ray Burn; by Charles Weyl.

MINING ENGINEERS' HANDBOOK

Edited by the late Robert Peele

2442 Pages. In Two Volumes

Volume I

SECTION

1. MINERALOGY by the late Alfred J. Moses and Paul F. Kerr.
2. GEOLOGY AND MINERAL DEPOSITS by the late James F. Kemp and Paul F. Kerr.
3. EARTH EXCAVATION by Halbert P. Gillette, Richard T. Dana, and Clinton L. Bogert.
4. EXPLOSIVES by H. G. Haskell, Fletcher B. Holmes, Arthur LaMotte, and F. J. LeMaistre.
5. ROCK EXCAVATION by Halbert P. Gillette, Richard T. Dana, Arthur P. Ackerman, and Samuel R. Russell.
6. TUNNELING by Charles F. Jackson.
7. SHAFT-SINKING IN ROCK by Homer L. Carr and John A. Church.
8. SHAFT-SINKING IN UNSTABLE AND WATERBEARING GROUND by Francis Donaldson, Edwin S. Jarrett, and Ralph H. Chambers.
9. BORING by Arthur F. Taggart and Robert S. Lewis.
10. PROSPECTING, DEVELOPMENT AND EXPLOITATION OF MINERAL DEPOSITS by James F. McClelland, W. W. Lynch, and Edward K. Judd.

10-A. GEOPHYSICAL PROSPECTING by Frederick W. Lee.

11. UNDERGROUND TRANSPORT by Edwin C. Holden.
12. HOISTING PLANT, SHAFT POCKETS AND ORE BINS by William M. Weigel and Philip B. Bucky.
13. DRAINAGE OF MINES by the late Robert Van Arsdale Norris and Robert E. Hobart.
14. MINE VENTILATION by the late F. Ernest Brackett and George E. McElroy.

Volume II

SECTION

15. COMPRESSED AIR PRACTICE by Richard T. Dana and A. W. Loomis.
16. ELECTRIC POWER FOR MINE SERVICE by George R. Wood and Charles M. Means.
17. SURVEYING by Charles B. Breed.
18. UNDERGROUND SURVEYING by Edward K. Judd.
19. MINE GEOLOGIC MAPS AND MODELS by Reno H. Sales.
20. MINE ORGANIZATION AND ACCOUNTS by J. R. Finlay and Arthur Notman.
21. COST OF MINING by J. R. Finlay and Arthur Notman.
22. WAGES AND WELFARE by Edward K. Judd.
23. MINE AIR, GASES, DUSTS, HYGIENE, EXPLOSIONS, AND ACCIDENTS by George S. Rice.
24. MINING LAWS by the late Horace V. Winchell and Archibald Douglas.
25. MINE EXAMINATIONS, VALUATIONS AND REPORTS by William Young Westervelt.
26. AERIAL TRAMWAYS AND CABLEWAYS by Edward B. Durham.
27. UNDERGROUND MECHANICAL LOADING, CONVEYING AND HANDLING by Walter M. Dake.
28. BREAKING, CRUSHING AND SORTING OF ORES by Arthur F. Taggart.
29. ORE SAMPLING by the late T. R. Woodbridge.
30. ASSAYING by the late E. J. Hall and Edward F. Kern.
31. TESTING OF ORES by Arthur F. Taggart.
32. SELLING, PURCHASING AND TREATMENT OF ORES by Arthur L. Walker.
33. GOLD AMALGAMATION AND CYANIDATION by Edward L. Dufourcq and John V. N. Dorr.
34. PREPARATION AND STORAGE OF ANTHRACITE COAL by Paul Sterling.
35. PREPARATION AND COKING OF BITUMINOUS COAL by the late H. McKean Conner, Noel Cunningham, S. M. Parmley, V. D. Hanson, D. H. Davis, and Howard N. Eavenson.
36. MATHEMATICS AND MECHANICS by C. H. Burnside.
37. CHEMICAL AND PHYSICAL NOTES AND TABLES by Edward K. Judd and the late Robert Peele.
38. ELEMENTS OF HYDRAULICS by J. K. Finch.
39. ENGINEERING THERMODYNAMICS by Edward D. Thurston.
40. POWER AND POWER MACHINERY by Theodore Baumeister, Jr.
41. MECHANICAL ENGINEERING MISCELLANY by H. L. Parr.
42. ELECTRICAL ENGINEERING by Walter I. Slichter.
43. ELEMENTS OF STRUCTURAL DESIGN by J. K. Finch.
44. PETROLEUM PRODUCTION METHODS by S. F. Shaw.
45. ENGINEERS' TABLES compiled by C. H. Burnside, James F. McClelland, and the late Robert Peele.

HANDBOOK OF MINERAL DRESSING

ORES AND INDUSTRIAL MINERALS

Edited by Arthur F. Taggart

1915 PAGES

SECTION

1. INTRODUCTION; by Arthur F. Taggart.

2. METALLIC MINERALS: USES, ORES, PRODUCTION, TREATMENT SCHEMES, SELLING (revised by Paul M. Tyler); by Arthur F. Taggart.

3. INDUSTRIAL MINERALS; by Paul M. Tyler.

3A. CEMENT; by C. H. Breerwood.

4. CRUSHING; by Arthur F. Taggart.

5. WET GRINDING: TUMBLING MILLS; OPERATION; by Arthur F. Taggart.

6. DRY GRINDING; by Harlowe Hardinge.

7. SCREEN SIZING: TYPES OF SCREENS; by Arthur F. Taggart.

8. CLASSIFICATION WITH WATER: MECHANICAL CLASSIFIERS; NONMECHANICAL DESLIMERS; HYDRAULIC CLASSIFIERS; by Arthur F. Taggart; revised as to Dorr apparatus in collaboration with the engineers of the Dorr Co.

9. AIR SIZING AND DUST COLLECTION: DUST COLLECTION; AIR SIZING; by Harlowe Hardinge and T. A. Frankish.

10. WASHING AND SCRUBBING; SCRUBBING: WASHING; by Arthur F. Taggart.

11. GRAVITY CONCENTRATION: PULSATED BEDS; SHAKEN BEDS; STIRRED BEDS; WATER-IMPULSE SEPARATORS; PNEUMATIC CONCENTRATION; by Arthur F. Taggart.

12. FLOTATION: COLLECTION; CONDITIONING; LEVITATION; FLOTATION MACHINES AND PROCESSES; FROTH FLOTATION; OPERATION; FLOTATION FLOWSHEETS; SULPHIDE FLOTATION; FLOTATION OF NON-SULPHIDES; by Arthur F. Taggart.

13. ELECTRICAL CONCENTRATION: MAGNETIC SEPARATION; ELECTROSTATIC SEPARATION; revised by M. D. Hassialis.

14. MISCELLANEOUS METHODS OF CONCENTRATION: HAND SORTING; AMALGAMATION; by Arthur F. Taggart.

15. DEWATERING: THICKENING; by Arthur F. Taggart; revised in collaboration with the engineers of the Dorr Co.

16. FILTRATION: TYPES OF FILTERS; revised by Donald F. Irvin.

17. DRYING; revised by Francis E. Finch.

18. STORAGE AND MILL TRANSPORT: STORAGE; revised by E. J. Tournier and E. K. Judd; TRANSPORT OF MATERIALS; by Henry A. Behre; revised by E. J. Tournier and E. K. Judd.

19. SAMPLING AND TESTING: SAMPLING; by Henry A. Behre; revised by M. D. Hassialis; TESTING; revised by M. D. Hassialis.

20. DESIGN AND CONSTRUCTION OF ORE-TREATMENT PLANTS; by the late John M. Callow and the staff of General Engineering Co.

21. MATHEMATICS: ARITHMETIC; ALGEBRA; GEOMETRY; TRIGONOMETRY; ANALYTIC GEOMETRY; CALCULUS; by the late Percey F. Smith.

22. TABLES: MATHEMATICAL TABLES; by the late Percey F. Smith; MISCELLANEOUS TABLES; by Arthur F. Taggart.

OTHER WILEY HANDBOOKS

THE ENGINEERS' MANUAL

By Ralph G. Hudson. Second Edition. 340 pages. 5 by $7\frac{7}{8}$. 236 figures. Flexible binding.

ARCHITECTS' AND BUILDERS' HANDBOOK

By the late Frank E. Kidder. Harry Parker, Editor-in-chief, with the collaboration of a staff of 18 specialists. 18th Edition. 2315 pages. $4\frac{5}{8}$ by $7\frac{1}{4}$. Flexible binding.

MERRIMAN'S AMERICAN CIVIL ENGINEERS' HANDBOOK

Thaddeus Merriman, late Editor-in-chief; Thomas H. Wiggin, Associate Editor-in-chief; with a staff of 21 specialists. Fifth Edition. 2263 pages. $4\frac{5}{8}$ by $7\frac{1}{4}$. One volume, atholeather; two volumes, real leather.

CHEMICAL ENGINEERS' MANUAL

By D. B. Keyes and A. G. Deem. 221 pages. 4[illegible] by [illegible] Flexible binding.

VEST-POCKET HANDBOOK OF MATHEMATICS FOR ENGINEERS

By the late L. A. Waterbury with special sections by the late G. A. Goodenough and H. H. Higbie. Third Edition. 278 pages. 3 by $5\frac{1}{2}$. Flexible binding.
